pounds become unstable, and dissociate into lower boiling hydrocarbons, which, under the temperature control imposed in the vapor line, leave the distilling system as fast as produced. Al_2Cl_6 is again formed, and is capable of combining further with other high boiling hydrocarbons remaining in the still, and free carbon is formed simultaneously. This view of the reaction here involved is confirmed, I believe, by the operating conditions mentioned heretofore as necessary for obtaining the desired results.

While the operation, using crude oil as the starting material, can be carried on to produce larger or smaller quantities of gasoline, in practice it is carried on so as to convert the gas oil fraction into low boiling hydrocarbons and leave most of the high boiling hydrocarbons, that is, the paraffins and lubricating oils. Accordingly, the operation is interrupted after a portion of the crude has been converted into low boiling products, and the high boiling oil remaining in the still is pumped off while hot and on cooling is worked up into the usual paraffin and lubricating products. The aluminium chloride remains in the still enmeshed in a mass of coke, and the methods of its recovery are found in my patents, which, if I may, I will refer to further on in this paper.

Results of Tests

As illustrative of the action of aluminium chloride on high boiling petroleum oils I shall give below results obtained on typical crudes. For the sake of convenience, the distillate obtained by distilling the crude before the addition of aluminium chloride will be termed "primary distillate," the oil remaining in the still being termed "primary residual oil"; the distillate obtained by distilling the primary residual oil with aluminium chloride will be termed "secondary distillate," and the oil remaining in the still "secondary residual oil." Fahrenheit temperature and Baumé gravity are used throughout. The distillation tests were made on 100 c.c. samples contained in standard Engler flasks connected to a 22-in. Liebig condenser. All flash points noted are in open cut tester. Viscosities noted are on the Saybolt universal viscosimeter at 100 deg. Fahr. W.W. and S.W. are abbreviations for water white and standard white respectively.

Texas crude of 20.8 gravity was distilled until free from moisture and until the naturally occurring gasoline and kerosene had been distilled over.

The following table compares the yield of products from Texas crude by the aluminium chloride process with the yield of products as obtained when the crude is distilled in the usual manner:

	Per Cent Crude, Aluminium Chloride Process	Per Cent Crude, Usual Process
Gasoline	17.75	Zero
Gas naphtha	13.03	0.10
Kerosenes	8.66	4.30
Gas oil	17.15	52.00
Lubricating oils	25.58	25.50
Asphaltic residual oil	....	12.00
Total	82.17	93.90
Loss	17.83	6.10
Total	100.00	100.00

In ordinary practice no gasoline is obtained from this type of Texas crude; by the aluminium chloride process 17.75 per cent is obtained and those who are familiar with the tests on petroleum products will see that this gasoline is as good as the natural gasoline made from any crude petroleum. The gas naphtha, which might very well be mixed with the gasoline, has been increased from 0.1 per cent to 13.03 per cent. It will be observed that these low boiling oils have been made at the expense of the gas oil fraction and the asphaltic residual oil, the latter being broken down completely. Gas oil is the least valuable constituent of the crude. The asphaltic residual oil is used for fuel or is made into asphalt. The yield of lubricating oil by the aluminium chloride process is about the same as that in the usual process, but the quality of the former is greatly improved by virture of the saturating effect of the aluminium chloride and the elimination of asphaltic and resinous constituents from the oil. I have samples here of these products that I shall be glad for any of you to examine.

It will not be necessary to go into so much detail with the remaining crudes of which I desire to speak, but I have wanted to give you these figures on Texas crude to show how regularly the reaction proceeds over a long period of time, what the physical characteristics of the products are, and the yield as compared with the usual process.

A Caddo (Louisiana) crude of 41 gravity was distilled to free it from moisture and natural gasoline:

Yield	Per Cent Crude
Primary distillate	26.19

Total	100.00	100.00

This crude belongs to the same type as Pennsylvania crude—the type known as paraffin base crude. Their products are clean smelling and require but little acid in refining. But even this type of crude is considerably improved by the aluminium chloride process, while at the same time the yield of gasoline is greatly increased. The paraffin residual oil from Caddo crude is black and tarry on account of the presence of asphaltic constituents, but these are not usually present in large enough amounts to prevent the manufacture of good paraffin and paraffin lubricating oil. The distillation with aluminium chloride destroys the asphaltic constituents, giving an amber colored residual oil which may be easily worked into a product, commercially known as vaseline, or into paraffin and paraffin lubricating oils. At the same time the yield of gasoline from the crude is increased from 18 per cent to 42.32 per cent.

An Oklahoma crude of 34 gravity was distilled to free it from moisture and natural gasoline.

The following table compares the yield of products from Oklahoma crude by the aluminium chloride pro-

cess and the yield of products as obtained in usual practice.

	Per Cent Crude Aluminum Chloride Process	Per Cent Crude Usual Process
Gasoline	34.82	12.50
Kerosene	29.47	41.00
Gas oil	5.36	35.00
Residual oil	14.07	9.00
	83.72	97.50
Loss	16.28	2.50
Total	100.00	100.00

The residual oil from this crude by the usual process is a black, tarry mass, containing large amount of asphaltic constituents and also paraffin. The amount of asphaltic constituents is so great, as a rule, that it is difficult to make paraffin and paraffin lubricating oils of the same grade as that obtained from Pennsylvania or Caddo residuums. By the aluminium chloride process this residual oil is cleaned of its asphaltic constituents, and paraffin wax and paraffin lubricating oils of excellent quality are made therefrom. At the same time, the yield of gasoline from the crude is greatly increased, at the expense of the less valuable fractions of the crude.

Although the crude petroleums from the various oil producing districts in this country differ greatly in quality and in chemical composition, yet they are generally divided into three types: Asphaltic-base crude, paraffin-base crude, and paraffin-asphaltic-base crude. The oils I have spoken of in this paper are representative of each of these types; Texas, asphaltic-base crude, Caddo, paraffin-base crude, and Oklahoma, paraffin-asphaltic-base crudes. To give figures on other crudes would be merely a repetition of the results obtained on one of these. I shall therefore not take the time to give further examples. I might add that among the samples here are products made by the aluminium chloride process from 14 gravity California crude and 20 gravity Mexican crude.

Recovery of Aluminium Chloride

But all the good results of this process would be of no commercial value if the aluminium chloride could not be reclaimed. This chemical when made on the ton scale is not so expensive as it is when made on the pound scale, but nevertheless its cost is high, and from a dollars and cents point of view, it is necessary to recover it. And this is done by the processes set forth in my patents.

After a time, 48 hr. or longer, aluminium chloride used in distilling oils, even the driest of oils, loses its catalytic activity and becomes converted into a coky mass. Analysis of the coky mass shows chlorine and aluminium present in the right proportions to form aluminium chloride, but the latter is, so to speak, masked. It does not display its ordinary reaction with petroleum hydrocarbons. The granular coky residue after it comes from the oil converting process, carries varying amounts of oils with it. If allowed to cool down in the presence of the body of oil, it may carry 40 to 50 per cent of its weight of oil. If the oil body has been separated while hot from the coky residue, the amount of oil will be reduced to 4 or 5 per cent.

After removing the oil, or the bulk of it, from the coky residue, the aluminium chloride can be extracted from the latter with water or steam to obtain a concentrated solution of hydrated aluminium chloride. Aluminium chloride in the hydrated state does not have the catalytic property of the anhydrous material, but the hydrated salt can be used as the raw material for making the anhydrous salt. To do this, advantage is taken of the property of hydrated aluminium chloride breaking up when moderately heated to form aluminium oxide and hydrochloric acid gas. The alumina when mixed with carbon and treated with hydrochloric acid vapors at a high temperature, react to form the anhydrous chloride, hydrogen and oxides of carbon. In utilizing this property, one portion of the hydrated chloride is heated to produce hydrochloric acid vapors and alumina, and these vapors on drying enter a further charge of alumina and carbon heated to redness. The hydrochloric acid vapors given off at a moderate temperature are thus utilized in further operations at high temperatures.

In another method of recovery, and the preferred one, the coky residue is heated to red heat in an atmosphere of chlorine which disengages the aluminium chloride from the carbon. Aluminium chloride volatilizes normally at a temperature around 365 deg. Fahr., but the coky residue may be heated to redness without much evolution of these vapors. If the heating is done in an atmosphere of chlorine the aluminium chloride is unlocked, so to speak, and vaporizes away from the carbon, and is condensed in suitable receivers.

Of course, the last and ultimate test of any process is whether it will work, and work successfully without undue petting. That the aluminium chloride process is now an assured commercial success, is, of course, due to its own merits. But I cannot forego this opportunity to speak of the generous aid from the Gulf Refining Company, which has made success possible, and the valuable advice and help from its officers.

Although this account by no means covers the full scope of the aluminium chloride reaction with petroleum oils, yet to speak further would lead me outside of my subject.

The New Mill of the Daly West Mining Co., Park City, Utah

By L. O. Howard

The destruction by fire, in December, 1913, of the mill and shaft house of the Daly West Mining Co. at Park City, Utah, gave the company an opportunity to simplify its practice. The old plant was characterized by all the complications and repeated retreatments, a multiplicity of screens and classifiers, endless succession of middling tables, etc., that the practice of a decade ago favored in the concentration of lead and zinc ores.

The old mill was of the hillside type, and in the same structure as the shaft- and boiler-house. This resulted in the total destruction of the surface plant when fire started in a portion of the works.

The ore of the Daly West mine is a sulphide of lead and zinc, with some copper, and about 3 oz. of silver for each per cent of lead, in a gangue of limestone and quartzite. It is mined to a depth of 2100 ft. through a two-compartment shaft. First-class ore, assaying about 18 per cent lead, 9 per cent zinc, 2 per cent copper, 52 oz. of silver, and 0.04 oz. of gold, is sorted out underground, hoisted to the 1200-ft. level, and hauled 2½ miles through the Ontario drain tunnel to Park City, near the site of the old Ontario mill. Second-class ore is hoisted to the surface. For some years this ore has assayed about 5 to 6 per cent lead, 5 to 6 per cent zinc, and 7 to 8 oz. silver.

THE OLD MILL

Preceding the description of present practice and for purposes of comparison, a brief outline of previous practice may be of interest. All ore was hoisted in cars on two three-deck cages and dumped over eight grizzlies into sixteen separate coarse and fine-ore bins, from which it was taken by belt conveyor to a Gates crusher set to 1 in. From the 1.5-in. oversize of the grizzlies, waste and first-class ore was sorted out.

Second-class ore was delivered to the mill bins. After sampling it dropped to the first set of rolls, then to the limiting trommel, where all ore over three-mesh was sent to finishing rolls, then to another three-mesh trommel. The oversize of this trommel was delivered to a two-mesh scalping trommel, which returned its oversize to the finishing rolls. The undersize from both three-mesh trommels was delivered to a series of trommels having screens of four-mesh, six-mesh and eight-mesh cloth. The respective oversizes were sent to four sets of two two-compartment Harz jigs each. Concentrate was taken off the four coarse jigs through the hutches and side-draw gates. The fine jigs made only hutch product and tailing.

Coarse tailing, after dewatering, was reground in three Sherman mills, which were modifications of the Huntington mill.

Following the last trommel came the first tanks of the classification system. The old mill had no hydraulic classifiers, but used a system of tanks and classifiers devised by the mill superintendent and known as Sherman tanks and Sherman classifiers. The latter were of special interest. They were cylindrical with conical bottoms, and set in series with a progressive increase in diameter and decrease in height. Fig. 1 shows some of these tanks in the ruins of the old mill. In the main

FIG. 1—A PORTION OF THE OLD DALY WEST MILL, SHOWING ARRANGEMENT OF SHERMAN CLASSIFIERS. NEW SHAFT-HOUSE AND HEAD FRAME IN BACKGROUND

mill the diameters were 4, 6, 8, 10 and 12 ft. Pulp was fed through a central cylinder, of one half the cross-sectional area of the outside cylinder, and the overflow passed upward between the two cylinders and into a launder at the periphery of the larger cylinder. From the spigots were drawn the feeds for the various concentrating machines.

From the first tanks another set of fine jigs was fed, which made a finished hutch, the tailing joining the reground tailing from the coarse jigs. This tailing went to the next two Sherman tanks, feeding six Wilfley tables, which made four products; concentrate to smelter, tailing, slime, and middling, which was sent to three more Wilfleys, which made similar products to the first, the middling from these being passed over two more Wilfleys.

The slime from the first Wilfleys, and the overflows from the various Sherman tanks, went to a set of five Sherman classifiers. Tailing from the three sets of Wilfleys and slime from the last two sets were passed over an eight-mesh screen, the undersize going to other Sherman classifiers in a separate structure, known as Mill No. 2, the oversize going to Mill No. 3.

The five Sherman classifiers in Mill No. 1, receiving the coarser overflows from the Sherman tanks, and some returns from later parts of the system, fed three Wilfley tables and two Sherman slime tables, which were similar to the old tray-type of Wilfley table. All these tables made finished concentrate, sent tailing to Mill No. 2 and returned middling to the five classifiers. The overflow of the last of these classifiers was further settled in a long tank, which fed two more Sherman slime tables, which made a finished concentrate and sent tailing to the tailing plant, Mill No. 2.

The Old Tailing Mill

Mill No. 2 was characterized by a long-extended series of tanks and classifiers of the Sherman type. Tailing was received in a 6 x 6 tank, the spigot product from which was screened over 8-mesh, undersize being treated, after passing through another small tank, on a 2-compartment Harz jig, where a finished concentrate was made, tailing going to No. 3 Mill. Oversize of 8-mesh was reground in a Sherman mill and sent to six Sherman classifiers, along with the overflow from the tanks. These tanks varied in diameter as follows: 3 ft., 4.5 ft., 5.5 ft., 7.5 ft., 10.5 ft. and 14 ft.

This set of classifiers fed three Wilfley tables and three Overstrom tables, all of which returned middling and slime to the classifier, made finished concentrate and sent tailing to mill No. 3.

The overflow from the classifiers was further settled in eighteen 6 x 6 tanks, which fed one slime table, making finished concentrate, middling to be returned to classifiers, and tailing to Mill No. 3. The final overflow from the eighteen tanks was used as wash water on the tables in Mill 2, not without further settling, however.

Mill No. 3

Mill No. 3 was simple. Here the incoming tailing was received in a settler, the material which settled being discarded (the first discard from the plant) and the overflow again settled. The spigot of the second settling tank discharged to an eighty-mesh screen, which rejected the oversize and fed the undersize to four slime tables, which also received the overflow of the second settler, after it had been further thickened in two more tanks. These slime tables made finished concentrate and tailing and returned middling to the second settler.

At a later time there was added a trommel and two more jigs to treat further the coarse material.

The writer has given the above description with some hope, but not too much expectation, that the reader will be able to visualize the practice. At least it will serve to emphasize the complication of the old plant and serve as a measure of the simplification attained in the new plant.

According to the report of the mill superintendent for 1913, the old plant treated 190 tons per 8-hr. shift, with an extraction of 99.6 per cent of the lead, 22 per cent of the zinc and 79.55 per cent of the silver. The high lead extraction is due to the custom of figuring the lead in zinc concentrate as part of the extraction. The mill treated 59,233 tons of ore assaying 5 per cent lead, 7.7 oz. of silver and 4.3 per cent of zinc, producing 8332 tons of lead concentrate assaying 34.54 per cent lead, 40.01 ounces silver and 1598 tons of zinc concentrate assaying 35.37 per cent zinc, 4.83 per cent lead and 19.27 oz. of silver. These figures would indicate an extraction of 97 per cent of the lead. It is not stated how the weight of crude ore was determined or how the sample was taken, so that the reason for this apparently high recovery is not evident.

The mill was driven electrically, power being generated by boilers, 300 horsepower being required.

The mill force consisted of twenty men per shift.

The illustrations of the present mill—Figs. 2, 3 and 4—show that much less floor space is required, and precaution has been taken to have the shaft-house, crusher-house and mill widely separated.

The New Mill Structures

The new mill, which went into commission in January of this year is housed in two structures, one 71 ft. long, 27 ft. wide and 60 ft. high from floor line to top of ore bins, housing the storage bins and the primary crushers. The main mill building has the approximate dimensions shown in the sketch, Fig. 5. The crusher-house is of frame construction, as is the mill proper, the latter being covered with corrugated iron. The

FIG. 2—VIEW OF DALY WEST MILL, LOOKING WEST

mill is of the hillside type, the fall from the head of the mill proper to the tailing launders in the tunnel beneath the mill being about 70 feet.

There are five levels. At the top are the receiving bins. On the floor below, the fourth, are two Franz jigs, above which are the feeding trommel and Akins classifier. On the third floor are the roughing Wilfleys, Harz jigs, Sherman tanks and regrinding rolls. On the second floor are eight concentrating tables and the flotation plant, and on the first, the Harz tailing jig and concentrate launders.

The accompanying flow sheet shows the greater simplicity of the new plant. The ore is hoisted in two 4-ton skips and dumped into bins in the head-frame, waste being dumped into its own bin and trammed to the dump.

The seoond-class ore is drawn on to an 18-inch belt conveyor, 270 ft. long, which delivers the ore to the bins at the top of the ore-house, at an elevation 12 ft. lower. The ore is received in two bins, 12 ft. x 12 ft. in cross-section, and 35 ft. deep, holding 600 tons or enough for three days' run. From the bins the ore is fed by 30-in. Stephens-Adamson belt feeders, adjustable to three speeds, over 3-ft. x 6-ft. grizzlies, having a 45-deg. slope, with 2-in. spacing of the bars, which are of cast iron, 3 in. deep, ¾ in. wide at the top and ¼ in. wide at the bottom.

Magnetic Removal of Steel from Feed

A 10-in. x 20-in. Blake crusher, made by the Colorado Iron Works, takes the oversize and discharges to a trommel, which is 48 in. by 72 in., and is covered with double-crimped wire screen, having two meshes to the inch. A 24-in. belt conveyor, 12 ft. long, takes the oversize of the trommel to a 48-in. Symons disc crusher. The head pulley of this conveyor is magnetized to remove all pieces of steel from the feed.

In operating the Symons crusher there has been at intervals some trouble due to choking which has been gradually overcome. Points of steel, 6 to 8 in. long, have gone into the crusher without other effect than to blow the fuses. Since the mill was started the crusher has given generally good results, but after six months' service further trouble was had due to the discs becoming wedged with babbitt, stripping the driving gears and interfering with the operation of the mill until new parts could be obtained from the manufacturer. At the time of the writer's visit the mill was crippled from this cause, so that the best work of the newer equipment could not be seen.

The discharge of the Symons crusher and the undersize from the trommel are taken from the ore-house to the mill bins by a 24-in. Robins belt conveyor, 210 ft. long, up a 6-deg. slope. Midway of the belt travel is a Blake-Denison weigher, having a capacity of 30 tons per hour.

Franz Jig Removes the First Concentrate

The ore is sampled as it falls into the bin by a box rotating on a vertical axis at the rate of one revolution in 10 minutes. After the cut has been made the box travels a half revolution, to a point where its front end comes in contact with an inclined rail which tilts the box so that it discharges through the back end to the sample chute.

From the bin the ore is fed into a 48-in. by 72-in. trommel, covered with a two-mesh screen of double-crimped wire cloth. The oversize goes directly to one of two Franz jigs, the undersize going to the other after the slime has been removed in a 51-in, Akins classifier.

These jigs are of the movable screen type and are more often seen in the Missouri zinc districts than in the West. The screens are 10 ft. long and 27 in. wide. On the coarse jig the screen size is changed at intervals, the first two feet having 5/16-in. apertures, the next three feet having ½-in. apertures and the remainder being divided between screens having apertures of ⅝-in. and ¾-in. respectively. The fine jig has 2½ ft. each of the following sizes: 3/16-in., ¼-in., 5/16-in., ⅜-in. Screens are of plate punched with round holes. Both jigs are run at 240 revolutions per minute, the fine jig having a stroke of ¾ in. and the coarse of 1 in. to 1¼ in.

The feed is divided in the proportion of 120 tons per

FIG. 3—VIEW OF DALY WEST MILL, LOOKING EAST

day to the coarse and 80 tons to the fine. The coarse jig makes three finished hutch products averaging 30 per cent lead, which go to the lead concentrate bins. The first two hutches of the fine jig are also finished products and will average about 35 per cent lead. The third hutch of the fine jig goes to two Wilfleys, which make a finished zinc concentrate and a tailing, which is retreated on the Harz jig on the lowest level of the mill.

Rolls Used for Regrinding

The tailing from the coarse jig is reground in 14-in. x 36-in. rolls, instead of Sherman mills, as in the old plant, and is elevated to a series of two sets of three Colorado Iron Works impact screens, where three sizes are made: on four-mesh, through four-mesh on eight-mesh, and through eight-mesh. The coarse is returned to the rolls. The middle size is treated on two three-compartment Harz jigs, which make two finished hutch concentrate products, and a third hutch and tailing, which are retreated on the same Wilfleys that receive the third hutch product of the fine Franz jig.

The undersize joins the slime from the Akins classifier and from the later table treatment, and is classified in a 5-spigot Richards-Janney classifier. Each spigot

FIG. 4—DALY WEST CRUSHER HOUSE WITH CONVEYOR SHEDS. MILL ON RIGHT. ASSAY OFFICE IN LEFT CENTER FOREGROUND

feeds two Wilfley tables, the oversize, after thickening, going to the flotation plant. Contrast this simple separation of sizes with the complicated mechanism of the old plant.

Fine Concentration on Wilfley Tables

The ten Wilfleys make similar products, a finished lead, concentrate, tailing, and middling, which is retreated for a finished zinc concentrate and a tailing on three Wilfleys, and head water, which is returned to the classifier.

The concentrates from the Harz jigs and Wilfley tables drop to separate lead and zinc launders suspended on hangers and running across the width of the mill in a tunnel on the lowest level. The head end of the launders is connected to a shaking device which causes the concentrate to flow forward to two sets of two elevators in series, which discharge into two Akins dewaterers, the drained concentrates dropping into lead and zinc bins. They are then trammed in one-ton cars through a tunnel to a sub-level of the ore-house, and are then elevated on a cage to the conveyor shed connecting shaft and ore-house, and trammed to the shaft. They are then lowered to the 1200-ft. level and hauled out through the Ontario tunnel to Park City, where they are loaded on wagons and hauled to the sampling works, a short distance below the city.

All the tailing from the concentrating department goes to a two-compartment Harz jig, on the lowest level, the hutch products being returned to the circuit ahead of the impact screens.

The tailing from this jig is sampled by a tilting box sampler before running into the tail race.

Flotation Department

The feed to the flotation plant consists of slime from the Richards-Janney classifier, which is thickened in one large and 23 small settling tanks of the type used in the old mill. The unit consists of two mixing cells and fourteen flotation cells, having a capacity of thirty tons of dry slime per day. The type is similar to that used by the Federal Lead Company. Each cell is 4 ft. 4 in. long by 20 in. wide and 5 ft. 8 in. deep at the tailing discharge end. They are set side by side, with their sides in common. The illustration, Fig. 7, shows an end view, and the shape of the cells is further illustrated diagramatically in the approximate sketch, Fig. 8.

The slime is fed into the first mixing chamber, where it is mechanically agitated by a vertical propeller driven by belt from a line shaft extending the length of the unit. From this compartment it is drawn into a second similar one and then into a third, which is part of the first flotation cell. Each flotation cell has two compartments, one similar to the mixing cells and another longer one, where the flotation is effected. A flotation concentrate is taken off each cell, the tailing passing through the whole system of cells in series.

The propeller in one cell draws the tailing from the bottom of the preceding flotation compartment and discharges through a slot at the top into its own flotation comparament. The froth floats to the opposite end of the flotation compartment and is skimmed off by a

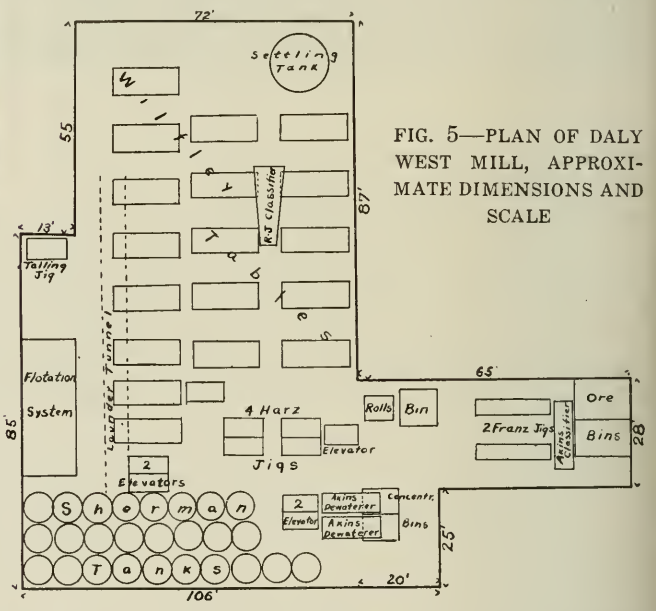

FIG. 5—PLAN OF DALY WEST MILL, APPROXIMATE DIMENSIONS AND SCALE

paddle wheel which drops it into the concentrate launder, where a jet of water breaks the froth. The concentrate flows to a centrifugal pump which lifts it to an elevator delivering to the concentrate bins. This concentrate is marketed as a lead product.

The tailing settles to the bottom edge of the flotation compartment and is drawn into the next cell and again subjected to flotation, until it has passed the final cell, when it goes to the tail race. Flotation tailing is sampled by dipper. The weight of material treated is ascertained by specific gravity determinations made on a large sample caught during a definite period. I am unable to give analyses of concentrate and tailing, which would undoubtedly be instructive, if the management would release them.

Pine oil is introduced drop by drop into the first mixing cell. The consumption of oil is stated to be about 50 gal. per month, which is equivalent to about 0.4 lb. per ton of slime treated.

Miscellaneous Operating Details

The mill is operated one 8-hr. shift daily, with a force of fifteen men, and treats 200 tons per shift. Operations are controlled by means of the data obtained at the following points: The weight of ore fed to the mill is obtained from the Blake-Denison weigher, and the analysis of feed is made on the sample taken at

the end of the conveyor belt which brings the crushed ore to the mill from the crusher or ore-house; weight of concentrate is known and analyses are made on samples taken by pipe sampler from each car as it is taken from the concentrate bin; analyses of tailing are made on the sample taken by tilting box sampler from the

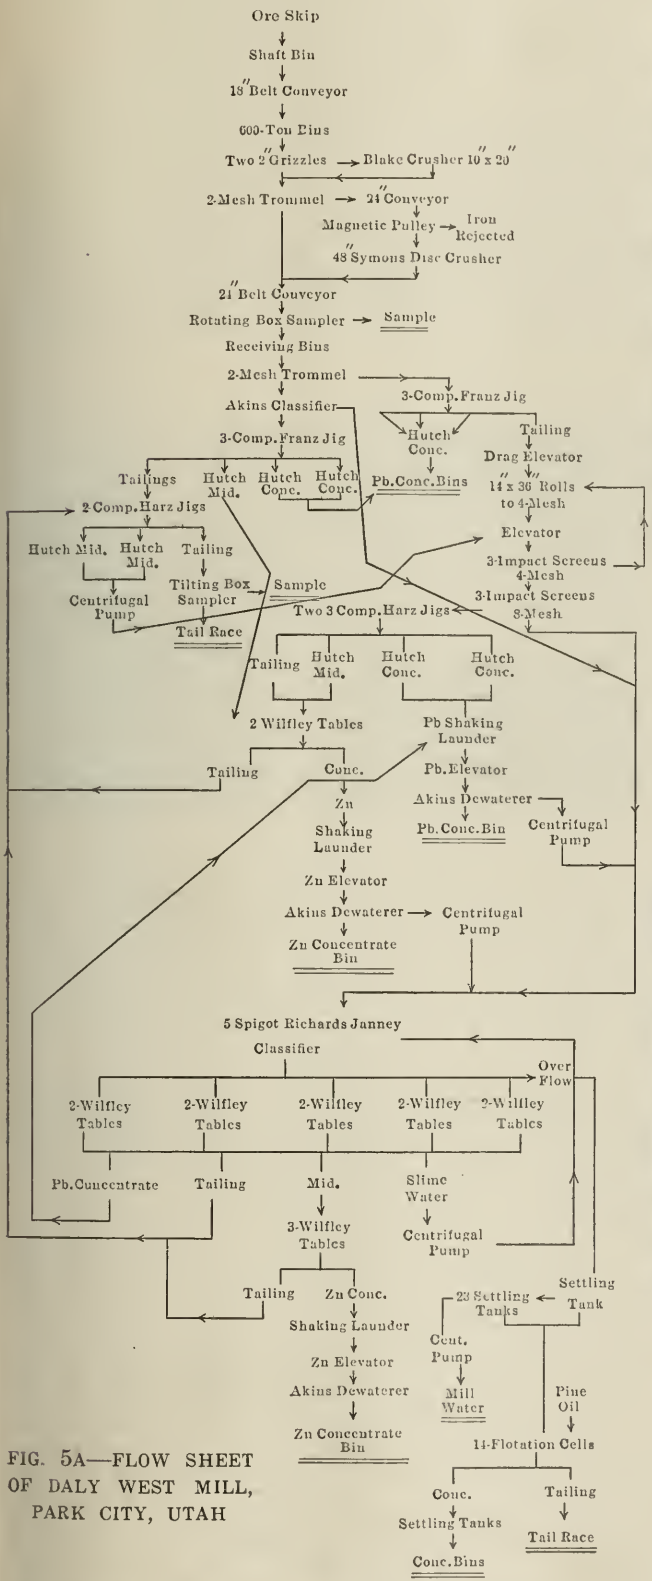

FIG. 5A—FLOW SHEET OF DALY WEST MILL, PARK CITY, UTAH

discharge of the tailing jig; the tailing from the flotation department, which does not go to the tailing jig, is sampled by dipper and the weight obained by specific gravity determinations made on pulp discharged for a known period. Regular samples are not taken during the course of the ore through the mill, but in case of any irregularity in the general tailing assay the suspected machines are subjected to a check sampling in order to remedy the trouble. As a result of this practice, I am unable to give figures on the work of individual machines, or on the grade of concentrate produced at different stages, or to give any information on the specific efficiency of different sections of the plant.

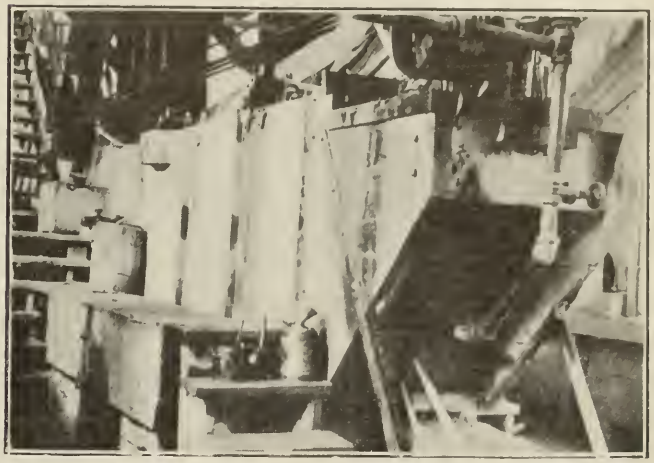

FIG. 6—FRANZ JIG IN DALY WEST MILL

Much of the equipment used in the new mill was salvaged from the ruins of the old. Head pulleys and belting for some of the elevators, classifier tanks, concentrating tables, shafting, conveying idlers, and some of the motors came from this source.

All tables now in use are the No. 5 Wilfleys, three Overstrom tables being held in reserve. The riffling is the No. 10 type, every other riffle being cut off a few inches short. In addition the so-called Thompson type

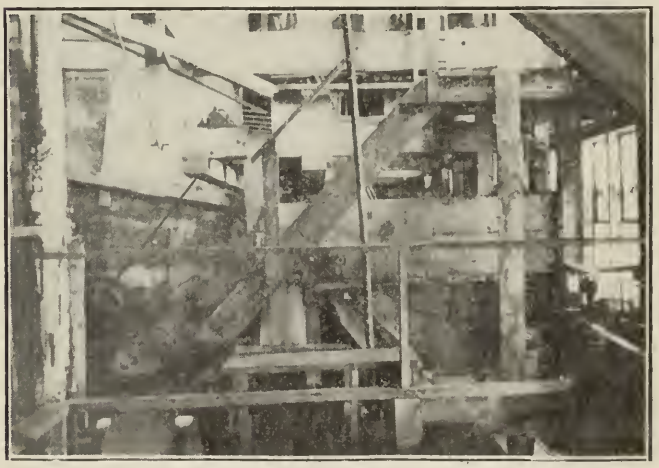

FIG. 7—FLOTATION CELLS, DALY WEST MILL

of riffle has been added. The alternate long riffles, which would ordinarily terminate in the well-known Wilfley diagonal, are extended a few inches upward toward the feed side of the table and then brought out parallel to the table to a second diagonal line. At other plants this type is said to have led to greatly increased capacity. Detailed figures as to results in the Daly West mill are not obtainable, although an average may be estimated by the reader.

Cleaning water is applied to the tables through perforations on the upper side of a two-inch pipe; this arrangement is shown clearly in the illustration of the lower table floor, Fig. 9. Water is brought from below

the floor to the tables, thus doing away with the overhead water pipes, and their attendant troubles.

The analysis of the metallurgical results of operation cannot be given until the publication of the annual report of the company for 1915, for the policy

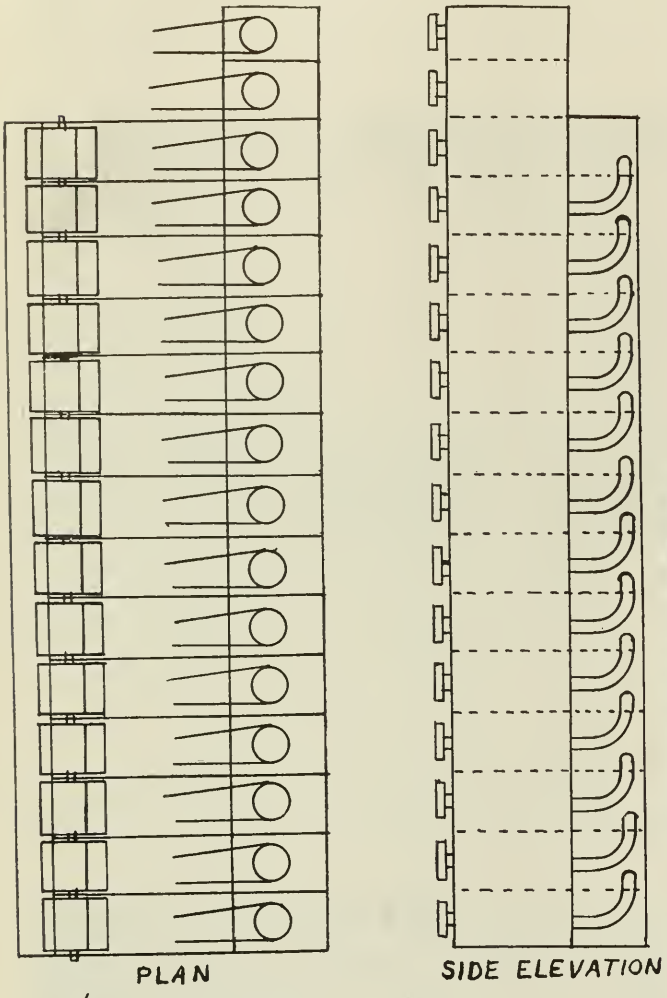

FIG. 8—FLOTATION APPARATUS, DALY WEST MILL

of the company has always been to give out but little information except through this source. However, a comparison of equipment used in this and the old mill may be of interest. Table 1 shows a list of the more important equipment in the old and the new plant side by side.

It will be noted that preliminary crushing and screening and regrinding units have been greatly decreased, as have the number and complications of the jigs. The number of elevators has been increased, but the load on them is diminished, as four of the elevators are for concentrates.

The compact flotation system has replaced the complicated classification and retreatment of slimes and has done away with the twelve slime tables. There still remain a large number of dewatering tanks preceding the flotation plant, used to thicken the feed to it. It would be interesting to know what a Dorr thickener would do if substituted for these numerous tanks. Of

course they have the advantage of absolutely no cost of operation, little maintenance and cheap first cost, in this instance being already on hand. The chief disadvantage is the large floor area required for them. I do not know their efficiency, but assume that they do satisfactory work.

Hydraulic classification in the form of one Richards-

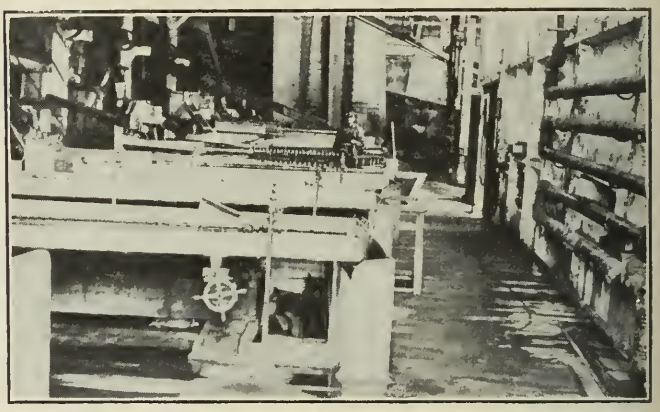

FIG. 9—LOWER TABLE FLOOR, DALY WEST MILL

Janney classifier has taken the place of numerous tanks in preparing the feed for the fine concentrating machines.

Milling water is obtained from lakes 1000 ft. above the mill and 3 miles south, being stored for mill use in large wooden tanks on the hill above the plant.

Power

Power is obtained from the lines of the Utah Power & Light Co. at 12,000 volts, and is transformed to 440 volts at the mill. The larger motor driving the crusher system is a Westinghouse, the others being General Electric. The list of motors follows:

No.	H.P.	Duty
1	75	Driving one 10 x 20 Blake crusher, one 48-in. Symons crusher, one trommel and 24-in. conveyor, 12 ft. long.
1	15	Driving 24-in. conveyor belt 210 ft. long, and one trommel
1	35	Driving one Akins classifier, two Franz jigs, and a tailing excavator.
1	100	Driving one set 14x36 rolls, Franz tailing trommel two centrifugal pumps, 15 Wilfley tables, Richards-Janney classifier, and four elevators.
1	40	Driving two Harz jigs, six impact screens, and one elevator.
1	50	Driving 16 propellors of the flotation machine, and 14 concentrate skimmers.
1	15	Driving one Harz tailing jig, and one centrifugal pump.
1	3	Driving 18-in. belt conveyor, 270 feet long, with drop of 12 ft.

The total horsepower installed is 333.

For the opportunity of visiting the plant I am indebted to H. G. MacMillan, general manager of the Daly West Mining Company; for courtesies extended at the mine, to E. L. Talbot, mine and mill superintendent, and for data used in this article and generous aid in preparing the flowsheet, to J. C. Thompson, mill foreman.

Salt Lake City, Utah.

San Francisco Meeting of the American Institute of Chemical Engineers

TO try and write the story of the seventh semi-annual meeting of the American Institute of Chemical Engineers would be trying to do something impossible. The best we can do is to give an account of the official proceedings of the San Francisco meeting, held from Aug. 25 to 28.

Of course, in such a dry record the real charm of the meeting is lost. Such charm is individual. Everyone who was happy enough to go West this summer has his own story—a story of meeting at the most unexpected places Eastern friends and sharing their pleasure and enthusiasm inspired by the West. On a fine Sunday morning the writer found himself sitting next to Dr. S. P. Sadtler of Philadelphia in a Santa Fé dining car in New Mexico; on the next morning, on the rim of the Grand Canyon in Arizona, he was stopped by the smiling face and outstretched hand of Prof. James R. Withrow of Ohio State University, and on the same afternoon, at Grand View Point, he met Mr. Ernst Boley of the American Steel & Wire Company, and so it went on until, in San Diego, he made connection with Dr. J. C. Olsen's official party of the American Institute of Chemical Engineers, including Professor and Mrs. Edward Bartow of the University of Illinois, Miss Bartow and Miss Abbott, Mrs. and Miss Darrah, Dr. E. E. Reid of Johns Hopkins University, Professor and Mrs. H. C. Enders of Cooper Union, New York; Dr. W. L. Klotz of the Barrett Manufacturing Company, New York; Mr. W. H. Ulrich of Cooper Union, New York, and Mr. H. E. Zitkowski of the American Beet Sugar Company of Rocky Ford, Col.

Of the San Diego days and the meeting of the Institute at Los Angeles we have given an account in our issue of Sept. 1. At San Francisco the headquarters were at the new and very comfortable Hotel Plaza, on Union Square. The three technical sessions on Wednesday, Thursday, Friday, Aug. 25, 26, 27, were held in the Civic Center Auditorium in San Francisco, in the chemical laboratory of the University of California in Berkeley, and in the chemical laboratory of Leland Stanford University in Palo Alto respectively.

On Wednesday afternoon an excursion was made to Protrero, where the oil gas works were inspected and the interesting new process of manufacturing oil gas was explained by Mr. Edward C. Jones.

On Thursday evening a subscription dinner at Tait's was immensely enjoyed, while Saturday was given over to an excursion to Winehaven, with inspection of vineyards and wineries.

It goes without saying that San Francisco outdid itself again in hospitality. While it is impossible to give credit to all to whom credit is due, Prof. J. M. Stillman of Leland Stanford and Prof. Edmund O'Neill of the University of California must be especially mentioned as untiring in extending courtesies to their visiting friends.

WEDNESDAY MEETING

The meeting at the Civic Center Auditorium was called to order by Prof. J. M. STILLMAN, who presided during that session. After a very cordial speech of welcome by the representative of the Mayor of San Francisco, there was a brief business session, in which it was decided that the winter meeting will be held in Baltimore and the meeting in summer, 1916, in Cleveland.

The first paper was then presented by Mr. A. M. MCAFEE on "The Improvement of High-Boiling Petroleum Oils and the Manufacture of Gasoline as a By-product Therefrom By the Action of Aluminium Chloride." This paper is printed in full on page 592 of this issue.

Dr. ARTHUR L. LACHMAN, the distinguished author of that charming little book on "The Spirit of Organic Chemistry," followed with a very interesting paper on "The Engineering Features of Wine Making." Limitations of space force us to withhold the abstract of this paper for our next issue.

THURSDAY MEETING

Prof. EDMUND O'NEILL presided at the meeting on Thursday in the chemical laboratory of the University of California in Berkeley.

The first paper presented related to "Costs as Applied to Professional Businesses," the author being Dr. RALPH A. GOULD of San Francisco. "The professional man sells service directed by systematic training in contrast to the unskilled workman who sells simply service, and in further contrast to the manufacturer or merchant who sells material. All are entitled to remuneration as a result of their labor. The first and the last are, furthermore, entitled to profit because of their in-

vested capital, in one case training, in the other capital. The profits of the professional man are mainly dependent upon his ethics and his ability at his profession, while with the manufacturer or merchant profits are largely the result of the laws of supply and demand."

Dr. Gould's paper describes in a very interesting way how with a partner in a consulting chemical engineering business they figure the cost of doing business. Their figures show the exact status of each client's business; how much they made or lost and exactly when they made or lost it; whether members of the firm are putting in too much time on unprofitable work and whether the connection with an unprofitable client should be continued on the same basis. They show the average profit derived from profitable clients and give valuable figures upon which to base estimates relative to new contracts and "overhead" clients.

Dr. Gould's paper is of considerable originality and deserves the attention of all consulting engineers and chemists.

Mr. EDGAR BARUCH of Los Angeles then presented a paper on "Resources and Possibilities of Chemical Industry in the Southwest." This interesting paper, which is published in full at the end of this report, elicited quite an extended discussion, in which Dr. Olsen, Mr. Beckman and Dr. O'Neill participated.

The last paper of this session was presented by Dr. OTTO BEST of San Francisco on "Manufacture of Cream of Tartar." This authoritative paper is published in full on page 613 of this issue.

FRIDAY MEETING

Dr. S. P. SADTLER of Philadelphia presided at the meeting on Friday in the chemical laboratory of Leland Stanford University in Palo Alto.

The following four papers were presented at this meeting:

"The Present State of the Thiogen Industry," by Prof. S. W. YOUNG.

"The Smelter-Fume Problem and Agriculture," by Prof. J. P. MITCHELL.

"The Purification of Sewage By Aeration in the Presence of Activated Sludge," by Prof. EDWARD BARTOW.

"Cottrell Processes of Electrical Precipitation," by WALTER A. SMITH.

Limitations of space force us to reserve abstracts of these papers for our next issue.

* * *

Resources and Possibilities of Chemical Industry in the Southwest*

BY EDGAR BARUCH

Generally the "Southwest" is designated as that portion of the United States lying west of the crest of the Rocky Mountains and south of the northern line of California, Nevada and Utah, a territory which includes all of these states as well as all of Arizona and portions of Colorado and New Mexico. The facts of this paper have been purposely limited to the confines of California and Nevada, though enthusiastic Californians might have suggested that the single name California be substituted for the "Southwest." Some "Native Sons of the Golden West" often state that were California to be severed from this continent or even the rest of the world by some cataclysm of nature, the State would in no way lack any of the natural resources which are the basis of the comforts and luxuries of modern civilized communities. This statement like many others emanating from California is difficult for strangers to believe, but is in reality not far removed from the actual truth. The following considerations may help to bear out this fact.

Geographically the northern boundary of California and Nevada extends 525 miles on lat. 42 deg. north; the eastern side of Nevada is on the 114th West Meridian; the southern line of California is about 32 deg. south lat.; and the western boundary of California extends along more than 800 miles of the shores of the Pacific Ocean in a general northwesterly by southeasterly direction. California alone curiously covers the extreme distances both north and south and east and west, and these are so great that they have an important bearing not only on great variations in climate, but also in transportation problems and the development of resources.

California has an area of 158,000 square miles and a population, according to the 1910 census, of 2,377,000—(not counting the rich tourists). Nevada has an area of nearly 111,000 square miles and only 81,875 population. Just for comparison note that the combined area, 269,000 square miles, are greater by more than 25 per cent than the total area of France with its 40,000,000 population, or Germany with its slightly greater area and 65,000,000 people, while California and Nevada have a combined population of only approximately 2,500,000, of which about half are rather closely congregated in comparatively small areas in the vicinities of San Francisco and Los Angeles.

Of course, the surface areas of California and Nevada are not comparable with those of France and Germany in the ability of those countries to support a large population per square mile, for not much more than one-third of the area of California is arable, about one-third is mountainous (though largely covered with timber) and the rest is desert, while almost the entire State of Nevada is barren waste of desolate desert and parched mountain ranges on which even jack rabbits and coyotes cull but the leanest pickings of a meagre existence.

The rainfall varies from almost nothing in the desert regions to 50 and 60 inches per annum in the northwestern counties of California. With but few local exceptions the climate is divided into a short wet period and a relatively long dry spell, but the large streams of central and northern California flow the entire year, fed by the everlasting snows of the high Sierras.

In California there are two great mountain ranges, the Coast Range Mountains paralleling the entire coast and the Sierra Nevada Range which runs from Shasta in the north to Tehachapi in the south. These mountains well above 10,000 ft. in altitude run at a greater continuous unbroken height than the Rocky Mountains. They culminate in Mount Whitney at 14,502 ft., the highest point in the United States outside of Alaska, and from this point, but for low intervening ranges 8500 ft. in height it would be possible to look down into the lowest region of this continent, the floor of Death Valley several hundred feet below sea level.

In the upbuilding and subsequent faulting of the continent the mountains, particularly the Sierras, were left with very abrupt eastern fasures and relatively gentle western slopes. This accounts for the general direction of nearly all California mountain streams being westerly; there are practically no large streams running toward the east. Between the great mountain ranges in California there is an immense valley, which converges toward its center to empty its drainage into the ocean through the "Golden Gate," the only low break in the Coast Range. The two branches of this valley, the Sacramento and the San Joaquin, are traversed

*A paper read before the seventh semi-annual meeting of the American Institute of Chemical Engineers, San Francisco Meeting, at Berkeley on Aug. 26, 1914. Very slightly abstracted.

by rivers of the same names which flow together in the delta region east of San Francisco Bay. The great valleys have been built up of thousands of feet of mountain erosion and owing to the variation in climate, ample water on the eastern sides, and rich soils, are highly fertile and adaptable to almost every conceivable crop. The costal valleys are relatively small, but numerous and conform in various positions between the spurs and ridges of the more or less irregular minor ranges. Those most important are Eureka, Santa Rosa, Santa Clara, Pajaro, Santa Maria, Santa Barbara, Ventura, the Los Angeles and San Diego and their tributary valleys and Imperial Valley. Owens Valley running north and south takes the small eastern run off of the Sierras which for ages collected in the basin of Owens Lake. This water is now being partially tapped from the Owens River as a source of water supply for Los Angeles City, by the great project of which you have all undoubtedly heard.

From a glance at the map you will note that the great desert of the State of Nevada is literally interlaced with one continual succession of short mountain ranges, nearly all of which run north and south. In between these ranges, owing to the lack of water, the floors of the valleys are rather steeply sloping with the detrius of boulders, rocks and sand of the slowly decomposing surrounding hills. In the entire State there is not one stream worthy of mention whose run-off ever reaches the ocean. In consequence such torrential storms as at times visit local districts, drain rapidly into pocketed basins or valleys, of which there are hundreds, where they ultimately evaporate in the form of dry lakes of concentrated alkali salts. These same conditions occur in like manner in the southern desert region of California where the saline deposits have been of more interest for no other reason than their more favorable geographic location.

Having thus shown you in a most cursory manner a few of the facial features of the country let us attempt to trace therefrom a few of the facts which have made these characteristics of such great value as natural resources of inestimable wealth.

TRANSPORTATION FACILITIES

There are harbors all the way down the coast from Eureka to San Diego. San Francisco possesses probably the most wonderful harbor in the world, large enough to shelter every vessel of the globe (even before the Germans and the English started their efforts to put ships at the bottom of the sea). There are splendid open roadsteads at Ft. Bragg, Monterey, San Luis Obispo, Santa Barbara, Santa Monica and Redondo and well-protected harbors at San Pedro and San Diego.

The San Joaquin and Sacramento Rivers are both open to transportation for several hundred miles.

Streams like the Trinity and Eel Rivers and the perpetually snow-fed streams of the Sierras, the Feather, Butte, American, Merced, Kings and Kern Rivers as well as a dozen others are some of them already furnishing hundreds of thousands of electrical horsepower and are capable of supplying millions more.

MINERAL SUPPLY

The ribbed and scarred mountains besides being the source of water-power and timber offer an infinite array of minerals.

The "49ers" in their mad scramble for gold overlooked most other metals, minerals and resources. It was not until the discovery of the Comstock Lode that attention was even devoted to the silver lead ores and nearly fifty years elapsed before any copper was produced from the Shasta district and later in Nevada at Ely, Ludwig and other places. There are numerous reasons for the slow progress in the development of the mineral resources; transportation facilities were lacking; the technique of handling and milling ores was crude; cyaniding was unknown, which made only placer and free milling gold ores of high value available; water-power could only be utilized from wooden wheels at dam sites, and steam power by the expensive use of wood as fuel in timbered districts. Because coal oil and gas were unknown smelters did not exist and processes for handling complex ores have only been developed during comparatively recent years, by the concerted efforts of the chemists with the mining engineers—efforts which are still proceeding with unflagging energy and are daily budding into new and successful processes and methods. Think, for example, of the development of the Pelton and turbine wheels for power, the marvelous evolution of the dredges, the economies of the cyanide processes, the Cottrell improvements for obviating smelter fumes and the new processes for leaching copper ores.

The California gold production since 1850 has amounted to $1,600,000,000 and is still nearly $20,000,000 per annum. Nevada has produced $400,000,000 and now furnishes $12,000,000 gold annually. The low prices of lead and silver put such a quietus on the production of these metals that their important deposits have been all but forgotten.

California and Nevada still produce more than 85 per cent of the quicksilver from the United States, about 15,000 to 18,000 75-lb. flasks per year.

Platinum has long been found in the sluicing and dredging operations on the Trinity River and northern streams of the Sierras, but no consistent efforts were ever made to trace the occurrences to their sources. Quite recently some enormously rich deposits have been found in conjunction with zinc, in the Good Springs country in southern Nevada. Pockets of ores have been found running as high as $11,000 platinum, palladium and gold to the ton. The fact that the ore looks like a rusty clay probably accounts for ignorant prospectors having tramped over the ground for many years without cognizance of the wealth beneath their feet.

The zinc regions thus far known seem to be fairly well concentrated from Ivanpah to Good Springs. The occurrences are in the form of both calamine and sphalerite.

Tin was developed from cassiterite ores at Temescal in Riverside County some years ago, but the deposits are now lying idle.

Antimony has been long known, but shipments have only recently been started and a smelter is now in operation at San Pedro.

Bismuth has been found in veins south of Banning, and arsenic occurs frequently with gold ores on the Mother Lode. Chrome is found in large quantities on the western slopes of the southern Sierras.

Manganese is almost of common occurrence. The largest deposits are in the Coast Range mountains of Tehema and Mendocino Counties, at Tesla in Alameda County and in the Chocolate Mountains of Riverside County.

A Los Angeles engineer recently published a most illuminating article on the iron deposits of southern California in which he shows that by the most conservative estimates there are over 200,000,000 tons of iron ores available in the Providence, Eagle and Kingston mountains, all adjacent to railroads. The deposits average 64 per cent iron content against 55 per cent ores from the Mesaba Range, and there are fewer impurities, such as phosphorus, sulphur and silica. Is it not remarkable that with a yearly consumption of 900,000 tons of steel, and with limestone, fuel and nearby coke available, that these deposits remain untouched?

Not far distant from the iron are manganese and the only working deposits in the United States of tungsten. The electric smelting of iron at Heroult proved too expensive to be practical and the plants have been given over to the production of ferro-manganese. We have thus far badly neglected our opportunities of furnishing this country with high-grade steels.

The extent of the limestone formations, even in the southern sections, alone, almost beggar description. At Sloan, Nevada, range after range of mountains stand hundreds of feet above the floor of the desert solid unbroken masses of high-grade limestone. At many other points westward all the way to the coast there are hundreds of millions of tons of exposed lime rock. Big cement plants are to be found at Oro Grande, Colton and Riverside, also in the north at Santa Cruz, Napa Junction and Cement, while the lime deposits occur in the mountains all the way to the northern boundaries of the State.

Relatively, magnesite is of but small occurrence, though Califronia is the only State in the Union producing it. There is a small deposit at Winchester, a larger occurrence near Mojave and mines are now being worked near Fresno, at Red Mountain and in Sonoma and Napa Counties.

Kaolin, china porcelain and pottery clays are found at Ione in Amador County and Placer County with feldspar and silica not far distant, yet California imports yearly $300,000 worth of china and porcelain from the East. Brick and tile clays occur in river bottom lands in sections too numerous to mention. From the dark heavy clay soils of the ground on which they squatted the early Spanish and Mexican settlers made sun-dried bricks, from which they built their adobe huts.

Silica in the form of quartz can be obtained almost everywhere and there are fine deposits of white silica for paints and glass-sands in Nevada.

Sulphur was mined for many years in Humboldt County, Nevada, and fairly large occurrences are just south of Goldfield, while a very large new discovery has just been reported from Kern County.

Most of the world's supply of borax comes from California, from the great Borax Smith mines in Death Valley and more recently from the Ventura County deposits of colemanite.

The deserts furnish gypsum, talc, celestite, baryte and salt in profuse abundance and the dry lakes contain untold millions of tons of soda in the form of both carbonates and sulphates. At Searles Lake, of unfortunate exploitation, the American Trona Corporation spent more than $500,000 for a railroad before they had so much as evolved a process for working their raw materials. They planned to recover from the lake brines primarily potash, also sodium carbonate, sodium bicarbonate, sodium sulphate and borax. Many of the sinks of Nevada contain a considerable amount of potash; and much harmful exploitation and ill-directed effort has been expended trying to obtain potash from the sea weeds and kelps of the coast, from which the companies have hoped to recover iodine as well as many organic materials.

Throughout the two States there are small or sporadic deposits of flourite, bauxite, molybdenite, nitre, graphite, mica, asbestos, jasper, ochre, pyrites and alum, not to mention a hundred other less important minerals.

Mineral water and springs of all descriptions, hot and cold, mud, sulphur, soda, salt and lithia are to be found.

San Diego County furnishes us with the lithium salts of lepidolite from Pala, and from the same region are derived the semi-precious gems of tourmaline, aquamarine and kunzite. Elsewhere we obtain moonstones, garnets, tourquoise, onyx, opal, sardonyx, crysoprase, cat's eyes, variscite, rhodenite, californite, beryls, topazes, jades, abalone and pearls, even sapphires and not to be behind Arkansas occasional diamonds are noted.

Fuller's earth, little of which has been utilized occurs in Nevada and in the San Joaquin Basin.

There are numerous deposits of infusorial or diatomaceous earth in both California and Nevada. Probably the finest and largest deposit in the world is at Lompoc in Santa Barbara County. Through the efforts of the owners and their research chemists the value of their product has been demonstrated in many different industries. According to the specific gravity and purity of the material it is used in such diverse fields as the manufacture of sugar, edible fats, light brick, as an insulating medium, etc., some forty patents having been applied for or issued within the last few years covering the applications of their products to new uses. This is only one indication of the possibilities of well-directed chemical industry in the use of heretofore disregarded material.

We have an abundance of building materials such as slates, rhyolites, trachytes, volcanic tuffas, obsidianites and basalts. Marbles are plentiful, but quarries near existing railroads generally appear to be badly faulted and shattered, though the main difficulties in obtaining good slabs can usually be attributed to the ignorance with which our western deposits have been worked. Excellent varieties of colored, veined marbles are found at Carrara, Nevada, and green malapi conglomerates are obtained from near Barstow. All forms and colors of granites and sandstones are available of which you have seen many beautiful examples in the buildings of Los Angeles and San Francisco. Our cities need not go as far as Rome went, for their paving blocks, macadams, rubbles, gravels, sands and building materials.

OIL

In some of the valley regions there are large deposits of peats. Lignites and coals occur in the Coast Range Mountains. But of far more vast importance to chemical industry have been the discoveries and development of petroleum oils and natural gas during the last twenty years. With a production of 7,000,000 to 8,000,000 bbls. of crude oil per month no one need longer worry about any possible lack of fuel supply for our industries. California has at this writing approximately 55,000,000 bbls. of oil in storage above ground. Since the inception of the industry in 1890 approximately 750,000,000 bbls. have been produced and nearly 90 per cent of this amount within the last ten years.

We are refining as much of our oil as the markets will take and make casing head gas, gasoline, kerosene, distillates, lubricants and asphalts, but in view of the enormous sources of hydroelectric energy available for power it would appear that in burning our surplus oil we are practicing a criminal wastage of our resources for which we can hardly expect our descendants to forgive us. We have indeed been unwise as well as profligate with our heritage of natural wealth, to an extent from which we of the younger generation and our immediate children will suffer the effects. This condition applies particularly to our careless even wilful wastage of natural gas encountered in drilling for oil and which we in our haste for the nearest dollar have allowed to escape us to the cost and comfort of future generations. To be sure we are now beginning to pipe some of the excess gas from the wells to the cities, but distances in this country are great, investments large and subsequent prices for the gas are high.

Water gas from crude oil is the basis of most of our artificial supply. The only efforts made to utilize the

by products of this industry are in the making of carbon briquets; the napthalines, pitches and tars are all wasted.

The increased use of direct combustion oil engines of the Diesel or semi Diesel type should do much to effect economies in the consumption of oil fuels.

The shortness of my time limits more than the mere mention of such well established industries allied to the mineral resources as acid and powder manufacture, the production of fertilizers, glass and heavy chemicals.

With this hop, skip and a jump I fear that you have gained only a very faint conception of the extent and variety of our mineral products, but suffice it to say that of these materials California alone produced $103,000,000 worth in the year 1914.

AGRICULTURE

Agriculturally the resources of Nevada are too small to warrant attention at this time, but California more than makes amends for the deficiency.

The great valleys which twenty years ago supplied little more than grain and cattle are to-day undergoing constant transition toward more intensive farming and diversified crops. Wheat, barley, oats and corn are still grown in enormous quantities and now-a-days large crops of rice, on what were formerly called goose or bad lands. Hops for the brewing industries occupy much of the bottom areas of the Sacramento basin. One will find vineyards all the way from Red Bluff in the north to Bakersfield in the south, with the attendant industries of raisin growing, wine making and sometimes the production of argols. Interspersed with the vineyards you will see orchards of cherries, almonds, peaches, pears, apricots and prunes. Asparagus, potatoes and vegetables of all descriptions are grown on the river islands and deltas. The valley foothills grow olives, lemons, oranges and grape fruit, and in the higher altitudes the best of apples.

South of San Francisco, along the coastal valleys as far down as San Juan Capistrano, approximately 125,000 acres of sugar beets are planted annually, which yield about 500,000,000 lbs. of sugar, an amount two and one-half times in excess of the needs of our own population, not counting the equally large output of Hawaiian sugars from the two refineries on San Francisco Bay. Chemically and technically the best sugar industry has reached a high state of perfection though there are still many opportunities for improvements, particularly along the line of investigative agricultural chemistry and in the utilization of the waste products. The plants which have only molasses as an end product sell their material to either alfalfa-meal mills or to the distilleries for the production of alcohol. Those plants which have installations of the Steffens recovery process, in general, still send their waste waters, which contain distinctly valuable amounts of potash and nitrogen, to the sewers. In one or two instances these waters are pumped on to the fields as fertilizer, other plants are making efforts to concentrate their waste waters in conjunction with their lime cakes for the production of marketable fertilizers. About 3.5 tons of potash have heretofore gone to waste with every 1000 tons of beets worked.

The southern valleys, generally subject to fogs during the summer months, are well adapted and produce, in addition to sugar beets, large crops of beans, walnuts and olives. A recent improvement in the olive industry is a process for extracting tannic acid by drying bruised fruit—or mincing the meat, boiling it in its own oil and canning the product. In addition to the production of olive oil we grow peanuts and make the oil and butter therefrom. A fact not generally known is that California is producing annually about 600,000 lb. of Turkish cigarette tobacco.

The citrus products for which southern California is so well known are grown in the foothills and the semi-high regions where the orchards are least affected by the frosts. It is only of recent years that much attention has been paid to the possibilities of utilizing the fruits to the fullest advantage, particularly the so-called culled fruits. The associations of growers are maintaining separate laboratories, besides the special government stations, attempting to work out processes for the production of citric acid, oils of orange and lemon, citron, candied peel, marmalade, orange butter, orange wine and orange syrups.

The new farming districts of Imperial Valley produce alfalfa, cattle and cantaloupes. The finest grades of long-staple cotton are grown in this district and the cottonseed oil and cake industry is naturally following in the wake.

The fishing and canning industries along the coast are worthy of special mention. Sardines from San Pedro have for many years been boiled in California oil and put on the market in French-looking cans. But an industry, all our own, established at the same point is the production of canned tuna. Salmon have been caught in the Sacramento and the northern coast streams since the beginning of our history. Oysters, the small varieties, quite different from the large eastern type, are found in the bay regions.

The gradual encroachment of orchards and intensive farming on the old princely estates of the land barons, who formerly owned 40,000 to 60,000-acre tracts, has also demoralized the old-time cattle ranches of the low lands. The grazing grounds have been gradually driven further back into the hills and mountains, and only when the grass becomes short or the cattle are to be fattened for the markets are they herded into the valleys for alfalfa, grass or grain feeding. Dried beet pulp is also attracting considerable attention and the entire output of three of the southern beet sugar factories is either steam or kiln dried and sacked for dairy fodder; other mills pump the extracted beet slices to silos where the water drains off in part and the remainder after souring is highly valued for cattle fattening.

Our packing house industries are, of course, diminutive compared to those of the Middle West, none the less we have our tanneries, soap works and other allied branches of this work. It is, however, worthy of note that our hides all go East to be made into shoes which have to make another trip across the continent for our use. The majority of our wool and cotton follow the same course. The only textile mills we have weave cotton bags and canvas. . . .

You have probably already been wondering why this brief catalog of our resources and industries is so lengthy. I have been trying to convince you with a short survey that Californians can make good their boast that they lack no resources to make and supply them with all necessary physical comforts. Nature was probably never more bountiful to any country than this Golden West. We possess the resources for great industries based on electrochemical, metallurgical, mineralogical, agricultural, horicultural, husbandry and forestry pursuits.

PRESENT INDUSTRIAL LIMITATIONS

Why have these not been more firmly established and grown to greater extents? Why do we ship our crude products to the east and foreign countries for fabrication without even taking through the gates of our cities, to have them shipped back to us in only slightly altered form for our consumption? Why are our harbors only

transient points for all the riches of the tropics and the orient? Why have we been so slow to realize and to utilize to the fullest extent the resources, and to materialize into tangible assets the long dormant possibilities of our western kingdom?

The reasons are numerous. View our "splendid isolation" with the vast Pacific on one side of us, high mountains and broad deserts on the other, an almost barren uninhabited peninsula on the south and long reaches to civilization on the north. There are only four mountain outlets from California, ranging from nearly 4000 to 7000 feet in altitude. Bear in mind that we are more than 3000 miles from the eastern seaboard, 2000 miles from the center of population in this country; that it takes 6 days to reach Hawaii, the nearest islands of the Pacific, and three weeks to Japan, China or the Philippines, by fast mail boats.

Our Empire is traversed by only three trunk line railways with but few branch and spur line ramifications into the surrounding territories, and these lines largely parallel each other. In consequence, ore and timber deposits, with the possible exception of precious metals, are almost valueless unless by chance they lie practically adjacent to existing transportation. It is impossible to haul salt, gypsum, talc, magnesite, soda, potash, chrome or manganese from 10 to 50 miles over desert or mountain roads with any hope of putting such products on even the local markets at a profit. The first question asked of the prospector is "how far are you from the railroad?" Though we still have amongst our population many hopeful prospectors, sturdy mountaineers and tanned desert rats, they have mostly learned that excepting for gold they cannot wander far from the iron rails. In consequence there are still great undiscovered almost virgin regions in both California and Nevada.

Irrespective of long hauls to the railroads we have had much to contend with from the railroads themselves. No better picture of this phase of our development, has ever been penned than by Frank Norris in the "Octopus" in which he vividly describes the bitter hatred of the California pioneers for the Southern Pacific Railroad of the days of Collis P. Huntington. Though the old railroad tyrant has been long dead they failed to bury all railroad abuses with him. However, since the Harriman régime the Southern Pacific Railroad has improved wonderfully and the competition of the Santa Fe and the Western Pacific and the State and Interstate Railroad Commissions have done much to better conditions.

I am informed that in the east it is possible to generally figure 3½ mills per ton mile on railroad haul for ores. The lowest rates of which I am aware in this country are 5 mills per ton mile on certain sections of the Santa Fe. The beet sugar people pay 7 mills per ton mile for 70,000 tons of rock per annum over 197 miles of track. Recently I had some cheap ores (silica) to be moved 200 miles in Nevada. The first quotations were $15.90 per ton, and it took much coercion and many weeks of voluminous correspondence to ultimately obtain a rate of $3.90. If you desired to ship desert sand or ordinary rock from Nevada 400 miles to Los Angeles you would have to pay $4.00 per ton freight (10 mills per ton mile); to San Francisco, 500 miles, you would have to pay $6.00 or 12 mills per ton mile. The glass factories in the bay region claim that they pay only $5 per ton for Belgian sands after they have been transported 20,000 miles.

The lowest ore rates to the East via the Panama Canal are $7 per ton. Via Galveston on the Southern Pacific there is a $10 rate, but all material must be sacked. The lowest all-rail rates are $12 per ton. This is sort of a blanket rate to the majority of the railroad centers throughout the country. It costs $12 a ton to ship low-value ores to New York, Boston, Chicago, St. Louis, Denver or Salt Lake City and as anomalous as it may sound you might have to pay anywhere from $15 to $18 per ton if you wanted to stop your shipment at any point before it reached even Salt Lake City, the nearest terminus.

Our labor problems present many difficulties. With the total exclusion of the Chinese and the restrictions on Japanese, Hindoo and Mexican laborers we have discouraged and retarded many big enterprises. We are in need of foreign labor, a moderate number of thrifty Chinese or busy Japs would be of decided advantage to this country. We do not need Greek and Neapolitan fruit venders or organ grinders to crowd our cities, but we do need fruit pickers and mill workers.

Life in the rural and mountain regions is generally most attractive. Hunting and fishing still abound and there are good roads thereto in almost every section.

The city conditions are not much different from other parts of the United States. San Francisco as a world harbor is very cosmopolitan, a small New York. For many years it has been burdened like the old man of the sea with Unionism and labor troubles, yet see with what majesty she recovered from her devastating ruins. Los Angeles, a very moral town, is the next to the last abiding place of most of the successful farmers of the Middle West and many other people who can raise the cash to pay the railroad fare to what they think is a land of ease and indolence. The chief industries of this branch of the population are real estate and insurance.

I trust that I may have conveyed to you that we produce a far greater quantity of raw products, fruits, sugars, cereals, textiles, timbers, fuels and minerals than the people within our own borders can consume. The difficulties which lie in the way of hindering more rapid development are the lack of sufficient and reasonably priced transportation facilities for getting our products to markets. The sparsely settled country and the lack of population particularly of working classes, is the cause not only of restricted *local* markets but also of high labor costs for all products. The newness of the country has called for immense outlays of capital for development purposes, but investments in our big industries seem to be attractive to even foreign money as is witnessed by the interests of the Dutch Shell Oil Company and the General Petroleum Company in our oil resources and there is also much foreign capital invested in our copper and gold mines. We still need vast sums to help sane, rational development, but we trust that we shall no longer be oppressed with the scandalous exploitation schemes of scoundrelly promoters.

There are at present more pregnant opportunities for the development of resources than in the days of the pioneers of '49. We are only in need of much strong, honest effort and staunch capital to back it to make this one of the richest countries of the world.

It is frequently said that when one once visits California the longing to return never ceases until one comes back to live. We hope *you* have caught the lure of the "Golden West" and that we will some day see all of you chemists and engineers, you men who accomplish things, back amongst us in the near future, helping us with your hands and brains to change our possibilities into realities, and helping us to put to the best uses of mankind our great resources.

The activity of Japan in mining is represented by the fact that there are more than 1500 mines in operation, 52 gold, 112 gold and silver, 53 silver, 175 copper, 536 coal, 161 oil. Others are antimony, iron, manganese, graphite, peat, sulphur, etc. Many employ the most modern machinery.

The Fleming Dust Collecting System*

BY W. C. HANNA

As visitors pass out of the large acreage of orange and lemon groves owned by the California Portland Cement Company, and come within closer view of the splendidly equipped mill at the foot of Slover Mountain, those familiar with the general appearance of cement manufactories notice a decided difference in this one. There is something lacking which is common to the industry—or has been in years gone by. There are no kiln and dryer stacks with their objectionable trail of dust and fumes.

How it is possible to have such a condition in a factory of this size is explained by the buildings at one side of the plant, from the end of which large volumes of water vapor are pouring. These buildings and the machinery connected with them constitute the Fleming patent dust collecting system, which is receiving much attention from cement manufacturers throughout the United States, and back of which lies a history of interest to all connected with the cement industry.

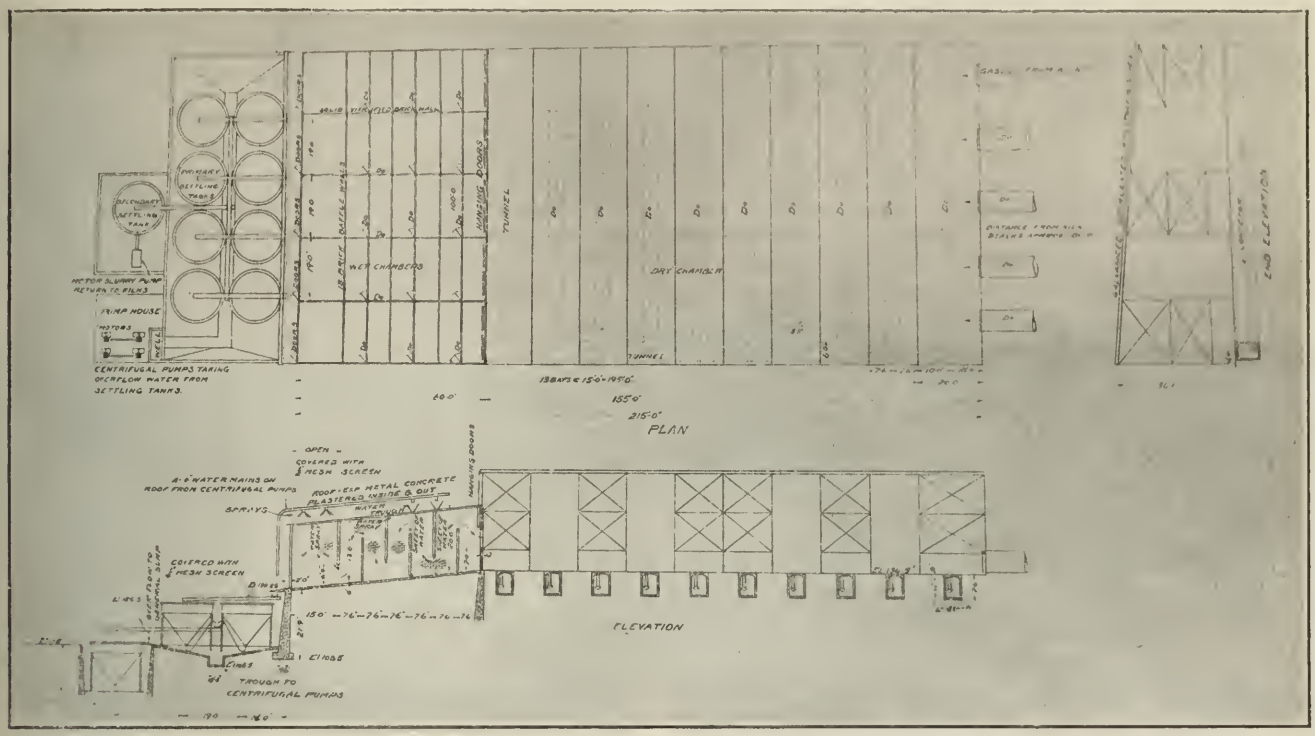

FIG. 1—THE FLEMING PATENT DUST COLLECTING SYSTEM

Orange growers in the vicinity of Slover Mountain began to complain in 1909 about dust emanations from the kilns and dryers of the cement plants operated at Colton. At that time the new or largest plant was one of the most modern in the United States and was considered by cement manufacturers a clean plant, and as there had never been any recorded injury to people or vegetation in the neighborhood of cement mills, the orange growers' complaints and threats were believed to be without grounds, but serious enough, however, to warrant an extensive line of investigations and experiments with all known methods for capturing the dust.

These investigations were continued with zeal, but nothing of sufficient effectiveness was found. In the meantime the orange growers, not being satisfied with the efforts of the cement company, brought suit against it and, in the trial during July and August of 1910, expert testimony from many parts of the world covered much of the field of cement manufacture, dust collecting devices, and agriculture as practised in the vicinity of Colton.

The Superior Court granted the orange growers an injunction in April, 1911, which became effective in June of that year, but, by that time, experiments at the old cement plant had proved so satisfactory that Mr. T. J. Fleming, secretary and general manager of the company, had most of the material on the ground for constructing his dust collecting system on a practical scale for five rotary kilns $7\frac{1}{2}$ ft. in diameter and 120 ft. long. By September, 1911, the first kiln was operating to the dust house and, shortly afterwards, all of the kilns were operating at full capacity with the Fleming System. Meanwhile, throughout the mill, a campaign against dust was made, resulting in all grinding machines, elevators, and conveyors being made practically dustless.

The orange growers were not yet satisfied with the efforts of the Cement Company and brought suit for contempt of court. The evidence was such that the court was not satisfied, so he appointed Dr. R. E. Swain of Leland Stanford University, as an impartial expert to make an examination of the system and report to him.

Dr. Swain's very complete investigations were made in February, 1912, and the report, which he made shortly afterwards, was so favorable that the court dismissed the case stating that the plant as operated was not a nuisance and was not being operated in contempt of court.

This same system of dust collecting has been in continuous use since that time and has proved to be, not only an efficient means of capturing the dust, but also to be more than self-supporting, there being a saving to the company in the dust captured, better output per barrel of fuel oil, and less shut downs than before the Fleming System was in operation.

*A paper read at the seventh semi-annual meeting of the American Institute of Chemical Engineers, at Los Angeles, California, on Aug. 18, 1915, in joint session with the Southern California Section of the American Chemical Society. An account of this meeting was given in our issue of Sept. 1, page 530.

PRINCIPLE OF SYSTEM

Very briefly, the installation consists of normal rotary kilns using dry process and oil for fuel. The draft for the kilns and dryers is produced by fans sucking at the end of separate flues. Instead of discharging the gases into the atmosphere, the same exhauster fan blows the dust and fume into a large chamber known as the dry dust settling chamber where the velocity of the gases is reduced about 90 to 95 per cent, resulting in a large amount of dust being deposited. The extremely fine dust which does not settle and the gases then go to the wet washing chambers where the gases are forced up and down several times while following a serpentine course through a system of seven baffle chambers, and the last of the original so-called cement dust is captured by sprays of water which are in each chamber. These sprays of water also bring into solution much of the gases, lime and alkalies. In connection with both the dry and the wet chambers there are means provided for removing the captured dust to the cement kilns.

DESCRIPTION OF PLANT

This paper will describe a unit in connection with three kilns 8½ ft. in diameter and 150 ft. in length with a capacity of 31 barrels of clinker per kiln hour, or about 2200 barrels per day, also one clay dryer which handles all of the clay used at the plant. This is the third large unit installed at Colton, each new unit, as installed, having a few improvements over the preceding one. The house has capacity for two more kilns of this same size.

FIG. 2—THREE KILNS AND FLUES LEADING TO FANS

The clay dryer flue is seen below the three large flues. Part of dry dust chamber shown in lower right hand part of picture. Sawed off stacks, with seal on top for five kilns 7½ ft. by 120 ft. seen in the extreme left.

The fans which produce the draft in the kilns are located at the end of what would normally be the stacks to the kilns, but which in this case are about 180 ft. long and which, instead of being perpendicular, first rise from the stack base at the feed end of kiln then curve over and slope downward toward the fans. Each kiln is provided with a separate flue, fan and motor, so that the operation of any one kiln is independent. The flues are 6½ ft. in diameter, lined with fire brick for the first 20 feet, and they are provided with the necessary expansion joints.

The fans are of special exhauster type made by the B. F. Sturtevant Company. They are 5 ft. wide and 10 ft. in diameter, equipped with water cooled bearings and operate at a speed of about 145 r.p.m., each fan being driven by a 40 hp. motor, although only 11.7 hp. is required except when fan is first started. During the past year of continuous service there has not been a single hour lost due to fan trouble.

The results obtained by the kilns determine the speed at which fans are to be operated. Sometimes it is found to be desirable to give the kiln more draft, and the fan is operated at a faster speed, while at other times the reverse is true. The ease with which the draft in the kiln can be regulated is of great assistance in the economical operation of the rotary kilns.

A Thwing pyrometer is used in connection with the installation, the thermocouples being located in the flues near the fans, and the recorder in the kiln room where the cement burners can regulate the fires keeping the temperature at the fans not higher than 900 deg. Fahr. This together with the perfect control over the draft and of the speed of the kilns, makes the condition ideal for the manufacture of Portland cement clinker. The draft, induced as above, has proved to be far easier to control than a stack draft, the life of the kiln lining is almost permanent, provided kiln is not allowed to get cold, the ring formation reduced, and the clinker produced more uniform in quality.

DRY DUST SETTLING CHAMBER

The discharge from the fans is just about the same as from an ordinary kiln stack, only the blast is horizontal instead of perpendicular and at an elevation that is convenient for treating the gases laden with dust in the dry dust settling chamber.

This chamber into which the fans discharge the gases is 150 ft. long, 100 ft. wide and 31 ft. high. It is a steel frame structure, with sides and roof covered with corrugated galvanized iron in order to promote radiation of heat.

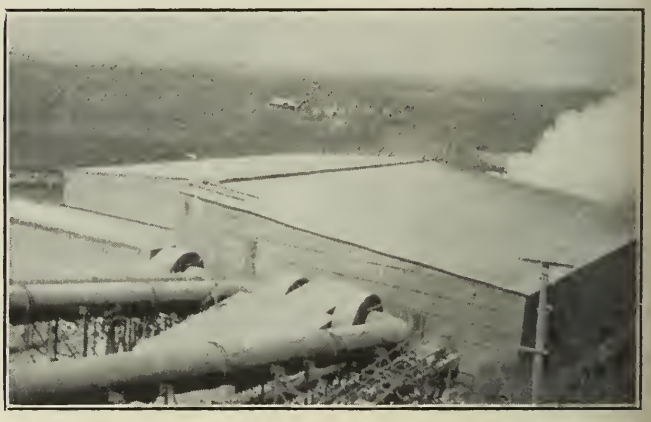

FIG. 3—THE FAN WITH PART OF FLUES

Also dry dust chamber, and water vapor pouring from the wet baffle chambers.

There are no barriers to a free passage of the flue gases within this chamber, except a set of baffle plates about ten feet wide extending across the chamber in a line about thirty feet in front of the inlet flue openings.

The temperature of the gases as they go to this chamber is 700 deg. to 900 deg. Fahr. and on emerging from the same the temperature is 300 deg. to 400 deg. Fahr. Due to this reduction of temperature, and to the large area of the house there is a 90 to 95 per cent reduction in the velocity of the flue gases, resulting in about two-thirds of the suspended dust particles or about thirty to forty tons of dust per day being deposited in this dry chamber.

There are ten cross tunnels beneath the floor of this department, and in each tunnel there is a screw conveyor with steel troughs and ten spouts, with gates, leading from the floor above into the conveyor for drawing off the dust.

Each of these cross tunnel conveyors discharge into

the conveyor running in the main tunnel and it, in turn, connects with a conveying system which carries the dust to a bin in the raw mill building. The dust is drawn from this bin and properly mixed with the material being fed to the kilns.

WET WASHING CHAMBER

The gases, with the remaining dust, go to the wet baffle chamber which is the same width as dry chamber and 60 ft. long. The frame work is of steel, the sloping floors are of concrete, the walls of brick and concrete, and roof of expanded metal encased by concrete.

It is divided into five separate compartments, each 60 ft. long and 20 ft. wide.

Each compartment receives the gases from the dry chamber through two openings, 6½ ft. by 9 ft., which may be closed by means of hanging concrete doors operated vertically from the roof.

Only three of these compartments are required and the two not in use can be kept in reserve in case any of the others should require new sprays or other work done on them.

Each of these compartments has six transverse baffle partitions alternately rising from the floor and descending from the roof, leaving six foot transverse openings through which the gases are forced, over the first baffle and under the second, and so on until they

FIG. 4—DRY CHAMBER AT LEFT, THEN WET BAFFLE CHAMBERS, THEN SETTLING TANKS

pass under the sixth baffle, emerge into the exit chamber, and through the roof, which is made of one-half inch mesh wire screening. The actual area of exit openings for each compartment is about 135 sq. ft. and the velocity of the gases about 250 ft. per minute.

Each baffle section in each of the five compartments is provided with a set of water sprays. The return water from the settling basins is used in all of the sections except the last one. Each spray with return water is adjusted to carry about twelve gallons of water and each fresh water spray delivers about six gallons per minute. In these wet baffle chambers the remaining one-third of the dust in suspension is removed and the temperature of the gases reduced to about 125 deg. Fahr. at the exit.

The water with its load of dust, falls to the sloping floor and runs to the end of house, where it falls into a screen covered trough extending the entire length of the end wall of the wet baffle chamber. Lateral troughs lead from this to the center of each of the eight primary conical, steel, settling tanks, 16 ft. in diameter.

The overflow from these, being almost free from suspended matter, falls through the open air, in order to cool it, to the reservoir below from which it is pumped as return water at about 100 deg. Fahr. by centrifugal pumps, back to the sprays.

The thin slurry from the bottom of the conical primary settling tanks is syphoned through gooseneck pipes to a common trough which leads to a secondary conical settling tank.

The clean overflow from this also goes to the common collecting reservoir, but its thick slurry, containing about twenty pounds of solids per cubic foot, is pumped to the slurry tank above the kiln stack bases from which it is continually fed to the rotary kilns.

The amount of water required to operate the Fleming system is much less than at first would be expected. The fresh water need not exceed 75 to 100 gal. per minute, and it has been found desirable to add this in the form of coarse sprays in the exit chamber, above the screen to the same, and in the baffle chamber just before exit chamber. The greatest part of the washing is done by the circulating water which amounts to at least 1000 to 1200 gal. per minute. The heaviest sprays of return water are located in the second baffle chamber after leaving the dry chamber.

The amount of dust captured each day in the dry dust chamber is about thirty to forty tons, while about fifteen tons is captured in the wet baffle chambers.

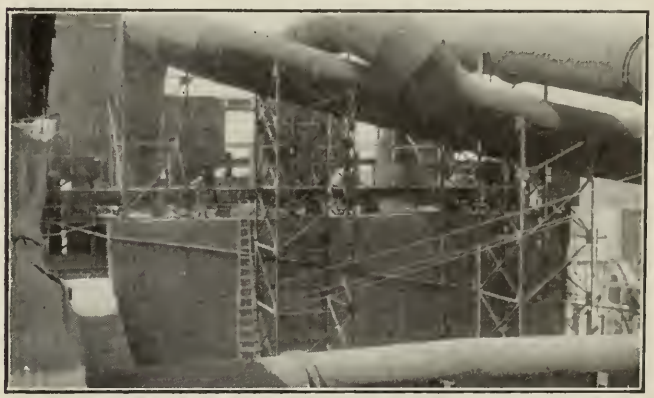

FIG. 5—THE KILN FLUES LEADING TO FANS

The flue at bottom of picture leads from the clay dryer to the dust house.

Where only rotary kilns are operated in connection with the dust collecting system, the proportions of calcium oxide, silica and alumina found in both the dry dust and slurry are found to be such that they can be returned to the kilns without special attention being given to them. Where dust from dryers, such as clay dryers, is also collected in the same system the dust will contain an excess of clay and it must be returned with proper care. At the Colton plant the dust is used so as to balance any irregularities in the composition of the raw mix as it goes to the kiln feed bins.

UTILIZATION OF THE COLLECTED DUST

The method of using the dust will probably be of interest so I will briefly tell you how it is blended.

The rotary kilns and the dust collecting system are in operation twenty-four hours each day, while the clay dryer operates at night long enough to fill the empty clay bins. The slurry from the wet baffle chambers, after being thickened in the tanks, is pumped about every hour over kiln stack bases to a tank holding almost one day's run, and the slurry kept in agitation by compressed air. The hundred spouts under the dry dust chamber are opened daily, only on the day shift,

and the dust conveyed to a bin of almost one days' capacity in the raw grinding department.

The amount of dust deposited in the collector from the kilns is very uniform and from the amount of clay used one day it can be closely estimated how much clay will be deposited in the chamber that night to be mixed with the kiln dust for use the next day and night.

The raw mix, as proportioned at the scales, is made of such composition that the dust must be added to it in order to give a suitable composition. The dry dust can be added to the ground raw mix at any desired speed, and from one to fifteen raw mills can operate without causing inconvenience. When everything is normal, the miller operates the dust feeder at a specified speed for each different number of mills that he may be operating, but in case the raw mix, as tested in the laboratory, is found to require a little more or less clay the laboratory orders the dust feeder to be speeded up or reduced sufficiently to give the desired mixture. As the dry raw mix runs into the kilns, a small stream of the well-mixed slurry from the slurry tank runs by gravity into the kilns.

The dust captured in the dry dust chamber is very fine, practically all passing a No. 200 sieve and about 97 per cent passing a No. 300 sieve. Both this dust and the extremely fine dust captured in the form of

FIG. 6—EXIT WATER

A—Water with load of dust falling from sloping floors into main trough. B—Lateral troughs over settling tanks. C—Surface of water in settling tanks.

slurry have much more sulphur, potasium and sodium than the raw mix, but after a few returns to the kilns they do not show any further increased percentages of these elements.

The water used in the wet baffle chambers very rapidly becomes heavily laden, chiefly with sulphur compounds of potasium, sodium and calcium, and when more than half a pound per cubic foot is found, some of the water is taken out and replaced by fresh water in order not to cause trouble with the sprays. Plans are being made to recover the potash.

The dust which is discharged into the air from the exit to house amounts to about one ton per day. This dust bears no resemblance to the original cement dust, it being for the most part sulphur compounds of potasium, sodium and calcium and about 88 per cent to 94 per cent soluble in water. This dust is produced by the draft drawing out the fine sprays of water from the wet washing system much the same as the wind carries inland the salt-water spray from ocean breakers.

LABOR AND POWER.

The Fleming system requires very little labor. The power consumption is reasonable, not exceeding 2000-kw. hours per day, of which 57 per cent is used on the return water pumps.

The cost of placing the Fleming system in an old plant would depend upon the general layout of the plant, the amount of room available and type of construction. In a new plant the apparatus can be placed with ease and at minimum cost.

In concluding my remarks with the customary contrast of results "before and after using," it is impossible to deal exclusively with the unit used thus far in this paper, as that unit has always operated with the dust collector in connection. Therefore, it will be necessary to take results obtained with one clay dryer and

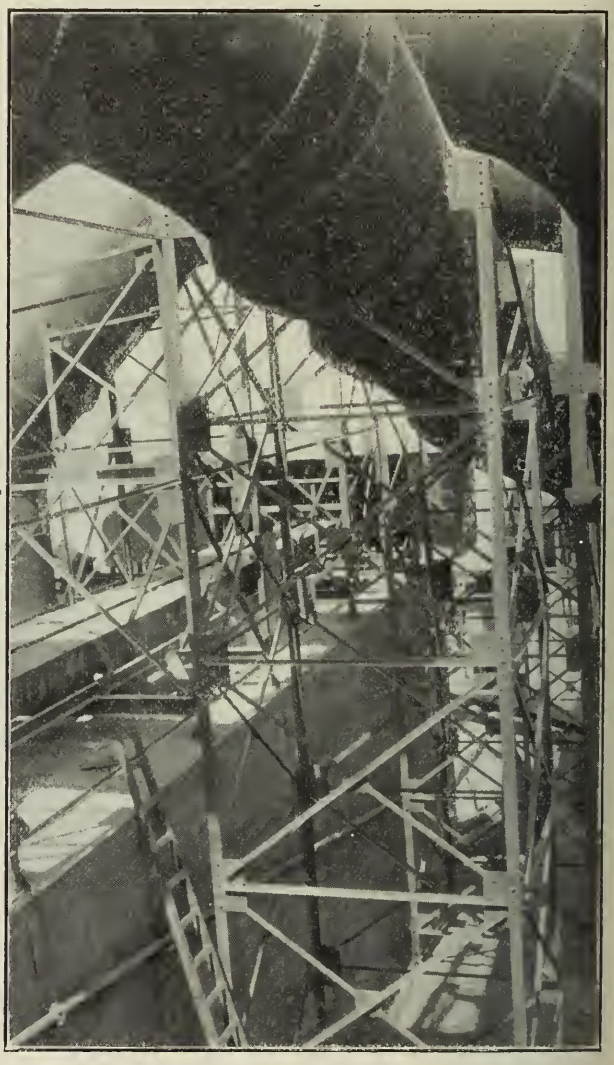

FIG. 7—KILN FLUES

Which first rise from stack base, then come over and slope downward toward the fans.

five kilns, 7½ ft. in diameter and 120 ft. long, which were operated for about 2½ years with normal practice, and then for the same length of time with the Fleming system.

With this dust collecting system in use there was obtained:—(1) About 24 per cent more clinker per barrel of fuel oil consumed; (2) about 5 per cent more clinker produced per hour of kiln operation; (3) about 2 per cent more actual operating time of kilns; (4) over 7 per cent less raw materials required for manufacturing a barrel of cement; (5) the quality of the output was improved; (6) dust from dryers and kilns collected and the nuisance abated.

California Portland Cement Company,
Colton, Cal.

Manufacture of Cream Tartar*

BY OTTO BEST

The history and development of the manufacture of cream tartar and its allied product, tartaric acid (Rochelle salt), in this country is a phenomenal one. Its rise began with the use of cream tartar as a constituent for baking powder, for which, by far, most of the cream tartar is being used.

From a small industry thirty to thirty-five years ago, it has developed in this country to a production of about 1,500,000 to 2,000,000 lb. per month.

It is a general belief that a goodly portion of this product derives its raw material from California, the more so as California produces on an average 35,000,000 to 50,000,000 gal. of wine annually.

However, as a matter of fact, California furnishes only a very small portion of the total used, about 400,000 to 500,000 lb. purity on raw material per year, which is not even one-half the monthly consumption of this country. The rest of the raw materials come mainly from France and Italy, very little from other countries.

RECOVERY OF RAW MATERIAL IN CALIFORNIA

A good many efforts have been made in California to recover more tartrate raw materials. The high-grade goods, argols, are saved completely. The lees, however, are not fully recovered. Most of the large wineries have recovery plants for this product, in which the main stress is laid on the recovery of the alcohol in the lees, the latter being distilled off as brandy.

The lee recovery in this case is, therefore, only incidental and not the main purpose. This is partially due to the low value of the product in comparison to the wine and brandy, and partially on account of the high labor and dirty work in connection with this work. At any rate, the recovery of lees in California is anything but complete.

EXTRACTION OF POMACE

A number of years ago there were several plants in California that aimed at recovery of tartrates from pomace, the residue left after the pressing of the grapes. These plants contributed for a number of years toward the production of tartrate raw material. They disappeared, however, entirely, mainly on account of changed conditions in the industry.

There is no doubt in my mind that with the application of modern means a good deal more tartrate could be recovered in California. The rapid strides of the temperance movement, and adverse legislation, no doubt has a depressing effect on the industry and has greatly stifled the enterprise in this direction.

RAW MATERIAL

The raw material is partly in the form of lees, a product averaging about 35 per cent cream tartar, with varying amounts of calcium tartrate, say 2 to 5 per cent, which is deposited by the first fermentation. It consists of about two-thirds dead yeast, with sulphur, wood chips, etc., and one-third tartrates. This product is, however, mainly used in Europe for the manufacture of tartaric acid.

ARGOLS AND LEES

The raw material in this country for cream tartar is mainly argols, the secondary deposit in the wine barrels after the fermented wine has been drawn off from the settled lees. This product averages about 70 per cent in cream tartar and 5 to 7 per cent in calcium tartrate.

Where gypsum is being used for the removal of some tartrates from wine, much more calcium tartrate is present. Such argols, very high in calcium tartrate, are used for the manufacture of tartaric acid.

The refineries of cream tartar are always connected with the manufacture of tartaric acid, as calcium tartrate and impure mother liquids of cream tartar have to be converted into tartaric acid. At least there is no technical method worked out on an economic basis which would permit reconversion of those impure products into cream tartar.

As the demand for tartaric acid is comparatively small, its manufacture is more or less considered a necessary evil, and its production reduced to a minimum.

There have been a number of processes employed in refining cream tartar.

Neutral Process

One of the earliest in the United States, at least, which appeared, but as early disappeared, was the so-called neutral process. It aimed at neutralization of cream tartar by alkali, and then precipitating again by acid according to the following equations:

$$2KHT + Na_2CO_3 = 2KNaT + CO_2 + H_2O$$

The KNaT was separated from the pulp by filtration, and the solution precipitated as follows:

$$2KNaT + H_2SO_4 = 2KHT + Na_2SO_4$$

About the practical details I know little. No doubt the process failed on account of the costly chemicals used, and technical difficulties.

Settling Process

The so-called *settling* process was successfully used for a number of years and, though rather crude, has decided advantage over the "neutral" process on account of its simplicity and cheapness of operation.

It was used in two modifications, which modifications refer to the working up of the residue into tartaric acid after extraction of most cream tartar.

The crude material was first ground and charged into a large wooden cooking tank, with a perforated copper basket, about 30 in. in diameter, reaching down to the bottom. The heating of the mother liquor to boil was carried out through long copper coils, while the basket was charged with live steam to keep the crude material in suspension.

It was the opinion of the cream tartar manufacturer that this stirring had to be very violent to get all cream tartar in solution. The basket had to "dance," as the official expression was. The wood chips and undissolved cream tartar passed through the holes of the basket and settled outside the basket.

After full charge was made with a solution of from 3 to 3½ per cent, china clay was added in order to make the suspended matter settle faster and more completely. The more china clay, the better, was another axiom of the refiner of the old day.

After settling, the fairly clean solution was drawn off into wooden or, later on, copper crystallizers.

The aim was to get large crystals, in order to be able to remove the mechanical impurities by a washing process, and these large crystals were only obtainable by a low saturation. While full saturation of cream tartar in pure solution is 6.9 g. in 100 c.c. at 100 deg. C., the real strength was rarely over 3.5 g. per 100 c.c.

After cooling, the cold mother liquid was pumped back again to be re-charged, and this process carried on so often until the mother liquor was too impure, and was then sent to the tartaric acid department to be worked into tartaric acid.

*A paper read at the seventh semi-annual meeting of the American Institute of Chemical Engineers, at Berkeley, Cal., Aug. 26, 1915.

WASHING OF FIRST (BROWN) CRYSTALS

The large, brown, cream tartar crystals, with much mechanical impurities, were crushed; that is, the aggregates broken up into large individual crystals, and these stirred up by mechanical devices.

One of these devices was a revolving drum, the so-called *rumbler*. The heavy crystals stayed on the bottom, while the lighter impurities would stay in suspension and could be drawn off from the crystals. The muddy mother liquor was used for tartaric acid manufacture. The crystals, if needed, were washed a second and a third time with mother liquor, until pure.

ACID TREATMENT OF FIRST CRYSTALS

The crystals, thus obtained, contained on an average 90 to 92 per cent cream tartar. The rest was mostly calcium tartrate, a little coloring matter, traces of iron, gypsum at times, etc.

The calcium tartrate cannot be removed by recrystallization, as it is freely soluble in a hot solution of cream tartar, from which it crystallizes or deposits, as cream tartar crystallizes on cooling. It is, therefore, removed by acid. To this interesting reaction I shall come back later on.

This washing with acid was usually combined with the removal of the mechanical impurities, as described before.

After the removal of excess acid by water, the crystals tested 98 to 99 per cent in cream tartar, though the earlier *finished* products averaged only 95 per cent in cream tartar.

REMOVAL OF CALCIUM TARTRATE BY COOKING UNDER PRESSURE

I wish to mention here a process which, for some time, was considered the only commercial process of removing calcium tartrate, and thus getting high-grade cream tartar.

It consisted in dissolving the crystals containing calcium tartrate under about 100 lb. pressure. Under this pressure calcium tartrate, with 4 molecules of crystallization water changes to the anhydrous compound, which is almost insoluble, more so in pure than in impure solutions. Through filtration and crystallization a high-grade cream tartar could be obtained. This process has been entirely abandoned.

RECRYSTALLIZATION

The 98 to 99 per cent product obtained was dissolved again, decolorized with lime-free bone black (bone black treated with hydrochloric acid), china clay added to settle bone black, and the settled solution crystallized in copper crystallizers of considerable size.

The crystals obtained from this solution were washed, dried, and ready for shipment.

The heavier mud from first (brown) cooking tank was charged and leached a second time, while the lighter mud was used as raw material for the manufacture of tartaric acid.

ACID TREATMENT OF MUD

In some factories this mud was treated with sufficient sulphuric acid to decompose all tartrates, bring them in solution, and filter and wash the mud in filter presses.

The clear solution was then neutralized with lime, or carbonate of lime, to precipitate the tartrates as calcium tartrate, an insoluble compound, and remove the potash and other impurities by washing.

DIRECT NEUTRALIZATION OF MUD

In other factories the neutralization was carried out without removing the mud. In this case the reaction takes place in two phases:

$$2KHT + Ca(OH)_2 = CaT + K_2T + H_2O$$
$$K_2T + CaSO_4 = CaT + K_2SO_4$$

If the precipitation is carried out right, the calcium tartrate is granular and heavy, which settles quickly, while the suspended matter settles very slowly. If wash water is drawn off before mud has a chance to settle, soluble and insoluble impurities are removed at the same time.

The process is very simple and avoids the cost of acid and the costly filtration. Yield is also satisfactory, so that the crude settling process has the preference over the acid filtration process.

However the calcium tartrate is obtained, after complete removal of all impurities, it is decomposed by sulphuric acid into gypsum and tartaric acid, the latter worked up as further on explained.

I wish, still, to state that this settling process was, for a number of years, practically the only process carried out successfully on a large scale.

High-Pressure Process of Cream Tartar Extraction

This process was the first attempt of getting the raw material in a filterable state, in order to remove the impurities right from the start, instead of carrying the mechanical impurities all through the process.

There is no doubt that the removal of the impurities from the start is sound in *principle*, though not always possible in practice, without too much sacrifice. Let us see how this process attempted the solution of the problem:

Argols or lees were ground and cooked under about 100 lb. pressure for about two hours. Through this cooking, all albumin and other constituents detrimental to filtration, were destroyed. At any rate, the solution, after this treatment, was filterable.

The clear solution, after filtration, was run into crystallizers and crystallized and otherwise treated as described, with this difference that mechanical impurities were removed by filtration and need not be removed by a "rumbler."

This process was mainly used for low-grade goods, lees. From a technical and mechanical standpoint it works well. However, the loss on raw material is very large, particularly in presence of calcium tartrate.

Systematic investigations have shown that the loss on cream tartar was in direct proportion to the amount of calcium tartrate present. The latter seems to decompose more readily than cream tartar. The lime forms fresh calcium tartrate, which again is decomposed, etc.

A further drawback of this process is that the mother liquors become very soon discolored and syrupy and have to be discarded.

Last, but not least, a pressure process, especially with an acid product, is never a desirable process technically. For these and other reasons it is to-day practically abandoned. It is interesting from a historical standpoint, mainly because it introduced filtration, and with it modern methods in the manufacture of cream tartar.

Roasting Process of Extracting Cream Tartar

We now come to the latest process, the so-called "roasting process."

Argols or lees are roasted at a temperature above the decomposition point of albumin, organic coloring matter, etc., but below the decomposition point of cream tartar and calcium tartrate. This temperature is around 150 deg. C.

The effect of this roasting is marvelous. While argols and lees, when extracted without roasting, are practically unfilterable, just a few dark-colored drops passing through the filter, after roasting the solution passes the filter almost like water, the filtered solution is absolutely clear, and of light straw yellow color.

The roasting is, therefore, not only for the purpose of an increased filtration, but is a great purifying process as well. The mother liquors from the roasted goods can be used over again much longer than from unroasted goods.

DIFFERENCE OF ROASTING AND HIGH-PRESSURE PROCESS

You will note the big difference between the two processes which aimed at filtering: The first process, cooking under pressure, increases the coloring and extract matter going into the mother liquors, and causes big losses on tartrates, besides larger technical difficulties.

The second process, dry roasting, improves the mother liquors by decreasing extract and coloring matter, is carried out *without any loss* on tartrates (I refer here to losses due to this roasting), as experiments on a small and large scale and operations on a technical scale for years have conclusively proven. It is, furthermore, simple and efficient.

After roasting, the raw material is ground coarsely and extracted in wooden vessels with agitators. Boiling is avoided. The charge is now filtered through bronze filter presses into copper crystallizers, and allowed to crystallize for four to five days. The filtration is very rapid.

With a pressure not to exceed 50 to 60 lb., 24,000 gal. could easily be filtered within about three hours without cleaning filter press. Whoever has tried to filter cream tartar will appreciate the technical success of this process.

The amount of filter cloth used was very low. With a monthly production of about 150,000 lb. cream tartar, the bill for filter cloth for this department was below $100.

As the labor and other items in connection with the roasting process and filtration are also low, and the yield on cream tartar much higher, than with the other processes, the roasting process must be considered the only rational and modern process.

COMPLETE EXTRACTION OF MUD WITHOUT ACID

The leached out mud is extracted a second and a third time with cream tartar mother liquor in a systematic way, and is then practically free from tartrates. It is not necessary to give this residual mud an acid treatment, or send it to the acid department. It is sufficiently low in tartrates to be discharged. It still contains some phosphates, nitrogen, potash, and can, therefore, be dried and used as a filler for fertilizer.

Another great advantage of this process is that the saturation of the solution can be much higher than with the settling process. The saturation can be brought up to 6 per cent (with the settling process about 3½ per cent), as we need not to settle nor depend on large crystals, as the cream tartar crystals are free from mechanical impurities. This, naturally, cheapens installation and manufacture.

FIRST (OR BROWN) CRYSTALS FROM ROASTING PROCESS

The brown crystals test about 90 to 92 per cent in cream tartar. The rest is calcium tartrate, as mentioned in the description of the previous process. The calcium tartrate crystals are usually yellow, and adhere to the edges and corners of the cream tartar crystals, as they crystallize out *after* the cream tartar is practically crystallized out.

They can clearly be distinguished from one another, as the cream tartar crystals have sharp edges and corners and are transparent, while the calcium tartrate crystals look amorphous, are not transparent, and are usually uniformly colored through a trace of iron. If free of iron they are white, but not transparent.

REMOVAL OF CALCIUM TARTRATE FROM RED CRYSTALS

On account of this property, that the calcium tartrate crystals stick to the surface of the cream tartar crystals (do not permeate the cream tartar crystals throughout), they can be dissolved in acid without fine grinding of cream tartar. The cream tartar crystals are merely crushed into individual crystals, and then treated with acid. These reactions in this connection are very interesting, as one (the first one) is reversible. Here are the reactions:

$$KHT + HCl \leftrightarrows KCl + H_2T$$
$$CaT + 2HCl = CaCl_2 + H_2T$$

The first reaction is reversible, for the reason that cream tartar is almost insoluble in KCl solution. The solubility of pure cream tartar in a 10 per cent KCl solution is 0.04 g. cream tartar in 100 c.c. The stronger the KCl, the greater the tendency of forming cream tartar back again. In reacting back, free hydrochloric acid is formed, which is capable of dissolving calcium tartrate. Thus the free hydrochloric acid is neutralized and more KCl can act on H_2T and form cream tartar and HCl. The hydrochloric acid again acts on the calcium tartrate, etc., etc.

PURITY OF ACID-TREATED CREAM TARTAR CRYSTALS AND LOSS ON CREAM TARTAR TO TARTARIC ACID

As stated, the reverse action takes place the more, the stronger the solution. For this reason I add strong hydrochloric acid, 20 to 22 deg. Bé to the fairly dry cream tartar, just enough to cover it. This is about equal in weight with the calcium tartrate.

Investigations showed that in the first twenty-four hours the purity was raised usually to about 95 per cent, while the mother liquor contained about 2 parts of cream tartar to 1 part of calcium tartrate (figured as calcium tartrate).

After forty-eight hours the purity would rise to 97.5 to 98 per cent purity, while the mother liquor contained about 1 part of cream tartar to 1 part of calcium tartrate in solution.

After seventy-two hours the purity of the cream tartar was usually 99 per cent, or above, and the mother liquor contained now about 1 part cream tartar and 2 parts calcium tartrate.

These are average figures from practice, and change according to concentration of hydrochloric acid and temperature; but mainly with the size of calcium tartrate, which varies considerably.

As will be seen, time is the essential factor of this reaction.

These figures were obtained when no agitation or stirring was applied.

Comparative figures, under vigorous stirring for a comparatively short time, say one-half to one hour, demonstrated that the amount of cream tartar in solution and the amount of hydrochloric acid were both much larger in the latter than in the former case.

In a previous chapter I mentioned that the manufacture of tartaric acid in this country was, more or less, considered a necessary evil. Since the hydrochloric acid solution of tartrates can only be worked into tartaric acid, it is important that as little as possible of the cream tartar is dissolved by the hydrochloric acid. Long standing with hydrochloric acid dissolves comparatively little cream tartar.

More cream tartar can be precipitated from this hydrochloric acid solution by partial neutralization of the excess hydrochloric acid.

The brown cream tartar crystals thus treated with hydrochloric acid are washed with water, and test now over 99 per cent in cream tartar.

RECRYSTALLIZATION AND DECOLORIZATION

They are redissolved, decolorized with boneblack, filtered and crystallized a second time, washed, dried, and are now colorless crystals of over 99.5 per cent in cream tartar.

When the white mother liquor does not furnish pure crystals any longer, it is discharged into the red batches. A corresponding amount of red cream tartar liquor is discharged into the tartaric acid department.

LOSS IN MANUFACTURE

The loss in manufacture of cream tartar is comparatively small, as all the impure products which cause the loss are discharged into the tartaric acid department.

This transfers the difficulties and losses merely from one department to the other.

The loss in the cream tartar manufacture are partially due to fermentation, which loss is very low, practically nil, with the roasting process; larger with the other processes.

FERMENTATION OF CRUDE MATERIAL

The fermentation may start with the raw material, stored away, when the same had not been completely dried. In order to establish this loss, a cream tartar test (Klein test) is made from the raw material and a potash determination, and the latter figured into cream tartar. If this figure is higher than the direct determination, loss through fermentation of raw material has occurred.

LOSS THROUGH COOKING

Some loss is due to cooking, possibly a little through roasting, though a direct determination never disclosed a loss in either direction.

There is no further source of loss, outside of some mechanical loss.

Manufacture of Tartaric Acid

We now come to the manufacture of tartaric acid. As indicated above, all products of cream tartar manufacture too impure for cream tartar are transferred to the tartaric department.

The various sources are: impure cream tartar, mother liquor, and the tartrates from the hydrochloric acid treatment. No mud need be treated in the roasting process, as the extraction in the cream tartar department is complete.

MANUFACTURE OF CALCIUM TARTRATE

These products are transformed into calcium tartrate, an insoluble compound, which can be washed for the removal of the impurities.

If we manufacture calcium tartrate from cream tartar crude material, two steps are needed, as explained before. These products, with excess hydrochloric acid, form enough $CaCl_2$ to precipitate the neutral tartrates as calcium tartrate without further addition of gypsum.

SOLUBILITY OF CALCIUM TARTRATE

The solubility of pure calcium tartrate is about 1 part in 6000 parts of cold water. This solubility is raised to 1 in 500 parts in *hot* water. It is well, therefore, to neutralize cold, if large losses are to be avoided.

Impurities in solution affect the solubility of calcium tartrate. $CaCl_2$ and KCl *decrease* the solubility of calcium tartrate. All other impurities seem to *increase* the solubility of calcium tartrate. Organic substances in solution, for instance, considerably increase its solubility; so do iron and aluminum salts, phosphates, sulphates, etc. This is the main reason why the loss in manufacture is transferred from cream tartar to tartaric acid.

PROPORTION OF CREAM TARTAR TO TARTARIC ACID

Usually only about 10 per cent of the production of cream tartar is obtained for tartaric acid manufacture, and by skillful manipulation it can be kept much lower. Correspondingly, the impurities in the tartaric acid department are increased. It needs very careful operation and full control of all operations to keep the loss down.

LOSS THROUGH PRECIPITATION AS CALCIUM TARTRATE

This precipitation entails the biggest loss of any individual step. It needs, therefore, the most attention and study. It also needs full attention, as in this step the impurities are removed, and if fully removed will make subsequent steps easier and losses smaller.

The neutralization was carried out by some manufacturers with lime, but most manufacturers use now carbonate of lime. After neutralization, the calcium tartrate is washed by decantation until all impurities are removed. This has to be done swiftly, as otherwise calcium tartrate will ferment and cause loss.

EVAPORATION OF TARTARIC ACID

The pure calcium tartrate is decomposed with a very small excess of H_2SO_4 evaporated at low temperature, say not to exceed 170 deg. Fahr., usually at first in open evaporators, then in vacuo, until saturated hot, and then run into crystallizers. The cooled-off mother liquor is evaporated a second, third, etc., time, as long as it still forms good crystals. Last impure liquor is reprecipitated.

All crystals are washed, dissolved, decolorized, filtered, evaporated and again crystallized to form commercial tartaric acid.

If evaporation is carried out in open vessels, the temperature has to be controlled carefully, otherwise large losses on tartaric acid will be incurred.

META-TARTARIC ACID

Another source of loss is due to the formation of meta-tartaric acid. This acid is formed through evaporation in open vessels, especially in presence of impurities. It is supposed to be a semi-anhydride of tartaric acid, non-crystallizable, with calcium and acid potassium salts much more soluble than the ordinary tartrates.

If present in larger quantities, tartaric acid will not crystallize, though evaporated much above the saturation point of tartaric acid.

Reprecipitating cold with lime or calcium carbonate will entail a large loss on account of the higher solubility of the calcium meta-tartrate over the ordinary tartrate of lime. When this calcium meta-tartrate is heated to boil, it is changed back to the ordinary calcium tartrate, and after decomposition with sulphuric acid will give crystallized tartaric acid again.

In a well regulated factory with vacuum evaporators, meta-tartaric acid will not be found.

A number of years ago I worked out an approximate determination of meta-tartaric acid. I did not follow it up for the reason that I prevented its formation.

The brown tartaric acid, as it comes from the crystallizers, is washed, dissolved in water, decolorized, evaporated in vacuo to saturation hot, crystals taken out after five or six days' standing, washed, dried, screened. and are now ready for shipment.

The mother liquor is evaporated a second and third time, as long as good crystals are obtained, and the last white mother liquor returned to the first brown.

REPRECIPITATION OF TARTARIC ACID AS CREAM TARTAR

There used to be a process of working up the last brown tartaric acid in order to recover cream tartar and to remove the impurities at the same time. This mother liquor, which contains many impurities and free sul-

phuric acid, was diluted, and the free sulphuric acid neutralized by lime. The gypsum formed was filtered off, and the remaining clear solution treated with excess KCl.

The reactions taking place were as follows:

$$H_2T + KCl = KHT + HCl$$

Considerable hydrochloric acid is being formed, when about 5 per cent KCl is in excess.

But there are impurities present, such as Fe, Al, K, etc., which will combine with the free acid and make precipitation more complete, while the metals stay in solution as chlorides, and are removed as such.

I give the following reaction as an illustration:

$$Al_2T_3 + 3KCl + 3HCl = 3KHT + 2AlCl_3$$

The two reactions are, of course, simultaneous.

This process, I believe, is abandoned, as it was too expensive on account of the costly potash salts used, and the large loss on tartrates. However, it was one practical attempt to revert tartaric acid into cream tartar, at the same time removing the impurities.

OTHER PROCESSES OF TARTARIC ACID MANUFACTURE

I wish to state that where tartaric acid is manufactured, not as a by-product of cream tartar manufacture but as the main or only product, as in many European countries, a number of processes are known for the manufacture of tartaric acid. These processes, however, are outside the scope of this paper, as we are in the first case interested in the industries as they were called into existence in this country through economic conditions.

REFINING IN ONE OPERATION, OR CRYSTALLIZATION

In general, I want to stay that some attempt has been made, both in cream tartar and tartaric acid manufacture, to refine these products in *one* crystallization, and I myself have carried out many experiments, without, however, having gone beyond the laboratory scale. Short cuts of this kind are very tempting, because of the shortening of the process and consequent smaller investment and cheaper productions. Such attempts have been successful in other branches of manufacture, like boracic acid, borax, etc. But to the best of my knowledge no such process has successfully been carried out in the manufacture of cream tartar and tartaric acid in this country.

In France, I was informed, a process was introduced on the line of the *neutral* process, which claims pure cream tartar in one operation. How successful it is technically, I cannot tell.

To reiterate: Of all processes advocated and carried out in America, the only survivor seems to be the "roasting process," which, in some form or other, is practically carried out in every large cream tartar refinery in this country. It is rational, because it removes the impurities, and with it the trouble *from the start;* it permits the introduction of modern filtering apparatus and appliances, without being too costly, to offset these advantages. It is a clean process from beginning to end, easily and fully controllable.

It gives high yield and rather *avoids*, than cures, trouble and disease.

These, in my mind, are the chief characteristics of a modern process, of which the "roasting process," in connection with cream tartar manufacture, is an example.

The California Slime Extraction Company, of Setter Creek, California, is installing a 5 by 10 ft. adjustable quick-discharge tube mill of Chalmers & Williams, of Chicago Heights.

Gold Milling in California—A Comparison

BY LEROY A. PALMER

Practice at the various mills in the Gold Belt of California presents a striking uniformity. The first mills used only amalgamating plates. Then the vanner came into use to treat the tailings which frequently carry a large portion of the values in connection with iron sulphides or "sulphurets," which name still clings in this country. Usually the vanners treated the pulp without any previous classification. Chlorination and, later, cyanide plants have been installed for the manufacture of bullion from the concentrates. During the past three years there has been a departure from standard practice on the part of two companies which have constructed and are operating all-sliming cyanide plants. These mills, the Globe Consolidated at Dedrick, Trinity County, and the Black Oak, at Soulsbyville, Tuolumne County, are the only ones treating gold ores in which amalgamation does not form the first step in the treatment.

This clinging to methods that have become obsolete in many other districts does not indicate lack of progress on the part of California millmen. Most of the ores, especially of the Mother Lode, are readily susceptible to this simple treatment and elaborate refinements would not yield such an increase in saving as would justify the additional expense. For this reason progress along the line of ore treatment in this district has been mechanical rather than metallurgical. The Mother Lode ores have the larger portion of their values in the free state, and every mill in this district depends on plates for the greater portion of its recovery. But as one leaves the Mother Lode proper and goes to one of the adjoining districts, such as the East Belt, he finds many mines at which the free values are in much smaller proportion and the treatment of the sulphides becomes more complex although the general similarity of the ores still obtains.

Two of the new mills in the Gold Belt are the Plymouth Consolidated, at Plymouth, Amador County, on the Mother Lode proper, and the Black Oak, at Soulsbyville, Tuolumne County, on the East Belt. They present an interesting comparison, as aside from the fact that each uses batteries for primary crushing, they have not a single point in common, although they are treating ores not greatly dissimilar. Yet each one is undoubtedly well chosen to meet the particular conditions under which it operates.

Plymouth Consolidated Mill

The Plymouth Consolidated mill, which commenced operation in August, 1914, represents the latest stage in the development of standard milling practice in the Mother Lode district. The Plymouth ore is typical of the "stringer leads" of this belt, consisting of alternating bands of quartz and slate, with considerable clay. The gold occurs free and in connection with "sulphurets," which are principally pyrite and arsenopyrite.

Crushing and Conveying

The ore is hoisted from a two-compartment and manway shaft in automatic dump skips and discharged to a small bin of 125 tons capacity. From this bin it is fed through a hand-operated sector gate to a 5K Gates crusher driven by a 35-hp. motor. It is of a friable nature, and consequently breaks in the stopes with a large proportion of fines, and the coarser chunks contain a considerable amount of clayey matter.

On this account it was found that the usual practice of separating the coarse and fine over a grizzly would result in an irregular feed to the conveyor. To obviate this the entire run of mine is sent through the

crusher, which is kept buried under ore and acts as a feeder to the conveyor to the mill bins. This method provides the conveyor with a regular feed without overloading, as would be the case if a grizzly were used, and when there would be times when practically all of the ore would pass through it to the belt and little or none would go to the crusher.

The Plymouth shaft is located in a flat so that it is impossible to deliver the ore to the top of the mill without a considerable elevation. The crusher is set below the level of the ground and discharges to an 18-in. "Lamina" rubber belt conveyor, the housing of which is shown at the left of the illustration (Fig. 1). This conveyor has a lift of 108 ft. and a horizontal length of 631 ft. It is driven in two sections, one 350 ft. and one 310 ft. long on the slope, with 10 and 15-hp. motors respectively. The inclination of the belt varies, but, as can be seen by referring to the illustration, the greater part of the lift comes on the second section, hence the necessity of a larger motor for the shorter belt. This portion of the conveyor attains a slope of 21° 30′, corresponding to that of the roof of the mill, and very nearly equal to the maximum on which these ores may be conveyed without rolling or sliding. The inclined belt discharges to a horizontal belt 85 ft. long driven by a 10-hp. motor and carrying a tripper by which the ore is distributed in the bin at any desired point. Link-belt equipment is used throughout the conveyor system. After handling approximately 110,000 tons of ore in eleven months, the rubber belts in this system show practically no wear, a strong argument in favor of the economy of the best class of equipment.

FIG. 1—PLYMOUTH CONSOLIDATED MILL

Fine Crushing and Grinding

The mill is of timber frame construction, with corrugated iron sides and roofing. As the illustration shows, it is well supplied with windows and skylights. It is well lighted at night by numerous large tungsten lamps. The floors are of concrete. The ore bins, which have a capacity of 1200 tons, are of heavy timber with flat bottoms. They are so proportioned that about 30 per cent of the ore, practically a day's run, will discharge from them by gravity, leaving a reserve supply of 840 tons which can be shoveled out in case of emergency. This is somewhat more than necessary to keep the mill running two days, 380 tons being the standard operating capacity.

The mill bins discharge by means of Challenge feeders driven from the stamp stems to thirty stamps arranged in six batteries of five each. Only five batteries are used at a time, except as noted later. The mortars are set on heavy concrete piers tied with crossed bolts. This gives a very satisfactory foundation and the batteries are practically free from vibration. The weight of the stamps used on Mother Lode ores has been gradually increased from time to time, and those at the Plymouth, weighing 1250 lb., are the heaviest yet installed, although they have a close second in the Black Oak to be mentioned later. The dies are set for a discharge from 5½ to 6½ in., the end dies being set ½ in. higher than the others. The tappets are set to give a drop of 7 in. and are allowed to wear to 7½ before taken up. The speed is 100 drops per minute, and the order 1-3-5-2-4. A 100-hp. motor drives the batteries.

The batteries crush through a six-mesh screen (No. 60 Rektang), which gives a free opening of 0.087 in. The pulp is collected in two launders, one to each fifteen stamps. These launders, unite, but after passing a sampler divide again and each goes to two classifiers in series. The first classifier is merely an inverted wooden pyramid measuring 20 in. on the upper edge, and the second is a 36 in. steel cone. These classifiers, so called, are in reality "sloughing off" devices, no counter current of water under pressure being employed and the separation being the result of the difference in the rate of settling of the various particles. The underflow of both classifiers of a series goes to the feed end of an 8-ft. by 22-in. Hardinge mill and the overflow is laundered to the discharge end of the mill. The

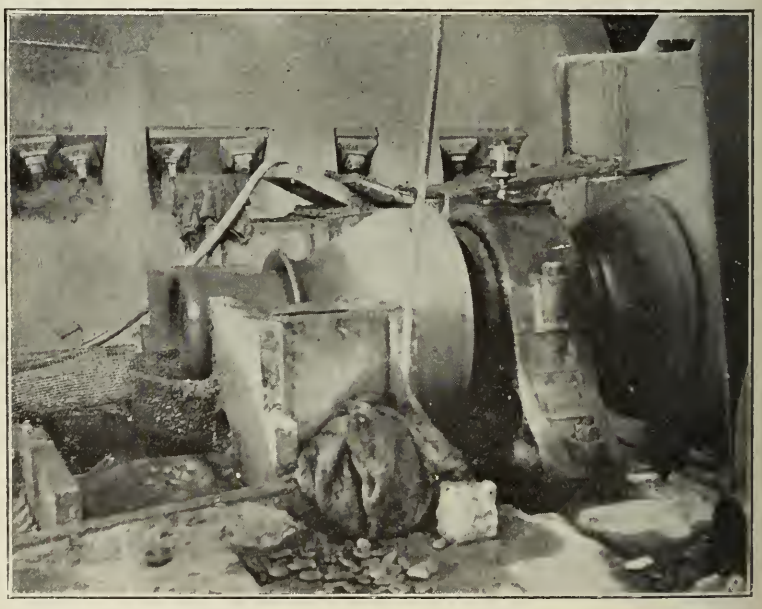

FIG. 2—HARDINGE AMALGAMATOR, PLYMOUTH MILL

slate in the ore is pretty well pulverized in the process of stamping, so that most of it overflows from the classifiers and the principal feed of the mills is pure quartz.

The mills have been watched closely and several tests made to determine the capacity and consistency of the pulp at which they would develop their highest efficiency. The dilutions of pulp tried were from 1 solid to from 0.666 to 0.950 water and various rates of feeding were tried out. As a result of these experiments it was found that the mill does its best work at a capacity of 140 tons per twenty-four hours with a pulp consisting of 1 part solid to from 0.70 to 0.75 water (Sp. Gr. 1.76-1.79).

An old hoist motor rated at 200 hp. is used to drive the tube mills, elevators and concentrating tables. This motor is very much larger than is actually required, as it is estimated that the power consumed by each tube mill is only 40 hp. Following is an average of the screen analyses of feed and discharge over a considerable period.

Size	Feed	Discharge
+ 20	30.0-40.0	0.5- 1.8
+ 30	20.0-25.0	5.5- 9.0
+ 40	11.0-13.0	10.0-13.0
+ 60	12.0-16.0	23.0-26.0
+ 80	4.5- 7.5	12.0-15.0
+100	2.5- 4.0	7.0-10.0
+200	3.0- 4.0	10.0-14.0
—200	3.0- 4.0	15.0-20.0

The minus 200 discharge of the mill was tested for sands and colloids by diluting with a large proportion of water, agitating and decanting all solids that would not settle within two minutes after agitation ceased. The process was repeated five or six times, and it was assumed that such solids as remained after the last decantation were in granular form and that all of the slime had been removed. According to these tests only 5 or 6 per cent of the discharge of the Hardinge mills is in the form of slime.

Danish pebbles are used in the mills with a consumption of 1½ lb. per ton of ore when the best grade of pebbles can be obtained. Local pebbles were tried and given a fair test, but it was found that their consumption was 6 to 7 lb. per ton of feed, and that the difference in cost was not sufficient to offset the difference in the amount used.

Amalgamation

Fifty-five to 70 per cent of the gold in the Plymouth ore is free. Forty per cent of the free gold is in flakes of appreciable size, greater than 1/64 in. in diameter. This makes it advisable to practise amalgamation in two stages, as any attempt to catch all of the gold, both coarse and fine, on one set of plates would result in an inordinate amount going into the plate tailings and thence into the concentrates. This is a result to be avoided if possible, as the smelter does not pay full value for the gold recovered from that source, and there is the further possibility of loss in the table tailings. Standard Mother Lode practice has been disregarded in that no attempt has been made to amalgamate in the batteries, although amalgamation in the Hardinge mills was tried when operations were first commenced. This was successful so far as the actual recovery of the gold was concerned, but was attended by a rather high loss of quicksilver and much inconvenience in cleaning up, and consequently was discontinued.

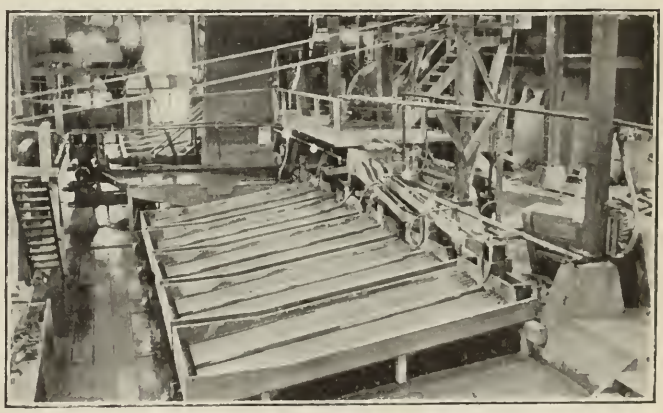

FIG. 3—TABLE PLATES AND WILFLEY TABLES, PLYMOUTH MILL

The next move was to attach a Hardinge amalgamator to one of the mills and a Plymouth amalgamator, to be described later, to the other. These have given very satisfactory service. The Hardinge amalgamator, Fig. 2, may be described as a miniature Hardinge mill which is attached to the discharge of the mill proper. It is of cast iron, and the object is to produce the same effect in amalgamation as the mill does; that is, to bring the

gold, especially that which is rusty or in coarse particles, into forceful contact with the quicksilver. The amalgamator gives the pulp a rolling action as it is discharged through it, and when it is run dry the discharge cone becomes coated with amalgam and balls of the latter form having diameters up to ¾ in. These balls materially assist in the amalgamation and at cleanup a few copper balls are put into the amalgamator for the same purpose.

After passing the Hardinge amalgamator the pulp is run over a 4-millimeter screen shown in the illustration for the purpose of removing chips and any small pebbles that may have been thrown out. Thence it runs over two silvered sluice plates, each 2½ ft. by 6 ft. on a grade of 2 in. per foot and through a launder to ten table plates (Fig. 3), each 3 ft. by 14 ft., set in pairs on a grade of 2½ in. per foot. Shallow traps are provided at the top, middle and bottom of the sluice plates and top and bottom of the table plates. The tailings from the table plates go to an elevator.

The above describes the process of primary amalgamation as carried on in one section of the mill. Practice in the other section differs slightly. Here the Hardinge mill discharge passes directly over the sluice plates and thence to a Plymouth amalgamator, Fig. 4. This amalgamator was designed and built in the Plymouth mill and has proved very successful. It is now in use at the Argonaut mill at Jackson, Col., and on one of the Natomas Consolidated gold dredges. It is a wooden box 6 ft. by 18 in. divided lengthwise into two compartments, one 12 in. and the other 6 in. wide. It receives 200 2-in. longitudinal strokes per minute, being actuated by the head motion of an Isbell vanner. The wider compartment has an iron bottom and is covered to a depth of ¼ in with quicksilver. The narrower compartment is provided with a regular amalgamating plate in the bottom. The pulp from the sluice plates passes to the wider compartment of this shaking amalgamator, where it is subjected to a rapid agitation in the quicksilver bath and then discharged over the plate in the second compartment to the table plates. This device is, in effect, a shaking amalgam trap for the recovery of the coarse gold. Before the installation of the Hardinge and Plymouth amalgamators free gold could be seen in the concentrates of the Wilfley tables, but these devices have remedied that trouble.

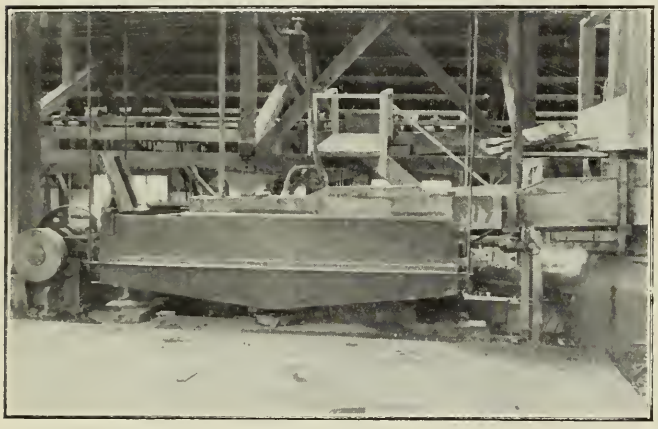

FIG. 4—PLYMOUTH AMALGAMATOR

The amalgamators, traps on the sluice plates, sluice plates and traps at the heads of the table plates are cleaned up daily. The table plates are cleaned twice a month. It is found that of the free gold recovered in the form of amalgam 53½ per cent is caught in the amalgamators and traps. Of the remaining 46½ per cent, 85 per cent, or 40 per cent of the total recovery, is caught on the sluice plates following the Hardinge mills and 6½ per cent of the total is caught on the table plates. Thus it will be seen that it is a distinct advantage with this ore to amalgamate in stages.

The amalgam from the amalgamators and traps retorts 50 to 60 per cent sponge; from the sluice plates, 35 to 45 per cent, and from the table plates, 20 to 25 per cent. The combined amalgam from all sources retorts from 42½ to 47 per cent, which is considerably higher than the 30 to 40 per cent which MacFarren gives as the average amount of sponge.

Concentration

All tailings from the table plates are run to an elevator with 15-in. belt, 26-ft. lift and a speed of 450 ft. per minute. As elevators are prone to give more or less trouble two have been installed at this plant at this point. One is run for a week, then shut down and given a thorough overhauling, while the other is used. These elevators are belt-driven to avoid any gear trouble. The boots are so set as to be readily accessible, with large doors so that if one does choke down practically all of the ore overflowed in the boot will run out by gravity when the door is opened. With these precautions no trouble has been experienced in their operation, and after eleven months of continuous work the belts show no appreciable signs of wear.

The elevator discharges to a 66-in. Callow cone, the underflow of which goes to a two-compartment Richards hindered-settling classifier. Each compartment of the classifier feeds a No. 6 Wilfley table, shown in the background of Fig. 3, that makes 245 ⅝-in. strokes per minute, producing tailings and concentrates but no middlings. The Wilfley concentrates contain about 11 per cent arsenic. They make up one-third of the tonnage product of the mill and three-fifths of its value.

FIG. 5—CLEAN-UP JIG, PLYMOUTH MILL

The tailings of the Wilfley tables are laundered to an 8-in. elevator, which raises them 22 ft. with a speed of 450 ft. per minute to two pyramidal settlers. The underflow of each settler returns to a Hardinge mill and the overflow is run to the tailrace and wasted.

The Wilfley tables are placed on the same level as the table plates. On the next level, which is the lowest, are the vanners, thirty of Isbell design, with 6-ft. belts making 195 1-in. strokes per minute. The Isbell machine was chosen because it makes a satisfactory grade of concentrates and the cost of upkeep is less than that of most of the other designs of vanners.

The overflow of the Callow cone which receives the pulp from the first elevator is laundered to two dis-

tributing tubs. Each of these tubs distributes to three other tubs, each of which feeds four vanners, twenty-four vanners taking the Callow overflow. The overflow of the Richards classifier is laundered to two distributing tubs, each of which feeds three vanners.

All concentrates, both table and vanner, discharge to tubs from which they are shoveled and, after drying, are sacked and shipped to the smelter at Selby for treatment. Sweepings and overflow from the concentrate boxes are led to a sump and shipped. When the mill is run at its full capacity, 380 tons a day, the output of concentrates is from 5 to 7½ tons, a concentration ratio of from 50 to 75 into one.

Cleanup and Sampling

Instead of using the usual clean-up barrel and pan, the sands from the plates and the daily traps are treated in a "clean-up jig" designed at this plant and illustrated in Fig. 5. This jig has vertical sides and the general

FIG. 6--BLACK OAK MILL

appearance of a large Calumet classifier. It receives 210 2-in. longitudinal strokes per minute from an eccentric without differential motion. The sands are fed in at the top over a ¼-in. screen, from which they pass over a baffle and are subjected to the agitation caused by the eccentric, which results in a stratification so that the sands overflow at the discharge and the amalgam settles to the bottom of the jig, where it may be tapped off at the plug shown. The jig concentrate is treated in a 2-ft. clean-up pan.

Sampling is done by automatic samplers. One sample is taken of battery pulp by taking a cut the full width of the launder below the batteries. This sample is further cut down by split samplers so as to give an average of the shift's run. Tailings are similarly sampled. A sample is also taken at thirty-minute intervals from the distributor to the battery bins. These samples will usually check the pulp samples from the battery with a maximum error of 10 cents per ton. Assays of talings and concentrates are posted daily for the information of the millmen. The extraction will run 90 per cent on an ore assaying $5 per ton or better. On lower grade ore it will be a little less.

The mill is handled by two men on each shift actually engaged in operation. These are an amalgamator, who also looks after the crushing machinery and who acts as foreman on the night shifts, and a vannerman. In addition the day shift has a foreman, repairmen, amalgamator helper and concentrate sacker. Crushing is done entirely on the night shift. Detailed costs of milling are not available at present, but the management states that the total costs of mining and milling, including new construction, development, etc., are from $2.70 to $3 per ton.

The Plymouth mill was designed with the idea of treating this ore as efficiently as possible, and it has been part of this general scheme to surround the operators with such conditions as would tend to promote their efficiency. Mention has been made of the lighting system. Heat is furnished in cold weather by numerous electric heaters. As the general location hereabouts is somewhat conducive to malaria all drinking water used in the mill is filtered. There is a change room in the mill supplied with hot and cold water and, shower baths are available at the main change house at the shaft. Motors are placed, as far as possible, out of the way, and all line shafts are readily accessible from broad runways. But best of all, and a feature that cannot be commended too highly, there is not a motor, belt or gear in the mill that is not so carefully protected but that a man could only be caught in it by deliberate intent on his part.

Horsepower

As stated, a larger motor than necessary is used for the Hardinge mills, elevators and tables. In the following summary the actual horsepower used on these machines is estimated with a liberal allowance for transmission and friction losses in a rather extensive system of line shafting.

Machine	Horsepower
Crusher	35
First conveyor	10
Second conveyor	15
Third conveyor	10
Stamps (twenty-five)	85
Hardinge mills (two)	80
Plymouth amalgamator	1
Elevators (two)	10
Wilfley tables (two)	3
Vanners (thirty)	25
Total	274

This equals an actual expenditure of about 0.7 hp. per ton of ore treated. Power is purchased from the Pacific

FIG. 7—CAM FLOOR BLACK OAK MILL

Gas & Electric Company at 44,000 volts, transformed at the mill and distributed at 440 volts.

Modified Practice

Under certain conditions the system described above is modified to some extent. When both Hardinge mills are used only twenty-five stamps are dropped, but if the grade of ore is low, or if a mill needs lining, one of them is cut out and all thirty stamps are dropped, three of the batteries being equipped with No. 296 Rektang

(19-mesh) screen. With the finer screen stamp duty per twenty-four hours is from 8½ to 9½ tons. This compares with 12½ to 16 tons through the 6-mesh screen according to the amount of hard quartz in the ore. Screen tests of the battery discharge through the 19-mesh screen show about the same percentage of +30 material in the pulp as from the Hardinge mill, but that the colloids will run 21-22 per cent. From the above it appears that forty-two stamps would be required to crush direct the same amount now handled by the twenty-five stamps and the two Hardinge mills.

Concentrate treatment has always been an important question in the handling of Mother Lode ores. At present the Plymouth is shipping to Selby and treatment charges range from $17.50 to $22 per ton, according to the grade. This item in itself amounts to approximately 30 cents per ton of ore treated aside from the freight

FIG. 8—LOWER FLOOR, BLACK OAK MILL, OLIVER FILTER IN BACKGROUND

and the fact that the smelter pays for gold at the rate of only $19 per ounce. At this writing the Plymouth is operating a 200-lb. experimental plant to determine the advisability of cyaniding the concentrates. It is also considering the possibility of cyaniding the Wilfley tailings instead of returning them for regrinding.

Black Oak Mill

The ore of the Black Oak is found in fissures in the "Soulsbyville granite," a notoriously hard rock consisting of true granite and granodiorite with ribs of diorite. It is a quartz gangue containing gold with small quantities of silver. About 40 per cent of the gold occurs in the free state and the remainder is associated with pyrite, arsenopyrite and very small amounts of galena. The gold and silver are the valuable constituents of the ore, the amount of lead in the galena being too small to make its recovery profitable.

The ore is hoisted from the shaft in self-dumping skips which discharge to the mine bin from which it is discharged over a grizzly. A rough sorting for the larger chunks of waste is carried on at the grizzly. The over-size is run through a 15-in. x 10-in. Blake crusher to the bin beneath, from which the ore is loaded through rack-and-pinion gates to cars and hand-trimmed to the mill. The mill, Fig. 6, is of 100-tons capacity, timber construction, built on a hillside with a down grade from the mine bin. The mill bins are slope-bottomed and have a capacity of 200 tons, sufficient for two days' run in case there is an interruption to hoisting from the mine.

Crushing and Classifying

The ore is fed from the mill bins to four five-stamp batteries, Fig. 7, by means of Challenge feeders actuated by the middle stamp stem, lime being added at the feeders in the desired proportion. The stamps weigh 1200 lb. each and make 106 6-in. drops per minute in the order of 1-5-3-2-4. The ore is crushed in a 4½-lb. cyanide solution. Three of the batteries are fitted with No. 18 Tyler "tan-cap" screens and one with a six-mesh screen. A 75-hp. motor drives the batteries.

The battery pulp is distributed to one simplex and one duplex Dorr classifier. The coarse product of the classifiers goes to a 4-ft. x 20-ft. Power and Mining Machinery Company tube mill and the fine to a 3½-in. centrifugal pump which is chain-belted to a 5-hp. motor and discharges to a 20-ft. x 10-ft. Dorr thickener.

The tube mill crushes 60 tons per twenty-four hours making 27 r.p.m. Danish pebbles are used at the rate of 4½ lb. per ton of ore crushed. It is driven by a 75-hp. motor. Seventy per cent of the discharge will pass 200-mesh. Instead of using lead acetate to assist in the precipitation, litharge is used by feeding it into the tube mill at the rate of 1 lb. per ton of ore. It is estimated that 70 per cent of the valuable constituents of the ore is in solution when it leaves the tube mill.

The tube mill is in a closed cricuit with the Dorr classifiers. The discharge goes to a bucket elevator with 4-in. x 8-in. buckets on 12-in. centers. This elevator has a lift of 16 ft. and a speed of 450 ft. per minute, returning the pulp to the classifiers. A 5-hp. motor drives the elevator and classifiers.

Decantation and Filtration

The fines from the Dorr classifier are sent by way of the centrifugal pump to the first Dorr thickener from which they are transferred by means of a Pohle air-lift to the first of a series of three Pachuca tanks, each 10 ft. x 30 ft. The slime is continuously agitated in these three tanks, finally overflowing the third tank to a second Dorr thickener the same size as the first. Here the pulp is brought to a consistency of 70 per cent mois-

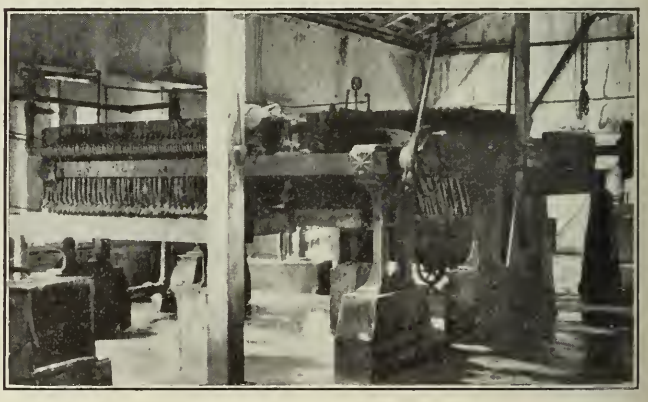

FIG. 9—SHRIVER AND MERRILL FILTER PRESSES, BLACK OAK MILL

ture (Sp. Gr. 1.32) and the overflow discharged to the collecting sump below the Oliver filter which also receives the pregnant solution from the filter.

The pulp from the second Dorr thickener goes to an Oliver continuous filter, 6 ft. x 12 ft. (Fig. 8) which makes a complete revolution in seven minutes. A 5-hp. motor drives the Dorr thickeners and Oliver filter.

Air for the Pachuca tanks and for discharging the cake from the Oliver filter is supplied under 45 lb. pressure by a 10-in. x 8-in. Ingersoll-Rand compressor working with a capacity of 100 cu. ft. of free air per minute, belted to a 25-hp. motor. Vacuum is furnished at 20 in. to 22 in. to the Oliver filter by a piston-inlet compressor working at 125 cu. ft. of free air per minute and driven by a 15-hp. motor.

The pregnant solution from the Oliver filter flows to a collecting tank of 600-gal. capacity, which, as noted, also receives the overflow of the Dorr thickener. From the collecting tank the solution is pumped by a 4½-in. x 6-in. Dorr horizontal duplex pump belted to a 5-hp. motor to a 34-frame Shriver filter press (Fig. 9), in which it is clarified. From the Shriver press the clarified solution goes to a 900-gal. tank in which the zinc dust is added and from which it is pumped to a 22-frame, 4-ft. Merrill press (Fig. 9) by a 5½-in. x 8-in. Platt triplex pump geared to a 5-hp. motor. The barren solution from the Merrill press is pumped to two 65-ton stock tanks where it is brought up to standard, 4½-lb. KCN per ton.

The zinc dust precipitate is loaded to an iron tray which is wheeled out and dried over an open fire. No acid treatment is given the precipitate, which is refined by slagging with borax and sand and melted in a No. 150 graphite crucible in an oil-fired Steele-Harvey tilting furnace.

Chemicals and Power

During the past year the consumption of chemicals per ton of ore has been as follows: Cyanide, 1.25 lb.; lime, 3.27 lb.; zinc, 1.30 lb.

All ore passing through the mill is sampled twice, once by a grab sample from each car as it is weighed and once by sampling at regular intervals at the feeder. Tailings are sampled automatically and the extraction as calculated from the head and tailing samples is checked against the actual bullion return, the two results usually agreeing within a small fraction of 1 per cent.

Power is purchased from the Sierra-San Francisco Power Company and delivered at 40,000 volts to the substation where it is stepped down for distribution at 440 volts. An average of power costs for the first two months of 1915 was 45 cents per ton of ore. Power is used as follows:

Machines.	Power.
Crusher	15 hp.
Stamps (20)	75 hp.
Tube mill	75 hp.
Centrifugal pump	5 hp.
Elevator and classifiers (2)	5 hp.
Compressor	25 hp.
Vacuum pump	15 hp.
Dorr thickeners (2) and Oliver filter.	5 hp.
Dorr pump	5 hp.
Platt pump	5 hp.
Return pump	25 hp.
Total	255 hp.

This indicates a consumption of 2.55 hp. per ton of ore treated.

Costs

An average for two years shows the following assays and extractions:

Year	Heads	Tails	Extraction
1913	$13.218	$0.574	95.58 per cent
1914	11.873	0.220	98.15 per cent

These figures are based on actual bullion recovery and tailings assays.

The following costs are given out:

Year	Tonnage	Power, supplies, etc.	Labor	Total
1913	25,853.7	$0.960	$0.620	$1.580
1914	11,518.8	1.331	0.908	2.239

The above costs include superintendence, clerical expense and all other overhead charges.

During 1914 the mine was carrying on extensive development work which limited production. On this account the mill was run at far less than normal capacity but as expenses were the same as with the full capacity there was a corresponding increase in the cost per ton. As the Black Oak was the first mill to cyanide these ores and 1913 was the first full year that it operated, it is reasonable to expect that the extraction record of 1914, when the operatives had had the benefit of some experience, will be maintained. For these reasons it is fair to judge the possibilities of this plant by its 1913 costs and 1914 extraction.

Comment

Two-stage crushing has been so universally adopted in other districts and so thoroughly discussed that there is hardly room for comment. Observations at these plants do not tend to the conclusion that it effects any saving in power but it is obvious that at such a mill as the Plymouth the form in which the pulp is discharged is a material advantage.

The Plymouth presents many innovations from a mechanical standpoint while the Black Oak was an innovation *in toto* so far as these ores are concerned.

While in general the ores may be considered similar there is sufficient difference to make a comparison difficult. One cannot but notice the difference in the power used in fine crushing and grinding, 0.43 hp. per ton in the Plymouth mill as against 1.5 hp. in the Black Oak. But the Plymouth ore is mixed with a soft slate while the Black Oak is associated with the extremely hard Soulsbyville granite which breaks much coarser in the stopes. This difference in hardness is brought out by the pebble consumption, 1.5 lb. per ton at the Plymouth against 4.5 lb. per ton at the Black Oak. Further the Hardinge mill discharges only 15-20 per cent of —200 material while the discharge of the Black Oak tube is 70 per cent of —200. It is probable also that the relative efficiencies of these two machines are a factor, as it is generally considered that a Hardinge mill consumes less power under the same conditions than a long tube.

Some comparison may be made of the relative economy of the two processes, especially with respect to the Black Oak whose detailed costs are presented. If we assume that 62½ per cent of the Plymouth ore is recovered on the plates and that the mill extraction is 90 per cent it appears that the extraction in the concentrating department is 73½ per cent. If we assume a $12 ore for the Black Oak, a recovery of 40 per cent on plates and an extraction on the concentrating machines corresponding to that of the Plymouth we should have a tailings loss of $1.91. This exceeds the corresponding loss from this source by cyaniding by $1.67 which is 9 cents more than the total costs for milling during 1913 which is the proper criterion of future service. Thus an attempt to follow the Plymouth system at the Black Oak would result in a loss per ton of $1.67 plus freight and smelter charges on concentrates and the difference in the value of the gold as paid for by the smelter, against which the only offset would be the difference in the cost of the two methods, amalgamation and concentration being accomplished at a considerably lower figure than cyaniding. Obviously cyaniding is the more economical method of treating these ores.

In the absence of detailed costs from the Plymouth a similar comparison can only be tentative. Under present conditions tailings losses are approximately 50 cents per ton, smelter charges, 30 cents and the difference in the rate of settlement for gold, say 15 cents. Freight charges are not available. If a 98 per cent extraction could be obtained so as to reduce the tailings losses by 40 cents the question would be whether the difference in milling costs would be more or less than the in-

creased saving, 40 cents, plus smelter charges, 30 cents, plus difference in payment for gold, 15 cents, plus freight on the concentrates and the cost of sacking.

From some information I have had regarding costs of treating these ores by amalgamation and concentration I am of the opinion that the present system is better adapted to the Plymouth ores even considering the greater tonnage of its plant than that of the Black Oak and the possibility that that 98 per cent extraction *might* be realized. In the absence of any data on cyaniding Mother Lode ores one cannot predict what saving could be made. I do not know about the Plymouth ore but many mines in this belt encounter graphite in sufficient amount seriously to interfere with cyaniding, which is a factor that would have to be taken into consideration.

While such a discussion is interesting from a theoretical point of view it must be borne in mind that the Plymouth mill was designed by a competent engineer and it is taken for granted that the system installed was selected as the most economical after due consideration of every phase. But it is interesting to note that there is a leaning toward a modification of the process to include cyaniding the concentrates and possibly the Wilfley tailings.

I am indebted to many officials and employees of the two companies whose operations are described, particularly Messrs. Roger Knox, superintendent; C. W. Hopkins, secretary, and F. W. Watts, mill superintendent of the Black Oak and S. R. Brown, mill superintendent of the Plymouth Consolidated.

San Francisco, Cal.

Efficiency of the Blast Furnace Operation

BY BIRGER F. BURMAN

Pure air contains besides oxygen and nitrogen about 0.04 per cent CO_2. It is also claimed that in the proportion assigned to nitrogen about 1 per cent consists of other rare inert gases such as argon, neon, krypton, zenon, helium, etc., as well as small quantities of hydrogen and water vapor. With the exception of water vapor only oxygen and nitrogen need be considered for practical purposes, and the composition of pure, dry air is therefore by many accepted to be:

	By Volume	By Weight
Oxygen	20.8 per cent	23.1 per cent
Nitrogen	79.2 per cent	76.9 per cent

As pure air is always accompanied by a certain amount of water vapor, dependent on the existing temperature and barometric pressure, the air mixture of oxygen, nitrogen and H_2O vapor, which concerns us directly, will constantly vary in composition. If pure air could be secured for practical purposes, the air mixture of oxygen and nitrogen with above composition would certainly be of maximum efficiency; and as only oxygen is of value for combustion the amount of this element as shown must give to the air mixture a 100 per cent efficiency.

Nitrogen and the other gases are not only inactive as far as combustion is concerned, but they dilute the products of combustion and absorb considerable amount of heat. However, they are not as harmful as H_2O vapor, which gas in addition must also be decomposed, thereby consuming fixed carbon according to the following reaction:

$$H_2O + C = H_2 + CO.$$

As 12-unit weights of carbon are involved, the consumption of fixed carbon will be 0.67 to every unit weight of H_2O vapor reduced. This carbon is a dead loss, but that is not all. The reaction cannot exist without addition of more heat. As it stands the loss is 1606 pound-calories per pound of H_2O vapor or 2408 pound-calories per pound of carbon involved. This heat is partly furnished by the sensible heat in the H_2O vapor and in the hot carbon, but even under favorable conditions it is not sufficient and extra carbon has to be utilized. In other words, the presence of water vapor lowers the temperature of combustion as it robs the pure-air combustion of a certain amount of heat.

The amount of H_2O vapor present in the blast is small, figured per cubic foot; but when millions are used in a day, the weight of water pumped into the blast furnace is enormous. It therefore becomes of supreme importance to endeavor to cut down the moisture content to the absolute minimum not only in order to save fuel, but also to secure a uniform composition of the blast, thus aiding the regular run of the operation.

If the air is at 60 deg. Fahr. dry and 47 deg. Fahr. wet* the relative humidity is 35 per cent and the weight of H_2O vapor per cubic foot of air mixture will be 0.000289 lb. At another time the respective temperatures are + 0 deg. Fahr. and — 2 deg. Fahr., giving also a 35 per cent humidity, but the weight of H_2O vapor will now be only 0.000024 lb. If during twenty-four hours a blast furnace receives 60,000,000 cu. ft. of blast, the water pumped in each case will be 17340 lb. and 1440 lb. Of course, in case of the colder blast only about 53,069,000 cu. ft. had to be pumped in order to make it equal the 60,000,000 at the higher temperature, but this makes the comparison still more unfavorable for the warmer and more humid blast, as the drier air will contain only 1274 lb. of water.

By cooling the air the H_2O vapor can be eliminated, but it is an expensive operation. While a dry-blast plant ought to be built at every blast-furnace plant the cost is by many considered prohibitive. A partial improvement may be secured by carrying the blast intake to the outside of the blowing engine room, thus pumping air of lower temperatures at little or no cost—if the first cost of building the intake be excepted. Water-cooling also forms another kind of less expensive but at the same time less satisfactory arrangement as far as results are concerned when compared with the dry-blast plant.

Volumes vary constantly, dependent on the temperatures and pressures to which they are subjected. One cubic foot of air mixture (containing no moisture) at zero will at a higher temperature, with the pressure remaining the same, take a larger volume, of which 1 cu. ft. must weigh less. The percentage of oxygen has not changed; consequently the amount of this element must also become less per cubic foot at the higher temperature. If now H_2O vapor is added, the weight of the oxygen in the cubic foot of air mixture will be somewhat less in the former case but much more so in the latter case, due to the increased amount of H_2O vapor at higher temperatures.

As oxygen is the only desirable element for combustion it is important to deliver to the blast furnace not only pure, dry air but also a regular amount of same. If, for instance, I was delivering 40,000 cu. ft. per min. under any and all conditions, I would constantly vary the amount of oxygen, which variations in case of no refrigeration would be still more intensified. The result would be difficulties in keeping up a regular run of the blast furnace with accompanying losses.

The only proper thing to do is to reverse these conditions and deliver to the blast furnace a constant amount of pure, dry air under any and all conditions, which, of course, will be equivalent to a constantly variable volume of air mixture per unit of time. At the same time the amount of H_2O vapor should be cut down to the minimum.

*At a bar. pressure of 29".

It will not be possible to deliver the proper amount of oxygen without a table giving the number of revolutions per minute at any desired temperature and relative humidity. Such a table is a necessary guide to the blowing-room foreman.

Before such a table can be worked out the displacement of the blowing cylinder must be ascertained. This should be carefully done, and after all measurements have been established the following calculations will determine it:

V = Volume of air cylinder, empty, including the two clearances and all the voids at the ports, ...cubic feet.

V_1 = Volume of the two clearances and all the voids at the ports minus volume of piston rod equal to the depth of one clearance,.....cubic feet.

V_2 = Volume of one piston,.....cubic feet.

V_3 = Volume of one piston rod of the length of the stroke plus the depth of two clearances, ...cubic feet.

V_4 = Volume of the open space per revolution:

$= 2V - (2V_2 + V_3)$ cubic feet.

In degrees Fahrenheit:

Dry temperature of air mixture, going into the cylinder .....t

Dry temperature of blast, leaving the cylinder ..... t_1.

In inches of mercury:

Barometric pressure.....P.

Blast pressure—absolute (gage + barometer) ..... P_1.

V_5 = Volume of air mixture (blast) per revolution at any time for one air cylinder:

$$= V_4 - \left(2V_1 \times \frac{459.4 + t}{459.4 + t_1} \times \frac{P_3}{P}\right) \text{ cubic feet.}$$

This formula may be considered close enough for practical purposes and represents the net displacement at any time. It can readily be seen that the volume of air mixture is dependent on a number of factors, and as the volume of the air, which is trapped in the space V_1, also is undergoing constant changes, the chances of success in working out a standard table of blast regulation, that would be at the same time correct and practicable, is very slight. However, as it would neither be practicable to have a separate table made out for the displacement, covering any and all conditions, a fairly accurate figure for volume V_5, to be used only as a basis for the Table of Blast Regulation, may be had by adopting the following analysis:

The rise in temperature of the blast during its passage through the blowing engine is considerable. Observations made by the author have given averages as high as 150 deg. Fahr. The blast pressure, we know, will vary anywhere from 8 to 20 lb. per square inch. Let us therefore assume that one atmosphere is the average compression; however, any plant probably has the average for a considerable length of time and in such a case this would be the figure to use. When the gage pressure is one atmosphere, the absolute pressure will be about two, consequently when the delivery port is closed and the piston starts on its return trip, the air mixture, trapped in space V_1, will be subjected to a contraction in volume of approximately 0.75, due to the temperature, and an expansion of about 2, due to the pressure, making a total expansion of about 1.5. The formula will therefore be $V_4 - 3V_1$, which, in the absence of records for temperatures and pressures, may be adopted.

Having established the displacement per revolution, the next step will be to assume a standard for the weight of pure, dry air to be delivered per minute during any and all conditions.

As the barometric pressure constantly varies, and it is not practicable and indeed not necessary either to have a table for every change; and, furthermore, as the barometer usually stands around 29 in., there need be only two tables in the blowing room: one, covering pressures between 28.5 in. and 29.4999 in., called the 29-in. table, and another table, taking in pressures between 29.5 in. and 30.4999 in., called the 30-in. table.

The table may be worked out for any range of temperatures but it will be found that 0 deg. to 100 deg. Fahr. is a very suitable one. Of course, in colder climates, the temperature will go lower than 0 deg. Fahr., just as in warmer countries it might rise above 100 deg. Fahr. In such a case the range should be extended to include such temperatures.

It is not necessary to include every per cent vapor saturation, 0, 10, 20, 30, 40, 50, 60, 70, 80, 90, 100 per cent answering all practical purposes.

EXAMPLE

Work out a table of blast regulation for 29-in. barometer pressure when: The blowing cylinder is 84 in. in diameter × 60-in. stroke and 3000 lb. is the standard for weight of pure, dry air to be delivered per minute under any and all conditions.

Blowing cylinder displacement:

V = 229.5 cu. ft.
V_1 = 7 cu. ft.
V_2 = 30 cu. ft.
V_3 = 2.3 cu. ft.
V_4 = 396.7 cu. ft.
V_5 = 396.7 — (3 × 7) = 375.7 cu. ft.

Net displacement is therefore 375.7 cu. ft.

In the formulas below:

t denotes dry temperature of air mixture in degrees Fahrenheit.

P denotes barometric pressure in inches of mercury.

P_1 denotes vapor pressure in inches of mercury.

P_2 denotes air pressure in inches of mercury.

"Standard conditions" represent 32 deg. Fahr. and 29.9212 in. barometric pressure.

Weight of dry air in 1 cu. ft. of any air mixture is

$$0.080728 \times \frac{459.4 + 32}{459.4 + t} \times \frac{P_2}{P} \times \frac{P}{29.9212} = \frac{1.32581 \times P_2}{459.4 + t} \text{ pounds.}$$

In case of no moisture being present the factor $\frac{P_2}{P}$ disappears and the formula will give $\frac{1.32581 \times P}{459.4 + t}$ pounds.

Applying these formulas to our case for 0 deg. Fahr. the weight of dry air in 365 cu. ft. of air mixture with no moisture present (relative humidity = 0 per cent) will be:

$$365\left(\frac{1.32581 \times 29}{459.4}\right) = 30.54782 \text{ lb.}$$

When the relative humidity is 100 per cent the vapor pressure P_1 is 0.0383 in., the air pressure P_2 is 28.9617 in., the barometric pressure P is 29 in., and the weight of dry air in 365 cu. ft. of air mixture will be:

$$365\left(\frac{1.32581 \times 28.9617}{459.4}\right) = 30.50748 \text{ lb.}$$

By dividing the respective weights into 3000 the quotient will be the revolutions per minute necessary to deliver the proper volume of dry air; thus for 0 per cent humidity 98.21 r.p.m. and for 100 per cent humidity 98.34 r.p.m.

The difference 98.34 — 98.21 = 0.12 may be equally distributed on the miscellaneous relative humidities and the revolutions per minute will therefore be:

Relative Humidity Per Cent	R.P.M.
0	98.21
10	98.22
20	98.24
30	98.25
40	98.26
50	98.28
60	98.29
70	98.30
80	98.32
90	98.33
100	98.34

The table will now be completed for 0 deg. by inserting these figures for revolutions per minute.

Applying again the formulas to our case for 100 deg. Fahr., the weight of dry air in 365 cu. ft. of air mixture with no moisture present (relative humidity = 0 per cent) will be:

In the following calculations the figure 365 has been used so as not to change calculations that had already been made. This will not alter the methods of calculations, although it is incorrect for the example itself.

$$365\left(\frac{1.32581 \times 29}{559.4}\right) = 25.08706 \text{ lb.}$$

When the relative humidity is 100 per cent the vapor pressure P_1 is 1.916 in., the air pressure P_2 is 27.084 in., the barometric pressure P is 29 in. and the weight of dry air in 365 cu. ft. of air mixture will be:

$$365\left(\frac{1.32581 \times 27.084}{559.4}\right) = 23.42958 \text{ lb.}$$

By dividing the respective weights into 3000 the quotient will be the revolutions per minute necessary to deliver the proper volume of dry air; thus for 0 per cent humidity 119.58 r.p.m. and for 100 per cent humidity 128.04 r.p.m.

The difference $128.04 - 119.58 = 8.46$ may in this case also be equally distributed on the miscellaneous relative humidities and the revolutions per minute will therefore be:

Relative Humidity Per Cent	R.P.M.
0	119.58
10	120.43
20	121.28
30	122.12
40	122.97
50	123.82
60	124.66
70	125.51
80	126.35
90	127.20
100	128.04

Complete the table for 100 deg. Fahr. by inserting above figures.

Having the two extremes recorded, the next step will be to complete calculations for each humidity separately. For instance, select the 100 per cent column and divide the difference $128.04 - 98.34 = 29.70$ into ten equal parts of 2.97 each. Complete the column for every tenth degree, which for 10 deg. Fahr. will give $98.34 + 2.97 = 101.31$, for 20 deg. Fahr. = 104.28, etc., until the revolutions per minute for 90 deg. Fahr. has been recorded. Thereafter do likewise for all temperatures between 0 deg. and 10 deg., 10 deg. and 20 deg., 20 deg. and 30 deg., etc., until the entire 100 per cent column has been completed. The other columns are figured out in a similar way.

It may be inconvenient to give the standard for dry air blown per minute in pounds, but this may easily be overcome by selecting a certain figure for the volume in cubic feet blown per minute at a certain temperature and relative humidity, and calculate the weight of dry air in this volume.

Example: What is the standard weight when I want to blow the equivalence of dry air in 40,000 cu. ft. of air mixture at 50 deg. Fahr. and 50 per cent vapor saturation?

The vapor pressure for 50 deg. Fahr. and 100 per cent saturation is 0.360 in., the vapor pressure for 50 deg. Fahr. and 50 per cent saturation $= 0.360 \times 0.50 = 0.180$ in., the air pressure for 50 deg. Fahr. and 50 per cent saturation is 28.82 in., all for a barometric pressure here assumed to be 29 in.

The weight of dry air in the 40,000 cu. ft. of air mixture is $40{,}000\left(\frac{1.32581 \times 28.82}{509.4}\right) = 3000$ lb. and the standard will therefore be 3000 lb. per minute, or pounds per 100 lb. of pig iron (see below).

Two 29-in. and 30-in. tables as described are an absolute necessity in any blowing room, even though they may not give entirely correct figures for the revolutions per minute due to causes over which there is no control. Generally speaking, the figures give good practical results. However, there are other factors that interfere with correct results even should T blow the right number of revolutions. It is therefore important to eliminate, if possible, such disturbing elements of which the following may be the most important:

1. Leakages in the air cylinders, valves, stoves, cold and hot blast mains. These can be overcome, and the stoppage of all such leaks should be the first work in the line of improvements.

2. Bad conditions of the blowing engine itself. This can also be overcome by frequently using the indicator, which is necessary in order to keep the valves set right.

3. Disturbances in the blast furnace, causing sudden differences in pressure of the blast.

The air mixture may enter the blowing cylinders under the following conditions:

1. As dry blast, when refrigeration has been carried on to the practical limit. In this case both the temperature and pressure will be almost constant with humidity practically nil. The displacement will likewise be a near constant, wherefore the number of revolutions must, as a matter of course, vary little or nothing. There will under such conditions be no need of any guiding "Table of Blast Regulation."

2. As partially dried blast, when the air mixture is more or less cooled, either artificially or by means of carrying the blast intakes to the outside of the blowing engine room. The manner of taking the temperatures will be different. In the former case provisions must be made in the air line close to the intakes of the blowing cylinders for the reading of the two thermometers. No slinging is required as the air current is swift enough. The dry bulb thermometer may be stationary, but the wet bulb should be so placed that the muslin can be dipped in the water, which must be pure and clean. Even a wick attached to the wet bulb and placed in a bottle of pure, clean water will in this case answer the purpose. This has the additional advantage of making the wet bulb also stationary. When the blast intake is carried to the outside of the building a similar wick arrangement for the wet bulb may do, placed either as above or at the entrance of the intake.

3. As natural air, taken directly from the blowing engine room. In this case sling psychrometer must be used and it is strongly recommended that the type used by the Weather Bureau be selected. In this the two thermometers are mounted in a frame, whirled around by means of shafting and miter gearing, the whole being encased, thus insuring the safety of the thermometers.

NOTE:
Vapor pressure is determined by means of Weather Bureau's Psychrometric Tables and air pressure = difference between the barometric and vapor pressures.
Relative humidity is given directly in the Weather Bureau's Psychrometric Tables, when the Depression of wet-bulb thermometer as shown in third column by "Diff." is known.
When using these records for blast furnace tests of several days' duration, averages must be taken on all reports combined. Do not establish average on averages.

TABLE OF BLAST REGULATION

For Barometric Pressure ..... Inches of Mercury

Standard for weight of dry air blown per minute, pounds

When refrigeration is made on the compressed air mixture either the second or third condition may take place. The manner of recording the temperatures will be accordingly.

Temperature readings need not be taken oftener than once an hour. However, it is important, that they are made on regular intervals, and it is a good policy to always do it on the hour.

There may be other methods of determining the amount of H_2O vapor in the atmospheric air as for instance by means of sulphuric acid, but, while this is the most correct one, it is hardly a practical method for continuous observations.

When the temperatures are known, the vapor pressure and relative humidity are determined by means of psychrometric tables, of which the one prepared by Prof. C. F. Marvin of the U. S. Weather Bureau is very complete.

By carefully conducting the operations in the blowing room it is possible to furnish a blast of more uniform quality. But this quality must be measured with some standard; otherwise I do not know its value. As was previously stated a certain air would be 100 per cent efficient if no moisture was present, because it would then contain the maximum amount of oxygen. Consequently this is the standard I need. But the volume must likewise at the same time be given. Therefore, while any convenient figure may be chosen, the air at "standard conditions" is the most logical. The weight of 1 cu. ft. of pure, dry air is then 0.080728 lb., but as this is too small a quantity 1000 cu. ft. may be more suitable. The standard will consequently be the weight of 1000 cu. ft. of pure, dry air at 32 deg. Fahr. and 29.9212 in. barometric pressure. This weight is 80.728 lb. If the air mixture, used at any time, is converted into volume at "standard conditions," the weight of pure, dry air in 1000 cu. ft. of this air mixture, multiplied by 100 and divided by 80.728, will give the air efficiency of the blast.

It has been shown above that the "Table of Blast Regulation" must be based on a standard weight of pure, dry air per minute. Of course, this standard may be assumed to correspond with a certain weight of pig iron produced. If, for instance, the standard in question is 3000 lb. per minute and the blast furnace is expected to turn out, say, 700 lb. of pig iron during the same unit of time, the standard for dry air per 100 lb. of pig iron would be 428.6 lb. Variations from this figure would in a certain measure indicate the uniformity of operations in the blowing room and will give the blast efficiency itself. Suppose 460 lb. of dry air had been blown per 100 lb. of pig iron, the blast efficiency would be $100 - \left(\frac{(460 - 428.6)100}{428.6}\right) = 92.67$ per cent.

When all the information is on hand calculations should be made on a certain small unit, as for instance, 1000 lb. of pig iron produced. The figures will otherwise be too bulky.

CALCULATIONS TO DETERMINE THE VALUE OF BLAST PRODUCTION

Determine first the time for which calculations shall be made. Assume this to be twenty-four hours.

The displacement of the air cylinder will next be considered and figured out as previously shown. In the formula

$$V_4 - \left(2V_1 \times \frac{459.4 + t}{459.4 + t_1} \times \frac{P_3}{P}\right)$$

t, t_1, P and P_3 are the average figures for the time in question and V_5 will give the result, which is the volume at existing conditions.

In degrees Fahrenheit:

t denotes dry temperature of air mixture, entering the blowing cylinders.

t_1 denotes dry temperature of air mixture, leaving the blowing cylinders.

t_2 denotes dry temperature of air mixture at entrance of stoves.

t_3 denotes dry temperature of air mixture at the blast furnace.

t_2 and t_3 are to be used for heat in the blast at these temperatures in connection with stove tests only.

In inches of mercury:

P denotes average barometric pressure.

P_1 denotes average vapor pressure (as given by the weather bureau's psychrometric tables).

P_2 denotes average air pressure and equals $P - P_1$.

P_3 denotes average absolute pressure of blast, leaving the blowing cylinders, and equals $P +$ gage pressure.

"Total pig" denotes total weight in pounds of pig iron, produced during the twenty-four hours.

$$\text{"Pig"} = \frac{\text{"total pig"}}{100}.$$

"Total revolutions" denotes total revolutions blown during the twenty-four hours.

"Total volume" denotes total volume of air mixture, blown during the twenty-four hours as per conditions V_5 and = "total revolutions" $\times$ V_5 cubic feet.

A. Volume of air mixture per 100 lb. of pig iron, produced $= \frac{\text{"total volume"}}{\text{"pig"}}$ cubic feet.

B. Weight of dry air in this air mixture

$$= A\left(\frac{1.32581 \times P_2}{459.4 + t}\right) \text{lb.}$$

C. Weight of H_2O vapor in this air mixture

$$= A\left(0.080728 \times \frac{459.4 + 32}{459.4 + t} \times \frac{P_1}{P} \times \frac{P}{29.9212}\right) 0.622.$$

$$= A\left(\frac{0.82465 \times P_1}{459.4 + t}\right) \text{lb.}$$

D. Weight of air mixture (blast) $= B + C$ lb.

At standard condition (32 deg. Fahr. and 29.9212-in. barometric pressure):

E. Volume of air mixture (blast)

$$= A \times \frac{491.4}{459.4 + t} \times \frac{P}{29.9212} \text{cu. ft.}$$

F. Volume of vapor in the air mixture $= \frac{16C}{0.81}$ cu. ft.

G. Volume of dry air in the air mixture $= E - F$ cu. ft.

In per cent the air mixture contains:

H. Vapor $= 100F \div E$ volume per cent.

I. Dry air $= 100 - H$ volume per cent.

K. Number of 1000 cu. ft. in the blast at standard conditions $= \frac{E}{1000}$.

L. Weight of dry air in the blast per 1000 cu. ft. at standard conditions $= \frac{B}{K}$ lb.

M. Air efficiency of the blast $= \frac{L}{0.80728}$ per cent.

N. Weight of water pumped into the blast furnace during the twenty-four hours $= C \times$ "pig" lb.

O. Heat in the air mixture, when entering the blowing cylinders (convert t deg. Fahr. into T deg. C.):

$G(0.0189T + 0.0000017T^2)$ pound calories.

$F(0.021\ T + 0.000009\ T^2)$ pound calories.

Total (————) pound calories.

Q. Heat in the blast when leaving the blowing cylinders (convert t_1 deg. Fahr. into T_1 deg. C.):

$G(0.0189T_1 + 0.0000017T_1^2)$ pound calories.
$F(0.021\ T_1 + 0.000009\ T_1^2)$ pound calories.
Total (————) pound calories.

R. Heat in the blast at entrance of stoves (convert t_2 deg. Fahr. into T_2 deg. C., and use only in connection with stove tests):

$G(0.0189T_2 + 0.0000017T_2^2)$ pound calories.
$F(0.021\ T_2 + 0.000009\ T_2^2)$ pound calories.
Total (————) pound calories.

S. Heat in the blast at entrance of the blast furnace (convert t_3 deg. Fahr. into T_3 deg. C. and use only in connection with stove tests):

$G(0.0189T_3 + 0.0000017T_3^2)$ pound calories.
$F(0.021\ T_3 + 0.000009\ T_3^2)$ pound calories.
Total (————) pound calories.

Technical Society Meetings and Lectures at the National Exposition of Chemical Industries

The following program is complete to date for America's first National Exposition of Chemical Industries, which opens in Grand Central Palace, New York City, on Monday, Sept. 20. The managers, Messrs. Nagelvoort and Roth, working with the co-operation of the International Exhibition Company, deserve a very great deal of credit for this diversified and interesting program, and also for the equally fine motion-picture program. Credit is given by the managers to all who have assisted in the endeavor to make the exhibition a success, especially the advisory committee and the Bureau of Commercial Economics of Washington, through their assistance in securing speakers and their kindness is loaning films. The program follows:

Monday, Sept. 20

Opening day. The exposition will be formally opened by a member of the Cabinet from Washington.

Tuesday, Sept. 21

2 p. m.—HOWARD GROSS, president Tariff Commission League, "Tariff Question," followed by discussion.

8 p. m.—Meeting the New York Section of American Electrochemical Society, under whose auspices the following papers will be given:

Introductory remarks by the chairman, Dr. COLIN G. FINK.

D. T. PIERCE, Barber Asphalt Co., "Asphalt and the Brownian Movements of the Colloids of Trinidad Asphalt" (an illustrated lecture).

LINN BRADLEY, the Research Corporation, "Solution of Smoke, Dust and Fume Nuisance by Electrical Precipitation."

HARRINGTON EMERSON, the Emerson Co., "Efficiency in the Conservation of our Natural Resources."

Wednesday, Sept. 22

2 p. m.—FREDERICK W. KEOUGH, National Association of Manufacturers, "Accident Prevention in the Chemical Industries."

WELDING RING, President American Exporters' Association, "Transportation and Shipping Facilities with Foreign Countries."

J. L. LIGHTNER, Hershey Chocolate Co., "The Manufacture of Chocolate."

8 p. m.—THOS. H. NORTON, Department of Commerce, "Foreign Markets for American Chemicals."

I. F. STONE, President National Aniline & Chemical Co., "The Aniline Dye Situation."

Thursday, Sept. 23

2 p. m.—Meeting of the American Paper & Pulp Association (Technical Section), under whose auspices the following papers have been promised:

Welcoming address by President FRANK L. MOORE.

D. L. BELLINGER, "Some Experiments in Refining Groundwood Slivers."

F. G. WHEELER, "A Method of Determining the Current Capacity of a Cell in an Electrolytic Bleach Plant."

MAX CLINE, "The Possibilities of Accurate Determinations of Groundwood in Papers."

The following lectures will also be given on this day:

2 p. m.—J. L. TAYLOR, Bureau of Explosives, "Explosives."

H. A. HUSTON, German Kali Works, "Potash."

G. B. HECKEL, New Jersey Zinc Co., "Paint."

ROBT. L. FRINK, president Frink Pyrometer Co., "The Relation of Chemistry and Mechanical Manipulation to the Evolution of the Glass Industry."

8 p. m.—CHARLES V. BACON, consulting chemist, "Manufacture and Uses of Vegetable Oils."

GEORGE FRANK LORD, DuPont DeNemours Powder Co., "Chemical Effect of Dynamiting the Soil."

PERCY WILSON, secretary Association American Portland Cement Manufacturers, "The History of Cement."

In the evening a smoker has also been arranged by the Chemists' Club, to be held at its clubhouse, 50 East Forty-first Street, for visiting chemists:

Friday, Sept. 24

2 p. m.—W. D. COOLIDGE, General Electric Co., "The 'X-Ray.'"

PHILLIP SHARPLES, Barrett Manufacturing Co., "The Development of Refined Tars for Use in Road Construction and Maintenance."

8 p. m.—Joint meetings of the New York Section American Chemical Society and the American Institute of Chemical Engineers, under whose auspices the following lectures will be given:

S. P. SADTLER, S. P. Sadtler & Sons, "Some American Contributions to Industrial Chemistry."

L. H. BAEKELAND, "Chemical Industry."

Saturday, Sept. 25

2 p. m.—RAYMOND F. BACON, director Mellon Institute, "Research and Progress in American Manufacturing."

For Saturday evening Dr. Thomas H. Norton has promised a paper on the results of some special work which he has done in the past two years, and which is hoped to have far-reaching consequences.

The Open Hearth Versus the Electric Furnace in the Manufacture of Commercial Steels

BY SIDNEY CORNELL

There has been a great deal of discussion lately about the cost of making steel in the electric furnace in competition with the open-hearth furnace, and recently the assertion has been made that the electric furnace can compete with the open hearth in the manufacture of commercial steels on a large scale.

The electric furnace has successfully competed in quality and in cost with the crucible process, and in many instances can produce steel at a cost less than in the small converter or Tropenas process, and is being used for making small and special castings at a very good showing in cost. The assertion that the electric furnace can do all that the modern open-hearth furnace can do in large and organized plants, and on commercial steels, is open to doubt, and the following analysis of the facts may be of value in clearing up the situation. The matter must be considered from a commercial standpoint, and for the manufacture of steel for rails, structural shapes, merchant bar, etc., the problem is nothing more than a balance of detailed costs and investment. In order to do this the following table has been compiled from data from a year's operation of a large open-hearth plant in a well-known steel company, and compared with what is claimed to be practice obtainable in an electric furnace plant of the same capacity.

The following comparison is made from records for an open-hearth plant consisting of 80-ton furnaces, having a production of about 200 tons of ingots per day for each furnace, and compared with a 20-ton electric furnace having approximately the same capacity per day. This comparison must be made assuming that an electric furnace plant of some ten furnaces is substituted for a plant of open-hearth furnaces containing ten furnaces, each plant being equipped with the necessary auxiliary apparatus, mixers, scrap yards, cinder ladles, ingot equipment, tracks, etc., etc.

The cost of a modern open-hearth plant with 80-ton units, is approximately $275,000 per furnace, including all auxiliary equipment, building, etc. The cost of a 20-ton electric furnace of the most advanced type is estimated at $500,000 per unit, and including the necessary electrical equipment. In connection with the electric furnace it is assumed that blast-furnace gas would be converted into electricity, and that modern practice cleans all blast-furnace gas, thus making the gas engine and equipment chargeable to the electric-furnace equipment, but not the gas-cleaning plant.

Table I is a tabulation of the materials necessary to make a ton of steel, and whether the electric or the open-hearth furnace is used or not, the quantity of raw materials is approximately the same. It is argued that the electric furnace can use inferior materials. Inferior materials necessarily are not in the most advantageous shape to handle, and often are more bulky than those of better quality, so that although in the auxiliary charge the electric furnace might use a slightly smaller quantity this would be offset in the more bulky principal materials, and accordingly more troublesome to handle.

The electric furnace will consume the same raw materials in the making of a ton of steel, the molds used will be the same, and the only credit will then be refractories, and producer gas, from the tabulation of Table I.

In Table I the cost of rebuilding is included in the refractories cost, which is given totaled for the electric furnace, and the cost of power is taken at a low figure $0.007 per kw.-hr. In a commercial plant such as is under consideration, the labor distribution for the handling of the quantity of materials necessary to make each ton of steel will be the same for either type of furnace, and in this work organization of a force is as imperative for a plant of electric furnaces as for an open-hearth plant. Further, an electric-furnace plant, being part of a steel works, would have to bear its share of the non-producing departments, and accordingly Table II applies for both purposes.

Table III (Labor in Repairs) will also hold good as much for an electric-furnace plant as for an open-hearth plant, because as may be noted, the large portion of the charges are not for the furnace proper, and the furnace proper is a comparatively small item.

Table I—Materials Charged per Ton of Steel

000 per unit, and including a 4500-kw. electrical equipment per unit, which, assuming the same rate of depreciation as the open-hearth plant, carries a burden of $1.110 per ton of steel produced, using 16 per cent as per above.

The electric furnace consumes electrodes, and a figure of $0.340 per ton of steel is given as a fair average. In the induction type of furnace this would be eliminated, but with an increase in power consumption.

The summary of the situation is given in Table IV.

There are some electric furnaces operating in this country of sufficient capacity to produce facts as to costs for the above comparison, but when an electric furnace operating on castings or special steels produces steel at a cost of approximately $20 per ton of steel, it is not logical to suppose that the same equipment can produce steel at a sufficiently low cost to compete with the open-hearth furnaces in the manufacture of commercial steels. All steel works produce scrap, which must be remelted and made of value, and the amount of

TABLE IV—SUMMARY

Item	Open Hearth	Electric Furnace
Investment, per unit, 200 tons daily capacity	$275,000 0000	$500,000 0000
Interest, depreciation, etc., 16 per cent	0.6100	1.1100

Plant overhead cost and producing labor (Table II)	0.8290	0.8290
Labor in repairs (Table III)	0.0600	0.0600
Electrodes		0.3400
Other overhead	0.0100	0.0100
Total cost per ton of steel	$15.6124	$20.0414

raw materials consumed in the manufacture of steel must remain approximately the same, so that other figures enter into the calculation such as have been tabulated. Accordingly, until the large factor in the cost of making electric furnace steel—the cost of power—is reduced, the electric furnace cannot compete with the open-hearth in the manufacture of steels for rails, structural shapes, merchant bars, etc. In order to do so electrical energy must be produced at a cost lower than $0.001 per kilowatt hour and the present electrical equipment using blast furnace gas cannot do better than $0.007 per kilowatt hour.

Analytical and Laboratory Balances.—CHRISTIAN BECKER, INC., in its recent catalog for balances for chemists and assayers announces the removal of its factory from New Rochelle, N. Y., to Jersey City, N. J., with an office at 92 Reade Street, New York. The catalog contains illustrated descriptions of its principal types of balances with data on capacity, sensitiveness and dimension.

Mercury production in Austria in 1913, according to the report of the Minister of Public Works, amounted to 820 metric tons, valued at $89,208, being an increase of 57.4 tons, but a decrease of $19,145 in value, as compared with the previous year. The entire production came from the Idria mine. Six other mines were then idle.

Production of Zinc Oxide from Low-Grade Carbonate Ore at Leadville

(Editorial Correspondence)

The year 1910 marked for Leadville the beginning of one of those eras of prosperity that make up the varied and interesting history of that remarkable mining district, for in that year the deposits of zinc carbonate were discovered and became the basis of a profitable industry.[1] Ore of shipping grade, say 30 per cent to 35 per cent zinc, was found in large quantities, and thousands of tons were shipped to smelters. It is estimated that during the year 1911 over $3,000,000 worth of zinc in the form of carbonate and silicate was mined and shipped. During the past five years production has continued, and from time to time the smelters have modified their requirements as to grade until at times carbonate ore containing as little as 20 per cent zinc has been marketed.

The limitations of the smelting process, however, prevented the economic treatment of lower grades of carbonate ore which existed in abundance. In Butler's study of the ores[2] he encountered all grades, ranging from practically pure smithsonite (carbonate of zinc) containing about 50 per cent zinc, down to limestone impregnated with zinc, iron and manganese, assaying 15 per cent zinc or less. Smithsonite predominates, and is usually dark reddish or yellowish brown in appearance, soft, porous and earthy. In some compact varieties the mineral is more granular, but without apparent crystalline structure.

Early Proposal of Igneous Concentration

Owing to the physical condition of the zinc carbonate and its intimate association with silica and oxidized forms of iron, the ore is not amenable to ordinary methods of gravity concentration; nor has success been met in recent efforts to adapt some form of flotation to the concentration of these ores. As a consequence, from the time of their discovery until recently, the economic treatment of the low-grade carbonates had not been accomplished. The situation early attracted the attention of metallurgists who realized that the eternal low-grade ore problem would have to be confronted here as elsewhere. Clerc[3] made numerous suggestions for the fire concentration of the ores, with the object of producing a high-grade zinc oxide for subsequent reduction to spelter. In general he voiced the sentiment of other metallurgists who regarded igneous concentration as a logical and feasible process.

In 1914 the Western Zinc Mining & Reducing Co. was organized among Oklahoma oil producers, and a mill was erected at Leadville for the production of zinc oxide from low-grade carbonate ore. The plant was

[1] "From 1860 to 1876 Leadville was a placer gold camp, and little actual mining was attempted, but the discovery of carbonate lead ore in 1874 directed the attention of miners underground. At first only lead and silver (in the form of cerussite and of cerargyrite) were mined, but later extensive deposits of oxidized manganese-iron ores were found; and deeper exploration revealed large bodies of sulphides—mainly galena, sphalerite and pyrite. In 1891 ore chiefly valuable for its gold content was first encountered, and, following the depreciation in the value of silver in 1893, Leadville attracted wide attention as a gold district, although the other metals named were still mined in large quantities. Early in 1910 most of the larger known deposits had been worked out, many of the mines had been abandoned, and it was believed that the great camp with its production of over $380,000,000 was practically exhausted. Then suddenly the mining world was electrified by the announcement that enormous quantities of oxidized zinc minerals had been discovered." Some Recent Developments at Leadville. By G. Montague Butler. *Economic Geology*, Vol. VIII, No. 1, January, 1913. Also *Quarterly*, Colorado School of Mines, April, 1913.

ready for operation in July, 1914, and a short trial run was made just prior to the outbreak of the European war, when the ensuing industrial disturbance in this country caused the company to cease operations. The plant was closed and remained idle until a few months ago, when it was taken over by the Western Zinc Oxide Co., a local organization, under the technical direction of Mr. A. B. Augustine, who originally designed the mill. Operation has now been continuous since.

The Leadville Works

The zinc oxide works at Leadville consists essentially of a furnace, cooling flue and bag house, with the necessary fans for furnace blast and bag house pressure.

FIG. 1—ZINC OXIDE WORKS, LEADVILLE, COLO.

The plant is simple in design and construction, and the process also is simple in principle and theory. Success in practice lies in intelligent supervision, the proper proportioning of furnace charge, blast pressure and air volume, and the education of workmen to a point where they have some conception of what the process is designed to accomplish. As the Leadville plant is situated at an altitude of over 10,000 ft., special consideration had to be given to the volume and pressure of air required for an oxidizing process. Fans, flues and bag house have been designed to meet these requirements, but many details incident to successful operation have had to be determined experimentally.

Wetherill Type of Furnace

The furnace is of the Wetherill type, 65 ft. long, 16 ft. 6 in. wide and 11 ft. high, built of brick and divided into eight double-ended arched fire-boxes extending across the furnace and having a fire-door at each end. The grate area of each double fire-box is 13 ft. 6 in. by 6 ft. 9 in.

The foundation is of concrete and forms eight water-tight compartments beneath the fire-boxes. These compartments are kept filled with water so that the moisture evaporated below the grates may keep the clinker open and porous and aid in the process of oxidation. According to the original design the water compartments were connected by small openings through the transverse walls; but as these openings have sometimes become clogged with cinder falling through the grates, preventing free circulation of water from one compartment to another, a separate water pipe to each compartment has been provided.

The grates are formed of perforated cast-iron plates 11 in. wide, 6 ft. 9 in. long and 1¼ in. thick. The perforations taper from a diameter of ¾ in. on the underside to ⅛ in. on the upper. The ends of the plates rest in the furnace walls and the centers are supported by rails extending across the furnace. The fire-boxes are arched in semi-circular form from the grate level. Above these arches and at right angles to them is the main central arch extending the full length of the furnace and communicating with the combustion chamber at the end.

Extending along the top of the furnace is a 24-in. air main, from which 8-in. pipes conduct air to the pits under the grate of each compartment. The volume of air delivered is regulated by sliding dampers in the 8-in. pipes. A Sturtevant blower supplies 4-oz. blast to the furnace at the rate of 32,000 cu. ft. per minute.

From the combustion chamber a U-shaped cooling flue 4 ft. in diameter and 600 ft. long extends to the bag house. The flue is supported on wooden trusses every 20 ft. It has expansion joints every 50 ft. and small dust hoppers every 10 ft.

Bag House

The bag house contains 288 cotton bags 24 in. in diameter and 26 ft. long, suspended in the usual manner and connected at the bottom with hoppers. The total filtering area is 47,000 sq. ft. The volume of gas handled is about 40,000 cu. ft. per minute, giving a unit filtering area of approximately 1.2 sq. ft. per cubic foot of gas per minute.[4]

The bags are arranged in lateral groups of twenty-four each, with a hopper for every four bags. Each lateral group has a separate connection with the oxide flue, so that the flow can be cut off periodically to shake the bags and clean the hoppers. A National exhaust fan draws the fume from the cooling flue and forces it into the main bag-house conduit and thence to the laterals and bags. The pressure is just sufficient to keep the gases moving through the cooling flue and to prevent back pressure on the furnace.

FIG. 2—PORTION OF COOLING FLUE

[4] This compares with 3.45 sq. ft. per cubic foot of gas per minute in lead smelting practice at Murray, Utah, the area being reduced to 2.5 sq. ft. when one compartment of the bag house is closed. See Notes on Bag Filtration Plants, by Anton Eilers, original communication to the Eighth International Congress of Applied Chemistry; also this journal, Sept. 12, 1912, p. 588.

Preparation of the Ore

The ore treated contains zinc mainly as carbonate, with but little silicate. The latter would not be suitable for the process as it would not decompose readily at the temperature of operation. The average grade is 18 per cent zinc, with a minimum of 16 per cent. The ore is purchased on analysis of a sample secured by taking every tenth shovelful as the lot is unloaded from the car. Lead is an undesirable element, but does not exist in quantities of more than 0.1 per cent in the ores treated.

FIG. 3—ONE SIDE OF EIGHT-COMPARTMENT FURNACE

Ores containing more than 2 per cent to 3 per cent lead are not purchased.

A Jeffrey swing-hammer pulverizer is used for crushing, the product being elevated and screened through a 3/16-in. trommel screen and the oversize returned to the pulverizer. This machine has displaced a Blake crusher and a set of rolls and is giving better satisfaction than the former equipment. The ore varies in moisture content, and some of it is so wet as to give trouble in crushing with jaw breakers and rolls. The swing-hammer machine obviates these difficulties and has shown a capacity of 50 tons in 8 hours, which is ample. The same pulverizer serves to prepare the anthracite coal which is used in the smelting mixture after being crushed to about 5/16-in.

Ore and coal are trammed to the furnace room and dumped on a concrete floor for mixing. A charge for one double-ended furnace compartment consists of 2000 lb. ore and 1100 lb. coal, divided into two equal portions for the fire-boxes on opposite sides of the furnace. Mixing is done by shoveling, the pile being turned over once dry, then wetted to contain about 20 per cent moisture and turned over again. In a larger plant mechanical methods of mixing might be more economical, but at the Leadville works the necessary furnace attendants have ample time to prepare the charge by hand and the method gives satisfaction.

Operation of the Furnace

The eight fire-boxes are charged at both sides simultaneously, and in rotation from No. 1 to No. 8. One hundred pounds of coal is first thrown over the hot grate, 50 lb. from each side, and when ignition has begun the charge of ore and coal is shoveled in and leveled. The blast is reduced in volume at the beginning of the operation and gradually increased as the charge becomes ignited. The furnace foreman regulates the blast and rabbles the charge occasionally to prevent the formation of blow holes and insure a bed of uniform density. In six or seven hours the zinc is driven out of the charge. The sinter is then withdrawn and taken to the dump, and a new charge added. At this rate of operation the furnace has a capacity of 30 tons of ore in 24 hours.

Under the present method of operating the sinter carries from 2 per cent to 4 per cent zinc, which is an improvement over earlier practice, resulting from a better proportioning of the slag-forming elements in the ore. The ores vary in iron and silica content, and are mixed to give a nearly neutral sinter, with iron slightly in excess owing to the greater abundance of that element.

The furnace temperature is about 1000 deg. C., but by the time the gases have passed through the long cooling flue they enter the bag house at a temperature of about 140 deg. C. Cooling by radiation is augmented by the admission of air at a number of the hoppers near the bag-house end of the flue.

The bags are shaken by hand every two hours and the hoppers are emptied once in 24 hours. The product is a high-grade white zinc oxide, containing 76-77 per cent zinc, equivalent to 95-96 per cent zinc oxide. It contains also from 1 to 1½ per cent lead, and is suitable for use as a pigment without reburning. The ratio of concentration is between 4 and 5 to 1, and production amounts to about 6 tons of oxide per day.

As matters now stand the Leadville works should become an economic factor in the mining and treatment of low-grade zinc carbonate ores. Time and experience have served to remove many of the difficulties encountered in the trial run of a year ago. Bag-house capacity is apparently ample, and slag and fume losses have been reduced to a minimum. The labor problem grows less acute as the men become educated in the details of operation, and the process is now working to the satisfaction of its promoters. The plant is favorably located with regard to transportation facilities, ore and fuel supply and power, and apparently no unfavorable conditions now exist to prevent continued success.

Antimony has been found in many places in Mexico, especially in Durango, Sonora and Oaxaca, and relatively small amounts of ore have been shipped to the United States for smelting; however, the Catorce deposits have been the best producers for the last 20 years. The mining ores run from 25 to 70 per cent pure antimony. Antimony appears in many ores treated at the lead smelter in San Luis Potosi, but its presence in these ores is deleterious, and in the bullion it is regarded as an impurity.

The vapor pressure of arsenic trioxide is the subject of Technical Paper No. 81, of the U. S. Bureau of Mines. The authors are H. V. Welch and L. H. Duschak. The paper embodies the results of an investigation undertaken with a view to the proper design and control of equipment for recovering arsenic from smelter gases.

Chemical Principles of the Blast Furnace

BY J. E. JOHNSON, JR.

(*Concluded from page* 543)

The Removal of the Sulphur

Sulphur may be introduced into the furnace by any of the raw materials, the fuel, the ore, or the flux, their responsibility for its introduction being in the order given.

The flux generally contains only traces of sulphur, but one case came under my observation in which the management of a charcoal furnace was greatly disturbed and equally puzzled to find the sulphur in their iron too high with no apparent reason for its being so. Analyses of the ore and then of the charcoal showing nothing out of ordinary, they finally analyzed the limestone and found enough sulphur to account for all the trouble. I think the amount was about 0.3 per cent, which was sufficient to spoil charcoal iron, because the slag on which it was made was so acid as to leave in the iron a considerable proportion of the sulphur in the charge.

Most of the ores of the Lake Superior region are very free from sulphur, although several of these on the Menominee range contain as much as two or three-tenths. The ores of the Virginia and Alabama iron districts contain in general only the faintest traces of sulphur, as do most of those of the East, but some of the magnetites of New Jersey and Eastern Pennsylvania are high in sulphur, in particular, the ore from the Cornwall mine near Lebanon, Pa., the largest and most famous single mine in the East, which has been worked continuously since revolutionary times; it contains on the average about 2 to 3 per cent of sulphur and cannot ordinarily be used in the furnace without giving it a preliminary roast, which reduces the sulphur in unconcentrated ore to between 0.5 and 1 per cent. A large proportion of this ore is now crushed fine and magnetically concentrated, after which the fine concentrates are nodulized in a rotary kiln, and this in good practice reduces the sulphur to 0.05 per cent or under. Some of the magnetites of Canada are also high in sulphur, running 3 to 4 per cent in their native condition, and these are either crushed fine, concentrated and agglomerated, or treated by roasting, which reduces the sulphur to within permissible limits for furnace use. In general if an ore is rich and pure enough in other respects to be worth the treatment it can be so roasted as to lower the sulphur within easily usable limits.

SULPHUR IN FUEL

Charcoal is free of sulphur to a far greater extent than any other furnace fuel, but varies within quite wide limits. Charcoal from hardwood, exclusive of its bark, nearly always contains well under 0.1 per cent and even down to 0.02 or 0.03 per cent, while the bark may simultaneously contain 0.2 or 0.3 per cent or even more sulphur; but the bark is such a small proportion of the whole that good hardwood charcoal probably averages under 0.1 per cent of the whole.

This small amount is largely absorbed even by the most acid slag, and only a small quantity enters the iron, under 0.02 with good raw materials, in ordinary practice.

This absence of sulphur and the consequent absence of need to run the furnace for desulphurization constitute the fundamental difference between charcoal and coke or anthracite practice and the irons resulting from them.

Coke contains all the way from 0.6 per cent to 2 per cent sulphur, which is present in two forms, ferric and ferrous sulphide, FeS_2 and FeS, and vegetable compounds.

The sulphur combined with iron occurs in the form of pyrite FeS_2 in the coal, but the heat of the coking operation drives off one molecule of sulphur from some of the pyrite and leaves it in the form of FeS in the coke, so that coke makers have a rule for general use that the diminution of sulphur is just about the same as the loss of weight in coking, so that the percentage of sulphur in coke is about the same as that of the coal from which it is made. I believe that the classification of coke into good and bad as regards sulphur in the minds of most furnacemen is based on whether it is above or below 1 per cent. The original Connellsville coke had only about this and the New River and Pocohontas considerably less, but the sulphur in some of the Western Pennsylvania fields outside the Connellsville basin are higher and much coke is now used running 1.25 per cent and upward in sulphur.

I have known of a case where a plant ran for a considerable period on coke of nearly 3 per cent sulphur, but as the manager said, "I had to disregard coke consumption in order to make good iron." In another case a plant was run for a term of years on coke of 1.75 per cent sulphur.

As the sulphur specifications for steel mill irons are "under 0.06 per cent," and for all merchant iron "0.05 per cent and under," or in some cases "0.03 per cent and under," it is obvious that nearly all the sulphur brought in by the raw materials must be eliminated.

The method by which this is done consists principally, if not solely, in carrying the sulphur off with the slag as calcium sulphide CaS, there being no considerable portion of the sulphur carried off by the gas. There may be volatilization of sulphur in the hearth, but if so, the vapor formed is caught by the slag as it rises through the bosh and brought back into the hearth, so that the net effect of such an action is nil. The existence of such a condition has never been investigated as far as I know. Sulphur is always thrown off by a hot coke-furnace slag, in many cases in heavy volume, but this may be due to the oxidation of CaS of the slag to CaO and SO_2 with the oxygen of the air, a reaction which could not take place in the reducing atmosphere of the hearth, so that this evolution of sulphur from slag in air is no proof of a similar condition in the furnace.

The reactions by which calcium sulphide is formed are not very definitely known, but involve the reducing action of carbon to assist the reduction of the calcium from the oxide to the sulphide presumably by reactions somewhat as follows:

$$FeS + CaO + C = Fe + CaS + CO$$

This is the reaction given by Prof. H. M. Howe in his "Iron, Steel and Other Alloys," and is probably correct in principle if not exact in detail. The sulphur which is present as an organic compound is presumably carried off in a similar way, but nothing definite is known about the details of the reaction. It seems certain, however, that the sulphur cannot reduce lime to calcium sulphide without the assistance of the reducing action of the carbon. As a matter of fact the reactions are probably not so simple as indicated, since the silica exerts a powerful attraction for the lime and there must be enough of the latter present to satisfy the silica before much sulphur is removed.

We encounter here for the first time the fact which should be impressed upon the mind of every student of this subject and which is too little realized or taught in metallurgy:

The chemistry of the blast furnace is not a chemistry of definite atomic proportions but it is a chemistry of infinitely varying balances among conflicting tendencies.

A homely illustration is that if you place a heavy book upon the seat of a rocking chair the chair will take up a certain position; if you push the book back the chair will tip back and if you pull the book forward the chair will tip forward, its motion being roughly proportional to the movement of the book. If the rule of definite atomic proportions held the rocker of the chair would consist of only two or three straight sections of definite length and making considerable angles with each other, and the book could be removed through considerable distances without affecting the position of the chair, then when it did move it would rock instantly from one straight section to the next and remain at rest in that until the book had been shifted through another considerable range.

Nothing could be further from the facts of furnace operation than the last illustration, nothing be more like than the first. Each change of conditions sufficiently large not to be masked by the continual variations of operation produces its proportional effect, and these effects shade from one to the other by imperceptible gradations. It is, I think, this law which scientists have tried to capture and brand as "The Phase Rule." It is perhaps the misfortune of my generation that we had passed our student days when this rule was enunciated to the public and so did not grasp the new conception which it tries to codify, so that the simple relations which are used to illustrate the workings of the phase rule do not seem to need or receive additional light from it, and the more difficult ones whose explanation is sought by its assistance are made the harder for us to understand by the introduction of its difficult terminology. To another generation trained to think in this terminology from their collegiate years it will, we may hope, prove a benefit, but for the purposes of this work plain statements of fact with such homely illustrations as the above must suffice.

Returning now to the subject of desulphurization, the condition surrounding it and the number of substances involved in the operation is too great to permit its investigation without a vast amount of experimental work and overcoming many difficulties. We know, however, as the result of observations on operation four factors upon which desulphurization depends: First, the relative excess of bases over acids in the slag (positive); second, the temperature of the slag (positive); third, the fluidity of the slag (positive); fourth, the concentration of sulphur in the slag (negative).

The bearing and results of these laws may be more properly discussed under the head of furnace operation and need not be further considered here.

The Reduction of Silicon, Phosphorus, and Manganese

These elements are all more difficult to reduce from their oxides than iron and therefore it should theoretically be possible to run the furnace so that iron would be reduced but none of these impurities. But as a matter of fact it is not possible to do so; if they are present in the charge they will be found in the iron to some extent. We can vary this extent very much in the case of two of them, but even here we cannot exclude them altogether under practical operating conditions, if at all.

This is for the reason that iron exercises a solvent action upon all three elements and forms a definite compound with at least one of them, and probably the others also. The difference between a physical solution like that of caustic soda in water and a chemical combination like that of caustic soda with hydrochloride acid is not so great or at least so readily distinguishable at the high temperatures in the health of the furnace, and I do not feel qualified to distinguish between them in all cases. But it seems likely that manganese forms with iron only a solution or perhaps with the carbon in the iron a double carbide, the silicon acts as if formed silicide and a solution of this silicide in the iron, while phosphorus is known to form two or three definite phosphides, and solutions of some of these in iron.

Without attempting to pass definitely upon the question of whether the iron merely dissolves the silicon and manganese or really combines with them, we know that it has a considerable affinity for all three of these elements, and this fact has a strong influence in their reduction from the oxide to the elemental condition in which they are taken up by the iron. This is important because all of them are more difficult to reduce than iron requiring a higher temperature and a greater quantity of heat per unit of element reduced than does iron, and if the reducing action were not assisted by the affinity of iron for these substances in their elemental condition it is probable that they would not be reduced at all or in much less degree than they are.

The case is analogous to that of copper smelting which utilizes the power of copper as a "catcher" for silver and gold. The ores of these metals are charged into the copper furnace and a very large proportion of their values is caught by the copper matte, from which they are subsequently recovered by electrolytic refining; but if the copper were not there to act as a catcher these values would largely be lost in the slag and the fumes.

It is believed that all three elements under discussion are deduced by solid carbon and not to any extent by CO.

Phosphorus is more completely reduced than either of the other two. This may be because of its stronger affinity for iron rather than to greater inherent reducibility, and practically all of this element present in the charge passes into the iron unless the furnace is working "cold" with a scouring slag, when as much as 10 per cent of it may, according to Sir Lothian Bell, pass into the slag. From my own observation, I should say that even a considerably greater percentage of it could be eliminated in this way, but as this never happens except when the furnace is working very badly it is a matter of no industrial or commercial importance, and I have never investigated it.

It is stated in Sexton and Primrose's "Metallurgy of Iron and Steel," pp. 61 and 62, that phosphorus is not reduced at all by incandescent carbon except in the presence of silicon in excess. The phosphorus is generally present in the ore as tricalcium-phosphate and the reaction is said to take place according to the equation:

$$Ca_3P_2O_8 + 3SiO_2 + 5C + Fe = 3CaOSiO_2 + 5CO + FeP_2$$

Silicon is always present in excess in the charge and so the phosphorus can always be reduced even if this be a necessary condition. In the absence of any experimental data on the reduction of phosphorus in a furnace working without silica in the charge it is really more or less an academic, rather than a practical question whether this is a necessary condition or not. But I incline to the belief that while incandescent carbon alone may be unable to reduce phosphorus from the calcium phosphate, incandescent carbon in the presence of molten iron in excess might be able to cause the reaction to take place even in the absence of the silica; this is, of course, equivalent in a rough way to saying that the affinity of iron for phosphorus is probably as great as that of lime for silica so that the occurrence of the former reaction would compensate for the absence of the latter, but for practical purposes this is merely speculative.

The percentage of the total manganese changed which is forced into the iron depends upon the temperature at which the furnace is worked and the basicisity of the slag, from a half to two-thirds of the whole amount charged will pass into the iron in ordinary coke practice and less than this in good charcoal practice because those furnaces are worked both colder and with a more acid slag, though charcoal furnaces *can* be worked to throw as great a percent into the iron as can be done with coke. A part of the manganese is lost in the slag and a part by vaporization in the hearth, the latter can be plainly seen at furnaces making ferromanganese passing out the stacks of the stoves and boilers as a very heavy yellow fume.

The relative amounts lost in these two ways depend on the hearth temperature and the composition of the slag. Raising the hearth temperature tends to increase the vaporization loss and to diminish the slag loss while acid slag increases the slag loss rapidly without much effect on the vaporization loss. Cases are on record of unsuccessful attempts to make ferromanganese in which nearly all the manganese charged passed out into the slag, only an insignificant amount passing into the metal.

Silicon is generally present in the charge in far greater quantity than is needed to supply the percentage desired in the iron. Generally the composition of the raw materials is such as to produce this condition whether we will or not, and if it is not so the furnaceman usually produces it by adding a silicious ore to the charge as it is easier to get the silicon desired into the iron when a superabundance is present than it is to obtain it by robbing the slag of the silicon it needs. In coke practice the silicon thrown into the iron is commonly less than 20 per cent of the silicon of the total silicon charged. On the other hand, I have run a charcoal furnace on rich low-silica ore and made high silicon iron, about 3 per cent, which required more than half the silica charged for its production, but this is not good practice.

It is stated by Sexton and Primrose (*Op. cit.*) that silicon is not reduced by carbon at temperatures below those of the electric arc which means that the affinity it has for iron is strong enough to make up the deficiency in the reducing power of carbon and so the silicon is reduced not to the elemental state, but the state of silicide of iron. This is borne out by the limitations of the manufacture of ferrosilicon in the blast furnace. This material containing as high as 13 per cent Si ordinarily, and higher occasionally, is regularly produced in blast furnaces using very high blast temperatures and a large quantity of fuel per ton of product, but when material containing more silicon than this is desired it is necessary to go to the electric furnace which is quite without those limitations of temperature under which the blast furnace suffers, and in that apparatus it is perfectly possible to produce a material containing from 50 per cent to 80 per cent Si, or higher for special purposes. This is probably explained by the fact that when the iron reaches say 15 per cent Si it is so nearly saturated for this element that it does not exercise any considerable affinity for any further amount and reduction of silicon accordingly ceases.

Since the above was written I have been informed by Prof. J. W. Richards that silica begins to be reduced by carbon at 2750 deg. Fahr. and is reduced quite freely at 3250 deg. Fahr. Whatever may be the conditions as to silica alone the facts of practice are as above stated.

It seems likely that all these elements are reduced on the surface of the incandescent coke in a way exactly similar to the reduction of litharge to lead on the surface of a piece of chemical by blowing on it with a blow pipe. The conditions in the furnace are exactly the same on a large scale. As these elements are reduced the trickling iron running down over the surface of the coke on which they are produced is immediately at hand to take them up.

It has several times been suggested that the silicon of the iron came from the silica of the coke. This suggestion has much to recommend it and is probably largely correct for ordinary conditions, but in the manufacture of forrosilicon in the blast furnace in which the silicon goes up as high as 13 per cent it is obvious that this cannot all come from the coke since ordinary coke contains less than 7 per cent silica corresponding only to about 3 per cent of silicon. This proves conclusively that the silica of the coke ash is not the only source of silicon and indicates the probability here as in so many other cases that the course followed is a compromise between two possible extremes, a balance between opposing influences. The reaction according to which this reduction takes place is then of the form:

$$yFe + SiO_2 + 2C = Fe_ySi + 2CO.$$

SLAG

The impurities of the fuel and of the ore must be eliminated from the furnace. In the early days this was probably done in the same way as taking the clinker out of a domestic fire by prying the clinker up from the bottom and raking it out, but in a furnace over thirty feet in height, which the early furnaces soon came to be, it obviously could not be taken out the top and an opening was provided in the hearth with a fore hearth in front of it, through which access could be had to the inside of the furnace by removing the heavy lid of the fore hearth. This was only done after cast when the blast was off, as at any other time the gas formed in the hearth would have blown out the opening and made work impossible in the vicinity.

Gradually it came to be realized that the slag could be made fusible by the addition of "flux" and that when this was done it was not so necessary to open up the front and "work her down," so that practice declined and died out, but not so many years ago as might be thought, since I can distinctly remember as a very small boy seeing a jib crane, hung from the stone pier of the front arch of the furnace, to the chain of which the keepers hung in turn a huge poker and a gigantic shovel, as I recollect it about two feet square, and perhaps some other tools which were laboriously operated by two or three men who were not as economical of their strength as is now customary.

This was a charcoal furnace, but I am informed that the same practice was retained at the anthracite furnaces perhaps even to a later date.

The early furnaces always used charcoal fuel in which the percentage of ash is small and that present largely lime and alkali while sulphur is almost absent. For these reasons lime was little needed and its use developed slowly, but when soft coal and anthracite came into use, with a much larger amount of ash and sulphur, the latter requiring a relatively basic slag to keep it out of the iron, the use of flux came into regular use.

The principal impurity in both ore and all mineral fuel is silica. Its importance comes from two sources; first, it is generally present in much larger quantity than any other substance, and second, it is a much more active acid, if not the only acid of importance in common practice.

Next in quantity and importance comes alumina, which is very weak chemically, practically neither acid

nor basic, but has a powerful effect on the physical characteristics of the slag.

These combine with mineral bases and the compounds so formed are far more fusible than any of the components separately. For instance, silica melts about 3180 deg. Fahr. and lime alone is infusible even in the oxyhydrogen blow pipe, but these two form compounds which melt about 2100 deg. Fahr.

Advantage is taken of this fact to convert the impurities of the charge into a fusible slag which runs from the furnace easily by adding mineral bases to the charge, even in charcoal practice where sulphur is almost entirely absent, and in coke practice the addition of lime is carried much further so as to render the slag basic enough to fix the sulphur and carry it out of the furnace.

In practice only two bases are ever used, lime and magnesia. This is for two reasons; first, they occur in the greatest abundance in nature, far exceeding all the other alkalies or alkaline earths put together, and in massive geological formations close to the earth's surfaces so that they can be cheaply obtained by quarrying, and second, because they are among the most powerful of all the bases chemically, particularly lime, which will even replace caustic soda in combining with some acids.

Lime alone is often used as flux, but never magnesia. This for two reasons; first, that lime carbonate, which contains only insignificant quantities of magnesium carbonate, occurs in vast quantities in nature, but the reverse is so seldom true as to make the latter compound many times more expensive than limestone; second, the chemical activity of lime is much greater than that of magnesia. It was claimed by Sir Lothian Bell that magnesia was worthless for purposes of desulphurization; experience has proven this not to be true when both lime and magnesia are used together and whether it would be true if magnesia alone were used for flux is a purely academic question since commercial considerations prevent its use for that purpose.

Much limestone contains magnesium carbonate in quantities varying from a trace up to true dolomite, the double carbonate of lime and magnesia, $CaO,Mgo(CO_2)_2$ in which when decarborated the bases are present in the proportion of 41.7 and 58.3 per cent owing to the difference in the atomic weights of Ca and Mg. Dolomite occurs in nature in great quantities also as does dolomitic limestone and these are used as flue either alone or in conjunction with limestone, according to considerations which may be more appropriately discussed under the head of operation.

The combination of those bases with the silica of the charge forms the silicates of lime and magnesia which constitute in all cases more than half the total slag volume and this acts as a solvent for many other ingredients of which the alumina, in my judgment, is one; the principal one in quantity, next to the basic silicates themselves, varying from 7 to 15 per cent in ordinary coke practice but going as high as 35 per cent in certain special cases. The ingredient next in quantity in coke practice is calcium sulphide CaS, ranging from 2 to 5 per cent, but in normal practice from 3 to 4 per cent.

There is always present a certain amount of iron in the form of FeO. This varies from a mere trace in a white cinder made in a hot-working furnace to several per cent in bad working, but under 1.0 per cent in any normal working furnace. Manganese oxide MnO is present in quantities depending on the amount of manganese in the charge, in ordinary irons running under 1 per cent in manganese, the MnO in the slag should be under 0.5 per cent and from this down to a trace. On the other hand when high-manganese irons, spiegel and ferromanganese are being made there are always several per cent of MnO in the slag, even in best practice.

In general the rule that one-third of the manganese charged will go into the slag even if the furnace be operated to throw as much as possible of it into the iron, will define the minimum amount to be expected in the slag, and this may be increased up to a large proportion of the whole amount charged by different furnace operation.

Titanium

Some ores and fuels contain other elements in small quantities which go into the slag or into the iron in varying proportions. One of the most common of these is titanium, which occurs in some cokes and in many ores in amounts varying from a trace up to 15 or 20 per cent, in the form of titanic acid TiO_2

This is extremely irreducible and infusible and its presence complicates the operation of the furnace materially, and for a very unusual reason; this is its affinity for nitrogen since with this and cyanogen it forms a cyano-nitride of titanium. This is highly infusible and does not dissolve in the slag, so remains in the hearth, and gradually fills it up to such a point that the furnace can no longer function properly. It was long held that the presence of a small quantity of this material rendered ore unfit for use in the blast furnace, but the whole question has recently been attacked anew and methods will probably be found whereby it can be fluxed. There is much reason to believe that the former verdict against it was on insufficient grounds.

In some cases the principal impurity in the ore is lime instead of silica, but there is seldom a sufficient excess to do more than flux the ash of the coke. When there is it is not customary to add silica by itself to the charge, but to use a portion of some other commercially available ore with an excess of silica, thereby avoiding the addition of barren material, either acid or basic, to the charge and so killing two birds with one stone.

The red hematites of Alabama and the Minette ores of Lorain and Luxembourg are the two most notable cases of ores of this kind.

The reaction between silica and lime is an exothermic one so that when they are heated to a temperature high enough to permit reaction between them the reaction goes forward more rapidly on account of the heat evolved. At the same time the quantity of heat evolved in this reaction is not comparable with that in many others, being only about 300 B.t.u. per lb. of compound produced as against several thousand in some other reaction. Perhaps for this reason the resulting product differs less in its properties from those of its component substances and acts more like a solution than a chemical compound as compared with those substances which react more violently together.

It is generally believed that the formation temperature of slags is higher than the temperature of fusion so that if lime and silica be heated together they have to be raised to a higher temperature before combining than the resulting slag would require to remelt it.

This is a more or less obvious corollary to the fact that the melting temperatures of the ingredient are higher than that of the compound. It has been found also that the fineness of grinding and the intimacy of contact of the particles have a powerful effect on the temperature of formation which is likewise to be expected for the same cause.

These are facts which are sometimes of capital importance in understanding the operation of the furnace, and we shall have occasion to return to them in discussing that subject.

THE FORMATION OF CYANIDES

This is a subject concerning which not much is known.

The intimate contact of the nitrogen of the blast with the incandescent coke near the tuyeres in an absolutely reducing atmosphere furnishes the condition of high temperature necessary to carry out the highly endothermic reaction between those two elements while there is always present a certain amount of alkali from the ash of the coke with which the cyanogen can unite to form alkaline cyanides, the presence of which around the hearth and bosh has often been noticed.

Several years ago an attempt was made to draw these cyanides from inside of the bosh and turn them to commercial use and while this attempt met some degree of technical success it was not continued and it is safe to say that commercially it was unsuccessful.

It has been suggested that these cyanides played an important part in the final reduction of the ore and it is entirely possible that this is so since cyanogen is a powerful reducing agent and most of the cyanides formed in the hearth must be volatilized and rise through the charge with the gas column until they are either broken up or condensed and carried back by the charge. But so far as I know no critical investigation of this subject has ever been carried on so that little of value is known about it.

Sir Lothian Bell investigated the subject more thoroughly than any one else of whom I have knowledge; his results were published in his "Chemical Phenomena of Iron Smelting," but did not go further than to establish the fact that cyanide occurred in considerable quantities in the hearth and bosh of the furnace.

CALCIUM CARBIDE

All the literature dealing with calcium carbide states that its temperature of formation is so high that this can only be reached in the electric furnace, but in tearing out the hearths of furnaces blown out for repairs and wetting down the material left in them, I have several times noticed the smell of acetylene so plainly that it was unmistakable, and considering that lumps of lime are often found in the hearth under such conditions, when the furnace has been running on a basic slag and that this lime must have come down in contact with incandescent coke at a very high temperature, it does not seem unlikely that a certain amount of calcium carbide should form. It is impossible to say to what extent this reaction takes place, but it has a certain interest in view of the calcium carbide theory of steel purification in the electric furnace, which is receiving quite general acceptance, and as showing that reactions which are commonly stated to take place only at the temperature of the electric arc, do really occur in a limited way at lower temperatures when the conditions are favorable, furnishing a further illustration of the general law of varying equilibrium between contending forces depending on the conditions of temperature, chemical concentration, etc.

There are probably many, if not many hundreds of other reactions, which go on in the hearth under the condition of extremely high temperatures and intensely reducing atmosphere which prevail there, but the above are the principal ones necessary to an understanding of the action of the blast furnace.

The Hollinger mill, Porcupine, Canada, is now treating Acme ore, twenty stamps being in operation. The other half of the new 40-stamp unit should now be in operation. When the entire capacity is being utilized, about 900 tons of Hollinger ore and 500 tons of Acme ore will be handled daily.

Synopsis of Recent Chemical and Metallurgical Literature

Chemical Engineering

Sulphate of Ammonia Production in 1914.—From a bulletin issued by the American Coal Products Company we learn that European statistics for 1914 are available only to a limited extent. The estimate of the world's output may be hazarded at 1,300,000 to 1,350,000 metric tons, as against 1,409,000 in 1913.

As regards the prospects for 1915 it is quite probable that an increase may result from the demand for explosives. For this benzol, toluol and ammonia are required and by-product recovery has been stimulated.

"The by-product coke oven still continues to be the main source of ammonia recovery, and the one that promises the most extension in the immediate future, coal gas works standing next in total output, though much greater in number and more widely distributed geographically. The by-product recovery gas producer, the shale oil distillation process, and the English blast furnaces using splint coal, are also responsible for a certain amount annually. Some is also obtained from the carbonization of bones, and from peat, there being two Italian plants reported as operating on this material.

"The methods by which atmospheric nitrogen is transformed into ammonia, viz., the synthetic process of Haber and La Rossignol, and the manufacture of calcium cyanamid, afterwards treated to liberate ammonia, appear to have been extensively pursued in Germany, because of the needs of war and agriculture. So far the Haber process has not been introduced elsewhere, but the production of ammonia from cyanamid has been carried on in Germany and Italy and to a limited extent elsewhere.

"It is both interesting and significant to note in this connection that a bill has recently been introduced in the German Federal Council to create a nitrogen monopoly in Germany extending to 1922.

"Commercially the season of 1914-15 was one of hope deferred rather than of fulfillment. The unfavorable prospects at the close of 1913 were adequately realized in a market that sagged continually throughout the first half of 1914. The outbreak of war, coming in the quiet season, did not change matters very much either way. The embargo placed on sulphate of ammonia exports by the German government in September, which might have operated favorably on English prices, was in effect neutralized by the unfavorable cotton situation in the United States and the increased risk and cost of ocean transport. Toward the close of 1914 more favorable conditions began to prevail and prices began to have an upward tendency. The monthly English quotations, however, have averaged from 25 to 50 shillings below those of the previous year, and the average for the year is 40 shillings lower."

The production of England was 426,413 gross tons, about 6200 tons less than 1913. The cause of the reduction is the war, the gas works having lost the most heavily. The consumption was 106,000 tons and exports 313,877 tons or nearly 12,000 tons less than 1913. There are no figures on German production, but so far as can be judged by trade conditions, there was an increase during the first half of the year. The total sales for home use by the Deutsche Ammoniak-Verkaufs-Vereinigung was 321,404 tons. Exports for the year were 75,868 metric tons and imports 34,628 metric tons. In the United States 183,000 net tons of sulphate were produced, being 12,000 tons less than 1913. This reduction came mostly in the last half of the year and was due to the influence of the war on the iron and

steel trade. The consumption was 272,000 tons as against 262,000 tons in 1913, showing an increase even though production decreased. The possible yearly recovery from coal now carbonized is 700,000 tons, showing that there is an enormous production available from coke, provided that it was all made in by-product ovens.

The Coking of Coal at Low Temperatures is the title of Bulletin No. 79 of the University of Illinois Engineering Experiment Station, the authors being S. W. PARR and H. L. OLIN. (Price, twenty-five cents.) This bulletin describes experiments which were a continuation of the work described in Bulletin 60, the later experiments being conducted on a larger scale. The object of the experiments was to test the coking properties of coals from different sections in Illinois, at temperatures between 400 and 500 deg. C., and to test the resulting by-products. The apparatus used in the coking experiments is shown in Fig. 1 in which *A* is a boiler-plate

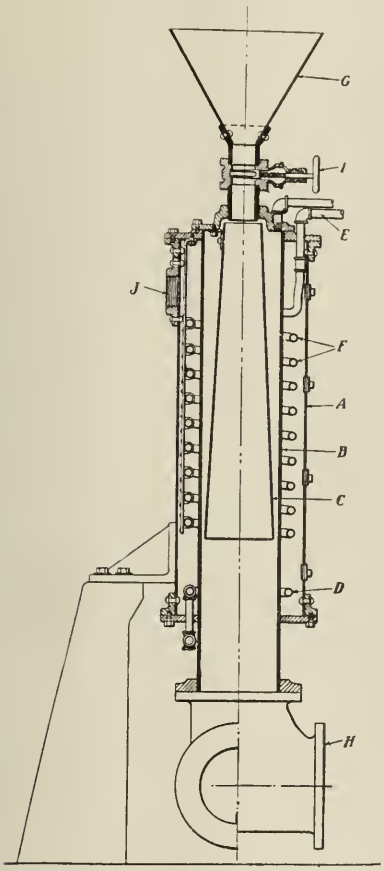

FIG. 1—CROSS-SECTION OF APPARATUS FOR LOW TEMPERATURE COAL DISTILLATION

shell lined with asbestos, *B* is another shell which forms the coking chamber and contains the light sheet iron cone *C* which is perforated. In order to obtain a non-oxidizing atmosphere steam was admitted at *E*. The non-oxidizing atmosphere was found to give better coking results as explained in Bulletin No. 60. The heat was supplied at burner *D* from gas and air mains, and the charge of crushed coal was fed into *G*. The coked residue was removed through *H*, and gases of combustion escaped through *J*. The distillates were conducted to a condenser, and the tars were passed through a water-sealed exit at the bottom.

It was found that better cokes were produced in some cases where fine coke dust was added to the charge, sometimes as much as 100 per cent being required. The coke from one of the experiments was tested in an Otto gas producer and the gas was found to contain negligible quantities of tar and would therefore be useful in internal combustion engines. The efficiencies of the producer compared favorably with those when using anthracite for which the producer was ordinarily used. Heavy hydro-carbons were removed to such an extent that the coke was found to be adapted to household use; being clean in handling and burning. On account of the low temperature the coke had from 18 to 22 per cent of volatile matter remaining, but since it was heated above 400 deg. no tar constituents should remain. This was confirmed by the gas producer tests.

The tar products were next examined and the following results were noted: Average specific gravity 1.069, 18 per cent low-boiling distillate passing over at 210 deg. pitch residue 30 per cent and free from precipitated carbon, high percentage of tar acids making the tar adaptable to wood preservation. Ten per cent of the crude tar was low-boiling distillate free from tar acids and available for use in internal combustion engines. Napthalene was absent and the free carbon in the crude tar was less than 2 per cent.

These experiments were not intended to devise a commercial apparatus but merely to point out in what direction work might be carried on to make a commercial process. The main point brought out in regard to the tar is that low temperatures tend to decrease the amount of comparatively valueless products such as naphthalene and heavy pitch and to increase the production of the lighted and more valuable hydro-carbons.

The Chemical Industries of Austria-Hungary and the War.—In *Chemiker-Zeitung*, July 7, 1915. ED. DONATH and G. ULRICH give an outline of the chemical industries in Austria-Hungary and the war's effect on them. The chief influence hindering normal production has been the inability to carry on commerce, and the lack of raw materials. The labor shortage has also had its effect. The coal industry was severely hampered at the beginning of the war partly from lack of labor and partly from want of means of transportation. It has improved, however, and is now operating at about three-fourths capacity. Inquiries for coal are numerous, but inquiries for coke are very small. There is, however, a big demand for coke by-products and Austria is making big demands on Prussian-Silesian coke production. Germany and Austria are rich in coal lands, Germany in bituminous coal and Austria in lignite, having shipped 7,000,000 tons to Germany in 1913, in which year Austria imported from Germany 12,152,500 tons coal and 1,051,670 tons of coke.

The production of oxygen has decreased since the beginning of the war. In normal times, there are six companies in Austria producing 6 to 7,000,000 cu. meters per year. For sulphuric acid manufacture Austria-Hungary has a plentiful supply of raw material, especially in the rich copper minerals in upper Hungary. Plentiful quantities of salt are available from Galicia and the Austrian Alps. The alkali industries can scarcely fill the needs for alkali salts. In general it can be said that the inorganic chemical industry has improved since its setback at the beginning of the war and new foundations are being established.

In the important fertilizer industry, the suppression of imports of Chile saltpetre must in time exhaust the supply on hand. The production of ammonium sulphate, the most powerful nitrogen fertilizer, is below other years, because the smelting furnaces which use coke are not running to full capacity. The necessity of keeping up a good production of coke for nitrogen by-products has been impressed upon the people by several authors and the Austrian Chemical Society has formed a committee consisting of representatives of different

industries to take up this question. In Norway calcium nitrate, nitric acid, sodium nitrate and ammonium nitrate are made by the Birkeland-Eyde and Schönherr furnaces and ammonia is made in Arendal by the Serpek process.

The great glass and glassware industry has decreased its output through lack of coal and means of transportation. Raw materials for the clay industries are plentiful. The cement industry has been very much affected, there being used in August and September, 1914, only about 40 per cent of the normal demand. The brick industry and steel and rolling mills were also hard hit.

In 1913 the Austro-Hungarian iron and steel industry was producing considerably under normal capacity; this is an international condition, which the Balkan War helped to create. Lately an improvement has taken place in this and the non-ferrous industry, since imports of metals were stopped, and consequently a larger production of copper, lead, zinc, etc., became necessary. There are many mines in Austria which are rich enough to keep up the normal requirements.

Iron and Steel

Electrical Steel by the Acid Process.—In an article on this subject in *Stahl and Eisen*, 1914, No. 3 Albert Müller discusses experiments on the production of acid-electric steel, and shows the advantages and disadvantages of the process as compared with the basic method. A three-ton Girod furnace was used with a hearth made of the following mixture: 80 per cent silica brick, 6 per cent fireproof clay, and 14 per cent tar as a binder. The walls were made of silica brick. The extent to which the lining is attacked in an acid and basic furnace is shown in the analyses given in Table I.

Table I—Composition of Acid and Basic Furnace Materials

	Electric Furnace Hearth—Before Melting		Electric Furnace Hearth—After 27 Heats,	Acid Furnace Walls	
Component	Basic, Per Cent	Acid, Per Cent	Acid, Per Cent	Before Melting, Per Cent	After 27 Heats, Per Cent
SiO_2	5,72	80,50	64,60	95,30	83,50
Ca O	46,50	4,30	12,90	1,85	3,55
Mg O	27,60	1,91	2,90	Spur	0,65
Al_2O_3	1,46	3,08	2,65	0,58	0,97
Fe_2O_3	1,85	0,38	0,43	0,57	4,50
Fe O	0,99	1,16	1,93	0,26	3,65
Mn O	0,40	0,27	12,05	0,19	2,36
P_2O_5	0,09	0,02	0,02	0,08	0,08
C	8,60	7,75	1,20	....	....
Ignition loss	14,35	7,80	....	....	....

Table I gives a comparison of the composition of hearth and walls of basic and acid furnaces, before and after melting, and shows clearly the change in silica content due to the charge and also the change in metallic oxides. It will be noticed that the carbon content of the hearth is reduced from 7.75 to 1.20 per cent in the acid furnace. In the basic furnace the carbon does not react with the charge. In the acid furnace, however, it plays an important part in the reduction of silica. In some cases this reduction is too great in the first melt. The reduction of silica by which the silicon content of the metal bath is increased in an acid furnace may be divided into four phases.

1. Reduction from charge, hearth, and walls at normal temperature and conditions. In this case it is mostly reduced from the hearth and walls.

2. Reduction by raising silica content of the slag by introducing sand.

3. Reduction by raising the temperature of the slag. This is accomplished by arcing.

4. Reduction by carbon, according to the formula $2C + SiO_2 = Si + 2CO$.

All of these reactions are more energetic as the temperature of the slag and steel bath is raised. The silica reduction is much stronger in a newly lined furnace. The large amount of silicon withdrawn from the lining and slag makes it unecessary to add ferrosilicon for the deoxidation. This silicon in the metal bath is a better deoxidizer than ferrosilicon which must be mechanically mixed with the metal bath. Manganese silicate in the slag is reduced to a minimum in the acid electric process.

The sulphur content during the process varies considerably but at the end of the charge is as low as the original sulphur content of the charge. In the oxidation period considerable of the sulphur reacts as follows: $FeS + 2FeO = 3Fe + SO_2$, the SO_2 escaping as in the puddling furnace. Some sulphur is added during the introduction of metallic constituents and coke.

In the basic process the iron sulphide is broken up as follows: $3FeS + 2CaO = 3Fe + 3CaS + 2CO$. Phosphorus in the basic furnace is carried into the slag as calcium phosphate, which is not possible in the acid furnace.

Special care is necessary for conducting an acid slagging process, and on account of the difficulty of melting silica a certain basicity of the slag must be maintained. During the early slagging the oxygen in the base to that in the acid should be 1:2. Later in the deoxidizing slag the ratio may be 1:4, but such a highly acid slag is very often undesirable on account of the high temperature required. The basicity may be raised by lime or magnesia. The lime content should be about 15 per cent as a 20 per cent lime slag attacks the lining. Magnesia is usually between 2 and 5 per cent in a good slag. Ferromanganese also raises the basicity of the slag, but if the MnO in the slag is too high (more than 15 per cent) it can be reduced by coke. The MnO content in an acid slag is usually ten times that in a basic. The acidity of an acid slag is 55-60 per cent SiO_2 for good melting and the oxygen in the base to that in the acid should be 1:3.

Good steel can be made in the acid electric furnace without special precautions, but the process is not easy and a good metallurgical knowledge is requisite. The following points are noted in comparing the acid with the basic electric steel process. For the acid process:

1. Less current demanded because of shorter melting period. The desulphurizing and oxydation practically occur together, and no dephosphorizing takes place.

2. Saving in material for deoxidation. All silicon coming from slag and lining.

3. Lower lining, maintenance and repair costs.

4. Lower cost for slag.

The acid electric furnace is applicable, when a material low in S and P is available, and the process produces a good middle quality steel. However, on account of the powerful reaction of the lining it is only available in certain cases.

Buying and Selling of Ores and Metals

The Buying and Selling of Ores and Metallurgical Products is the title of Technical Paper 83, just issued by the Bureau of Mines. Charles H. Fulton, the author, says: The buying and selling of ores and metallurgical products is a great and highly important business in the United States, and one that concerns not only the miner and the metallurgist but the industrial world in general. In this paper the attempt is made to outline clearly its underlying principles, the subject matter being based on personal experience and investigation. The author has endeavored to present the material impartially, and for that

reason many of the statements and figures regarding metallurgical practice should be taken as illustrative rather than as applying exactly to average operating conditions.

In estimating the value of an ore or an intermediate metallurgical product (other than a refined metal) the basis used is the price of the refined metal at some principal market center, such as New York, at the time the valuation is made. The average price of all copper for 1913 was 15.5 per pound, and for electrolytic copper 15.269 cents per pound. The prices for other metals for the year 1914 were as follows:

Lead, 3.862 cents per pound; spelter, 5.213 cents per pound; silver, 54.811 cents per troy ounce. Gold has the standard value, established by law, of $20.67 per troy ounce.

If the metal contents, in pounds for the base metals and in troy ounces for the precious metals, per avoirdupois ton be multiplied by the prevailing price of the refined metals, the sum of the products will be the gross value of the ore.

There is, however, a wide difference between the gross and the net value of a ton of ore. From the gross value must be deducted, first, the total cost of mining the ore, and then the total cost or charge for treatment, which includes some or all of the following items: Freight to treatment plant, milling or smelting charge, charge to compensate for losses of metal in treatment, charge for penalties imposed on undesirable constituents in the ore, charge for freight to refining center, charge for refining the metal, charge to cover the selling costs of the refined metal. Which of these charges are imposed and what the amount of each charge depends on the ore, the method of treatment, and the number of firms that handle the ore and metals in the process from ore to refined metal.

The types of companies that handle ores and metallurgical products may be classified as follows:

1. Mining and smelting companies or mining and milling companies, which control all the operations from the mining of the ore to the production and selling of the finished metal.

2. Mining companies, which mine and sell ore on certain schedules to smelting or milling companies.

3. Custom smelters or mills which purchase ores and also operate refineries and produce refined metals or sell intermediate metallurgical products to refineries.

Concerns of type 3 may control mines that furnish a part of their ore supply.

4. Refining companies, which purchase metallurgical products, such as matte, and crude metals, and some ores, and produce refined metals.

5. Selling agencies, which place the refined metals on the market.

It is apparent that an ore or the products derived from it may go through many hands before the finished metal reaches the market, and that metallurgical business may be complex. In this report the essentials of the commercial side of metallurgical work are discussed in some detail.

Morgan Producer Gas Machine and Dyblie Reversing Valves is the title of a catalog recently issued by the Morgan Construction Company of Worcester, Mass. This producer was described in this journal, June, 1915. The Dyblie reversing valves are described and numerous illustrations given of their operation in the catalog. A table is given showing the sizes of reversing valves for open-hearth furnaces. The frontispiece of the catalog is a striking etching of The Edgar Thomson Steel Works by the well-known artist, Mr. Joseph Pennell.

Recent Chemical and Metallurgical Patents

Iron and Steel

Titanium Alloys.—Alloys higher in titanium content than usual are patented by Dr. HANS GOLDSCHMIDT and Dr. OTTO WEIL of Germany and assigned to the Goldschmidt Thermit Co. The purpose of these alloys is to provide a means of adding a higher percentage of titanium to iron and steel baths, overcoming the objections previously maintained. The alloys consist of 15-35 per cent titanium, 1.5-3.5 per cent aluminium, and the balance iron. The aluminium lowers the melting point of the titanium and the alloying qualification is increased and the alloys are free from carbon. The alloy containing 24 per cent titanium and 3 per cent aluminium has been found very useful. (1,136,670, Apr. 20, 1915.)

Electrolytic Processes

Hydrogen Peroxides.—Apparatus for producing hydrogen peroxide is patented by Dr. WALTER WEBER and assigned to Henkel & Co., of Düsseldorf, Germany. It is an improvement over previous apparatus patented Sept. 30, 1913 (1,074,549). The previous apparatus did not permit of a higher concentration than 3 per cent and it was impossible to cool the anodes. The improved apparatus overcomes these disadvantages. Fig. 1 shows the essential features. A is a tube of suitable metal coated on the inside with a thin layer of copper amalgam or silver amalgam cathode. It is closed at both ends by screw caps B-B′, a rod shaped anode C is covered by a tubular diaphragm K. The electrolyte, sulphuric acid, is introduced through D into the tube A, and leaves through outlet E. Oxygen under 100 atmospheres pressure is passed in through F, and rises in the liquid. After electrolyzing with a current density of 5 amperes per sq. cm. at 2 volts, the peroxide solution and oxygen passes through G to another cell of the same type, and so on until the desired concentration is reached. (1,144,271, June 22, 1915,and 1,138,519, and 1,138,520, May 4, 1915.)

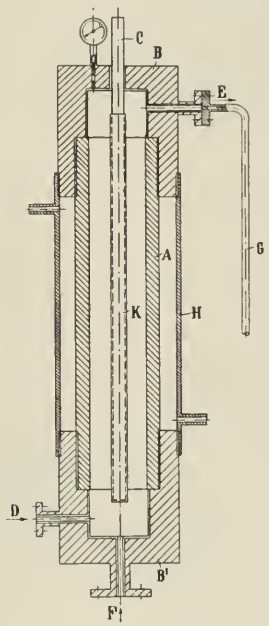

FIG. 1—HYDROGEN PEROXIDE CELL

Potassium Chlorate.—A process of making potassium chlorate by electrolysis is patented by WALTER LAIB of Rittman, Ohio, and assigned to The Ohio Salt Co. In this process a nearly saturated solution of potassium chloride (with a small quantity of chromate) is electrolyzed at a temperature of 35 deg. C. in a cell with carbon or graphite anodes and iron cathodes. This solution is then conducted to a second cell where it is heated by the current up to 70 deg. C. using a platinum anode and iron cathode. In this cell the concentration of chlorate is materially increased and any hypochlorite is converted into chlorate. The solution is then led to a crystallizing vat. The advantages claimed for the process are a saving in cost of anodes over the use of platinum anodes alone and the elimination of hypochlorites. (1,143,586, June 15, 1915.)

Manganese Peroxide Anodes.—A patent issued to Mr. PERCY C. C. ISHERWOOD of England, discloses a process for manufacturing anodes from manganese dioxide ore after treatment for the removal of such

impurities as iron, nickel, or cobalt. The ore is first ground into a finely divided condition, leached with sulphuric or nitric acid, then mixed to a paste with a quantity of manganese nitrate solution and heated. This drives off the oxides of nitrogen and the mass becomes agglomerated. Repeated treatment reduces the porosity of the product. These manganese peroxide anodes are used in copper, zinc or nickel salt solutions as insoluble anodes, and it is claimed that no impurities pass into the electrolyte. (1,143,828, June 22, 1915.)

Fixation of Atmospheric Nitrogen

Oxides of Nitrogen from Air.—A novel apparatus for utilizing the heat of the arc in making oxides of nitrogen from air is disclosed in a patent of Mr. Francis I. du Pont of Wilmington, Del. In the latest form, the apparatus consists of what might be termed a six-cylinder engine, in which air is drawn in through a valve, compressed and then heated by an arc. This causes the air to expand and forces the piston down or up as it may be; at the same time oxides of nitrogen are formed which are discharged together with the expanded air through a discharge valve. Several automatic adjustments are necessary, viz.: valve action, and the top electrode in the cylinder must be made to move down and touch the bottom electrode just at the beginning of expansion. As the top electrode is moved up, an arc is formed and this arc continues for two-thirds of the stroke of the moving electrode or one-third of a revolution of the crank shaft. The six-cylinder arrangement thus permits of a continuous consumption of current in that each cylinder uses the current for one-third of every other revolution. The cylinder is made in the form of a tube of insulating material; glass or silica, to prevent arcing on the sides of same, thus insuring that the air will be heated to the desired temperature. At the temperature of the arc the nitrogen oxide is formed and the cooling of the air due to expansion prevents to a large extent the redecomposition of the oxides of nitrogen formed. A good working current is given as 2 to 10 amperes at 3500 to 5000 volts. The oxides with the air are discharged into a conduit which leads to the apparatus in which they are to be used. The novel characteristic features of the invention are summed up as follows: "In the first place the electric arc is maintained during expansions, whereby heating, expansion and conversion of the heat into mechanical energy proceed simultaneously, whereby all the heat (except that which is carried off by the gases when expanded to atmospheric pressure and that which, due to the imperfection of mechanical devices, is unavoidably lost) is converted into mechanical energy. In other words, drawing out the arc during expansion, continually generates new heat, which is simultaneously converted into mechanical energy, and after the arc breaks and the generation of heat ceases, the gases continue to expand and convert heat into mechanical energy." (1,147,150, July 20, 1915.)

Carbonitrides.—A process for manufacturing carbonitrides is patented by Mr. Samuel Peacock of Chicago and assigned to the du Pont de Nemours Powder Co. The essential feature of this patent is the fixation of nitrogen by a metallic oxide and carbon, forming a compound which approximates the formula $Ca_3N_2C_3N_4$ in the case of calcium, and similar formulas in the case of other oxides such as silicon or aluminium. The manner of carrying out this operation is shown in Fig. 2 in which 1 represents a feeder for the charge which goes into the conically shaped revolving furnace. It consists of finely divided dry calcium oxide and finely divided dry coke or charcoal, in the ratio of 56 parts by weight of the former to 24 parts of the latter. An excess of carbon sometimes as high as 25 or 30 per cent is used, since it prevents the formation of calcium nitrides. Five and 6 are resistors for heating to 1500 deg. C. the charge which is gradually worked toward the discharge end by the revolving of the furnace. Twenty-four is a suction pump to withdraw air and gases formed in the reaction. The air is removed from the furnace before starting the operations and nitrogen is introduced in sufficient quantity. The resulting product is calcium carbonitride $Ca_3C_3N_6$. In boiling water or acids it is decomposed into ammonia and carbonates or into ammonium and metal salts of the acid used. (1,137,524, Apr. 27, 1915.)

Electric Furnaces

Calcium Carbide.—Improvements in the manufacture of calcium carbide are described in a patent of Mr. Frederick M. Becket of Niagara Falls, assigned

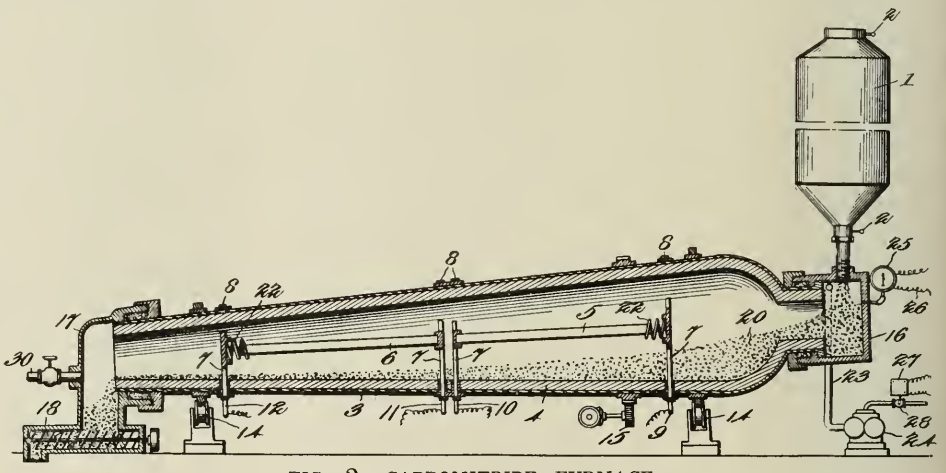

FIG. 2—CARBONITRIDE FURNACE

to the Union Carbide Co. In this process the lime and coal are agglomerated in a by-product coke oven by a coking operation. This is to take the place of briquetting or molding operations and is claimed to be much more economical. In briquetting processes the lime is usually mixed with coke, charcoal or anthracite together with a suitable binder usually a hydrocarbon or carbohydrate. The briquets are formed under high pressure, and baked, if necessary, previous to smelting in the electric furnace.

In the present process calcined limestone is mixed directly with a definite amount of bituminous coal rich in volatile matter. This mixture is then subjected to a coking operation in a by-product coke oven. Grades of coal containing 30 to 36 per cent of volatile hydrocarbons have been used successfully. A coal from the Youghiogheny district in Pennsylvania having the following analysis:

Volatile matter	35.84 per cent
Fixed carbon	53.77 per cent
Ash	10.39 per cent
Total	100.00 per cent
Moisture as received	1.60 per cent

was mixed with freshly burned lime in the propor-

tion of 110 parts of coal to 100 parts of lime, and the mixture was coked in by-product coke ovens of the regular type, the gas, tar, and ammonia being collected as in the usual coking process. The evolved gas was burned for the coking and proved to be sufficient for this purpose. After coking, the resulting mass is crushed to lumps, which may be about the size of the fist, and these lumps then conveyed hot, to the electric furnace. These aggregates are mechanically strong and will endure considerable weathering.

It is necessary to adjust the proportions of lime and coal so that the carbon remaining after the coking operation is practically that required for the reaction.

$$CaO + 3C = CaC_2 + CO,$$

which requires a proportion of fixed carbon equal to about 64 per cent of the lime used. It is this high proportion of fixed carbon required which renders it practicable to supply with the fixed carbon in the coal, a sufficient quantity of bituminous matter to form the strong aggregates. The resulting mixture has been found to have a higher resistance than the ordinary mixtures of lump lime and lump coke, and gives higher yields with less wear on the electrodes. (1,137,567, April 27, 1915.)

A New Multiple-Type Recording Instrument for Pyrometers

The instrument shown in the adjoining illustration has been put upon the American market by Mr. Charles Engelhard, 30 Church Street, New York, in connection with his Heraeus Le Chatelier pyrometer. It is manufactured by Messrs. Siemens & Halske, A. G., Berlin, and conforms in every respect to the high grade instruments for which they are recognized.

The moving system is similar to other types of their instruments, having a double pivoted movement of the D'Arsonval type. The weight of the moving system is extremely small, making it absolutely dead-beat. The ratio between the resistance of the moving coil and the series resistance is so very small that the temperature coefficient is far below that of even a low-resistance instrument. The total resistance of the instrument ranges between 300 and 400 ohms.

Besides being provided with a recording movement, it has also a direct indicating scale, and annunciator, showing the thermo-couple connected at any particular time so that observations may be taken from the instrument as readily as from a direct indicator. The record is formed on a maximum of six thermo-couples, all upon the same chart which is of the continuous roll type, and each record distinguished from every other by being printed in a different symbol. This makes it impossible to confuse the individual records, even though they intermingle or cross at very small angles, and makes it possible to allow the full width of the chart for each record.

But a single galvanometer is employed, the six records being made possible by inserting in the circuit an automatic, mercury contact, switch. This switch is enclosed in the case of the instrument, and forms a part thereof.

The change from one symbol to the next, in accordance with the rotation of the switch, is accomplished by using a roller, situated beneath the chart with six edges, each edge engraved with a different symbol. Over this roller and beneath the chart, slowly moves an inked ribbon. The galvanometer needle, which has a flat surface on its underside, is intermittently depressed every twenty seconds, pressing against the chart, which in turn is pressed against the inked ribbon and engraved edge beneath, so that the symbol on the edge of the roller is printed on the reverse side of the semitransparent chart.

Besides accomplishing absolute distinction between individual records, this method allows the galvanometer needle to swing entirely free between each depression, eliminating all error due to friction. The method further eliminates the necessity of renewing inks or other recording medium.

MULTIPLE RECORDER FOR PYROMETERS

Five hours of record can be observed at all times, as the chart passes down over the face of the instrument. It is then automatically rewound upon a spool in its original form.

The endeavor has been to make this instrument foolproof and thoroughly automatic in every sense. It takes the place of six individual recorders, is compact, extremely accurate, has the advantage of high resistance, and is not affected by vibrations.

Determination of Critical Points in Iron, Steel and Alloys

The Scientific Materials Co. of Pittsburgh, has developed and placed on the market a complete apparatus for the accurate determination of critical points in iron, steel and non-ferrous alloys. A view of the complete outfit is shown in Fig. 1 (p. 644).

The importance to the industries of accurate data on transformation points cannot be underestimated, as the whole field of heat treatment depends upon these phenomena. The Scimatco method is an adaptation of the most sensitive and accurate method which has been devised for detecting and measuring small thermal changes in solid bodies. It is based upon automatic comparison of the temperature, during heating and cooling, of the metal test specimen with that of another "neutral" body, which has no transformation points of its own (at least not within the temperature ranges studied). Both are heated and cooled together in one vertical heating chamber under absolutely uniform conditions.

A convenient manner of introducing the thermocouples into the test piece and neutral body which insures the rapid action of the heat and eliminates scale formation (oxidation) is provided. The critical points are read directly on a specially designed duplex instrument and a special chronograph is provided from the records of which all kinds of curves may be plotted.

In Fig. 2 the general arrangement of heating chamber and bodies is shown, W is a coil of resistance wire underneath a metallic plate T, which serves as a tem-

perature equalizer. The test specimen with holes drilled for thermo-elements is shown at S and the neutral body at N. The holes T_1 and T_3 should be at the same distance from the furnace walls.

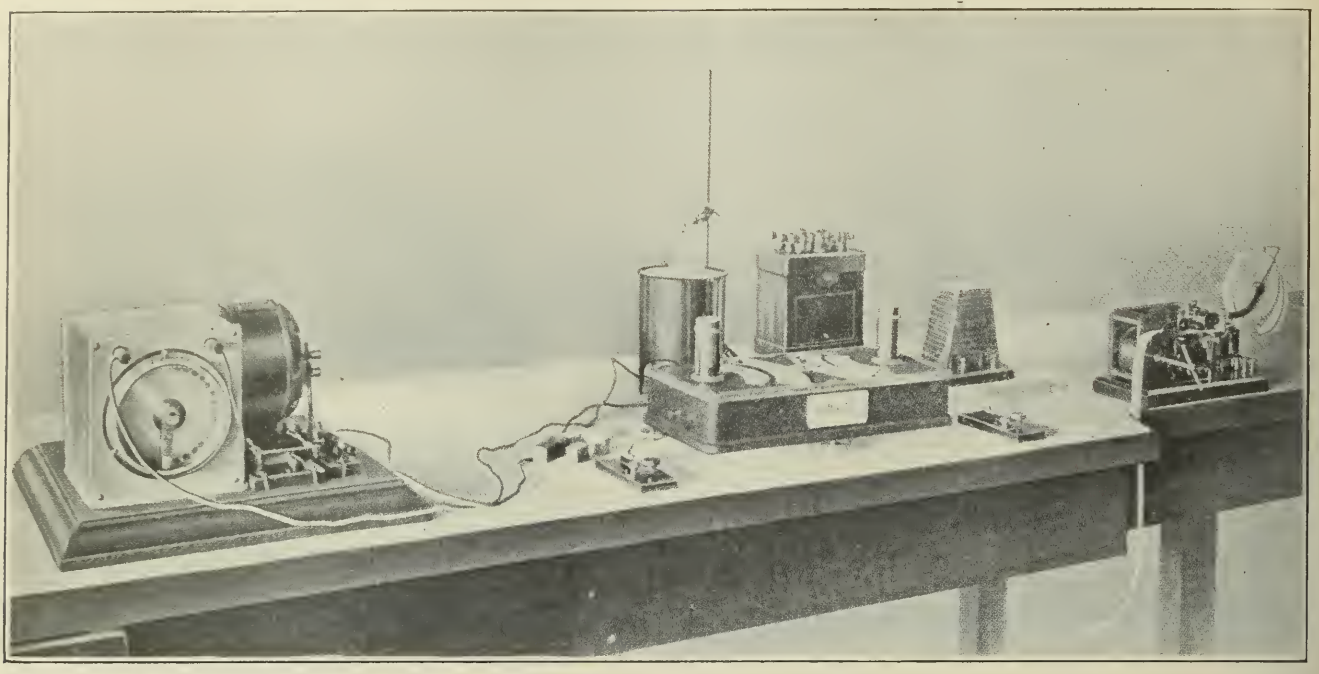

FIG. 1—COMPLETE SCIMATCO OUTFIT FOR THE ACCURATE AND CONVENIENT DETERMINATION OF TRANSFORMATION POINTS

Two platinum, platinum-rhodium thermo-couples are used, one to indicate the actual temperature of S and the other to indicate any difference in temperature between S and M. These thermo-elements are mounted in special insulating tubes and placed in the drilled holes, as shown in Fig. 3. Scale formation is prevented in this manner.

The duplex galvanometer has one scale for indicating the temperature of the test piece and another scale for indicating differences in temperature of the neutral and test pieces. In case it is desired to take the factor of time into account the special three-pen chronograph and automatic contact clock are provided. These record mens and speed of heating and cooling and duration of critical ranges. From these records any kind of curve may be plotted.

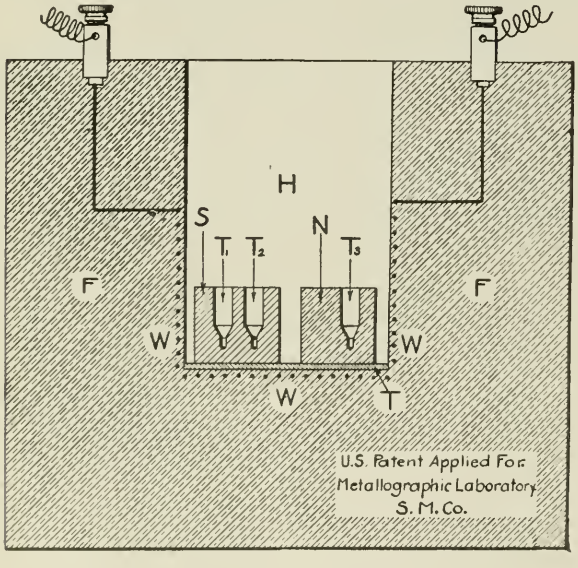

FIG. 2—VIEW OF VERTICAL HEATING CHAMBER WITH TEMPERATURE EQUALIZER AND BODIES

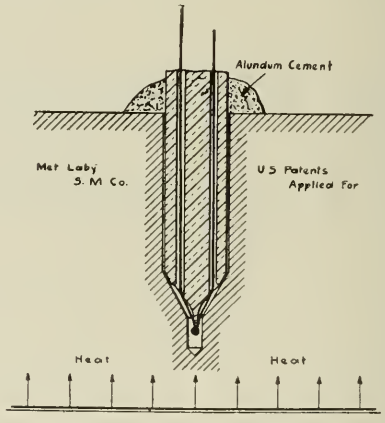

FIG. 3—POSITION OF THERMO-JOINT AND MOUNTING IN THE STEEL BODY

An automatic rheostat for even heating and cooling completes the apparatus, all of which may be seen in Fig. 1.

A metallic alloy suitable for use as packing rings on locomotives using superheated steam is the subject of a patent by G. C. Holder, of Altoona, Pa. The alloy consists of nickel, 3 to 9 per cent; copper, 20 to 30 per cent and lead, 61 to 77 per cent. The hardness of the alloy can be changed by varying the copper content. The composition is comparatively strong and elastic.

The Bausch and Lomb Optical Co. of Rochester, N. Y., has issued a catalog of Optical Instruments for Inspection and Testing of Materials. This catalog describes microscopes for the examination of ores, metals, rocks, concrete, wood, leather, fabrics, paints, varnishes, oils, dyes, inks, drugs, chemicals and foodstuffs. Metallographical apparatus is also included.

Titan Bronze

Through the picturesque Bald Eagle Valley, in Centre County, Pa., runs the Spring Creek. On its banks, in a spot perhaps two miles from the county seat, Bellefonte, there was established, in 1797, the Milesburg Iron Works. Hard by lies the little village of Milesburg, laid out and developed simultaneously with the iron works.

FIG. 1—ROLLING MILL DEPARTMENT OF TITAN METAL CO., BELLEFONTE, PA.

In common they derived their name from their founder, Col. Samuel Miles. During the half century following, the business changed hands six times until in 1849 J. M. McCoy, J. H. Linn and Moses Thompson joined a former part owner, James Irving, in forming the firm of Irving, McCoy & Co. In 1860 Irving withdrew and from that day to this the business has been operated under the name of McCoy, Linn & Co. It is now part of the McCoy estates and is actively managed by Mr. John McCoy.

When the charcoal iron industry was at its height there were operated at Milesburg a blast furnace, charcoal forge, puddling mill, rolling mill and wire mill. Except for the blast furnace the plant lay idle for considerably over a decade until April, 1915. But despite reports to the effect that no iron is now produced in Centre County, McCoy, Linn & Co. have never ceased to operate what is now one of the very few remaining cold-blast, charcoal iron furnaces now active in this section of the State.

After lying thus idle during these many years, title to part of the McCoy property was taken over by the Titan Metal Co. of Bellefonte, Pa., in April of this year. This company is incorporated under the laws of the State of Pennsylvania and is being financed by the business men of Bellefonte. Its officers are C. E. Wagner, president; John Walker, vice-president; W. P. Sieg, secretary and general manager, and F. E. Naginey, treasurer.

The chief product of this company—titan bronze—bids fair to revolutionize certain lines of industry lying within its field.

Titan bronze has been perfected after a number of years of research and experimental work on an elaborate scale. It has high tensile strength and is forgeable. For drop forging it is superior to any similar metal on the market. One of its peculiarly valuable properties is that it can easily be worked hot to a finished form with high tensile strength, and in press work without injuring the dies.

It is supplied in bars, cold rolled and cold drawn, having a tensile strength of 110,000 lb.; in hot-rolled bars and in hot or cold-rolled sheets for hot or cold forming; in castings and recasting ingots. In the very near future the metal world is promised further valuable developments in the form of bronze-covered sheets and bronze wire.

Titan bronze, because of its extremely plastic nature at working temperature, is especially well adapted for

FIG. 2—DROP FORGING OF TITAN BRONZE. LARGE DIAMETER ROD USED TO SHOW SPREAD OF METAL IN FLASH

drop forgings, gears and pinions, hot press work, roller bearings, balls, valve seats, pump rods, etc.

An ordinary hot-rolled bar of titan bronze will show the following properties: tensile strength, 80,000 lb.; elastic limit, 45,000 lb.; elongation, 25 per cent; reduction of area, 45 per cent.

A tremendous amount of work has been done since the new company took title to the old plant. The substance of a modern fire-proof structure, unsurpassed by

any works of the size in the country, has risen from the skeleton of the old plant. The rolling mill is equipped to handle non-ferrous metals of every description and an inspection of the foundry, stamping mill, casting, drop forge and machine shops affords conclusive evidence that the new concern is well equipped to handle its product in every conceivable form.

Hydraulic Hardness Testing Machine

A new hardness testing machine has been developed and placed on the market by Messrs. Eimer and Amend of New York. This machine works on the well-known Brinell principle of making indentations in the metal and measuring the width of same. It is represented in Fig. 1.

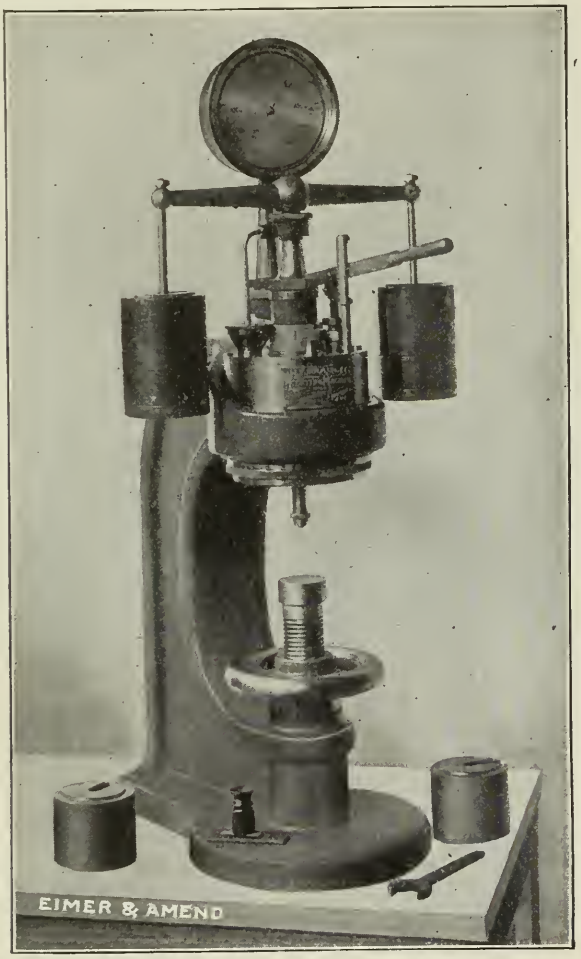

FIG. 1—HYDRAULIC TESTING MACHINE

In order to conform to the demands of most testing laboratories the heavy goose-neck style has been adopted. Controlling weights are provided if desired. By their use wrong readings are entirely excluded; if the manometer should get out of order this device will show the error.

The main parts of the machine are: the hydraulic press, the hand pump, and the pressure gauge with the attachment for the controlling weights. The machine is filled with oil and a pressure of 3000 kilograms (6614 lbs.) is produced by about ten strokes of the hand pump.

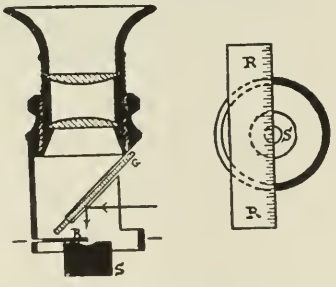

FIG. 2—MICROSCOPE

A special microscope shown in Fig. 2 is provided to read the width of impressions. The reflector G furnishes a strong illumination for the test piece S and with the aid of the small steel rule R fitted in the bottom of the cylinder, the exact diameter can be read to 1/10 of a millimeter.

Personal

Dr. **H. K. Benson** of the University of Washington, Seattle, Wash., is making a trip East and will attend the National Exhibition of Chemical Industries in New York City.

Mr. **William C. Coffin** has severed his connection with the Jones & Laughlin Steel Company, to become vice-president of the Knox Pressed & Welded Steel Company of Pittsburgh, Pa. Mr. Coffin was vice-president of the Riter-Conley Manufacturing Company from 1898 to 1908, and since then has been structural engineer of the Jones & Laughlin Steel Company. Mr. Coffin's new office will also include the duties of general sales manager. With the acquisition of Mr. Coffin the officers of the Knox Pressed & Welded Steel Company now are Luther L. Knox, president; William C. Coffin, vice-president and sales manager; Irvin F. Lehman, secretary and treasurer. The approaching completion of the new Knox plant was the deciding factor that brought Mr. Coffin to this company. The new plant of the Knox Pressed & Welded Steel Company will be given over to riveted and welded steel plate work, while the company's present plant at Farrell, Pa., will be continued in the manufacture of the Knox patented water-cooled devices for open-hearth and heating furnaces.

Dr. **C. H. Herty** of the University of North Carolina, president of the American Chemical Society, was recently in New York and did very effective good work for the National Exhibition of Chemical Industries, of whose advisory committee he is a member.

Mr. **Lewis A. Riley, 2d.**, mechanical and gas engineer, has taken over the agency in the United States and Canada for the Lymn system of by-product gas producers, which has made such rapid strides in Europe during the past five years. The Lymn system is an improvement and development of the Mond system of by-product gas production; it was described in some detail in our July issue, page 456. Mr. Riley has taken offices in the Vanderbilt Concourse Building, 52 Vanderbilt Avenue, New York City.

Book Review

The Mining Manual and Mining Year Book for 1915. By **Walter R. Skinner.** 968 pages. Price 15s. net (Post free in U. S. 17s.). London: Walter R. Skinner.

In this edition of this large annual devoted to data on the mining companies of the world, companies are arranged alphabetically instead of being divided into sections as heretofore. The reference data are very complete and contain besides the statements as to capital, data of registration, etc., an analysis of the last balance sheet, dividends from the start, details of ore reserves, borehole results and description and capacity of treatment plant. The volume contains particulars of 2420 companies and also an index of 2580 additional companies whose field of action has either ceased or is not of public interest. Alphabetical lists of mining directors, secretaries, engineers and mine managers are included as usual and a dictionary of mining terms is added. These features make a very complete work and it should prove of value to any one requiring up-to-date information on mining companies.

What the Chemical Industry Has a Right to Expect from the American Nation

"The only true basis on which the *independence* of our country can rest, are agriculture and manufacture. To the promotion of these nothing tends to a higher degree than *chemistry*." These words were placed as a motto above the exhibit in the American Electrochemical Society booth in the First National Exposition of Chemical Industries in New York City last week. They were taken from Thomas P. Smith's oration before the Chemical Society of Philadelphia on April 11, 1789. They are as fresh and true to-day as they were 117 years ago. But the American nation as a whole is only now beginning to grasp the idea of the intimate relationship between its very independence and chemistry.

The European war brought about suddenly this recognition. The general public then realized for the first time how interwoven the work of the chemist is with the whole industrial life of the country, and because the existing chemical industries could not supply all the country's needs, those who were left in want (because they had never shown any particular appreciation of American chemical industries) combined with American newspapers in an abuse of the American chemist that was as unfair as it was stupid. But the American chemist quietly went his way and did things, many things. Part of this activity will stop when the war stops, as it has to do with war materials. But by far the most of the present activity in the chemical industries will be lasting for the benefit of the whole country, if the American nation is willing that it be so. What is it that the chemical industry has a right to expect from the American nation? Nothing more nor less than a fair attitude of mind of the American nation toward American chemistry: a fair appreciation of its accomplishments and aims, a fair recognition of the fact that chemical brains need capital for realization of their ideas and that capital needs fair protection, not forever, but for a sufficient time to permit the chemical manufacturers to adjust themselves to the changed conditions and new requirements. Whatever was said in the meetings held in connection with the Chemical Exposition by Dr. Baekeland, Mr. Gross, Dr. Herty, Mr. Stone, and others on needed reforms, may be summed up in the single demand for plain fairness. And this augurs well. For the American people may be misled for a while, but ultimately they will always be found fair and right.

A Scarcity of Steel

It is being said in the steel trade that there is a scarcity of steel. It requires some knowledge of steel trade parlance to appreciate the significance of the

statement. The meaning is not that the supply has been curtailed so as to result in a scarcity, nor is it yet that the demand for steel products has outrun the supply. The precise meaning the trade attaches to the expression is that the steel ingot making capacity has been found to be far short of the supply of raw materials for steel making on the one hand, and far short of the rolling and other steel finishing capacity on the other hand.

The steel industry as a whole is busy, but the steel-making departments are the busiest. The steel interests still have a few idle blast furnaces that could be blown in, and there are many merchant furnaces idle. There is an abundance of ore, and coke is so plentiful that Connellsville furnace coke for spot shipment has been selling at one-half the price it commanded the last time the market price of steel billets mounted to the present level. The majority of the steel-finishing departments are not fully employed, and some can hardly be regarded as moderately well employed. Exception must be made of bar and rod mills and of wire-drawing departments, which are under pressure.

The present condition, of there being a scarcity of raw steel, relative to supplies for the steel-making departments, and capacity for converting ingots into merchantable material, is due in part to the abnormal character of a part of the present demand for steel. In the first place, a large tonnage of steel is being produced under stringent specifications as to cropping, whereby the tonnage of steel rolled, in proportion to the tonnage of ingots produced, is reduced. In the second place, there is a heavy demand for forging billets, to be used in the manufacture of large shells, and thus steel is taken that ordinarily would be rolled beyond the billet form.

It is possible that the output of steel ingots from the steel-making facilities in employment is less than it would be were demand of its usual character. The necessity of making much steel of special grade may prolong the time in the case of open-hearth heats and may possibly reduce the tonnage per heat. Not enough is known to justify the making of a generalization.

Expositions and Exhibits

There is nothing more effective to drive home a lesson than a direct appeal to the senses. What no amount of lecturing can accomplish is often easily impressed on the mind through the eye which sees, admires and understands, and it is this combination of the perception of beauty with instruction which makes the success of expositions.

No one who has seen the San Francisco Exposition can have escaped the sorrowful reflection that so much beauty shall soon be gone forever. Yet expositions are essentially ephemeral. They come and go like thieves in the night. A permanent exposition seems an impossibility; it surely is if it is to be self-supporting. While the success of an exposition cannot and should not be measured by dollars and cents, yet the financial success or lack of success is at least one pretty safe indication whether or not an exposition has fulfilled its higher missionary function. To be a financial success an exposition must be limited in time; it should be long enough to be seen by all who should be interested, and short enough to reduce the operating expenses to a minimum. This period of time must be correctly judged and will vary from case to case. To limit the highly successful Chemical Exposition in New York City last week to six days, seems to have been exactly right, although we have heard more than once an expression of regret that the show would be over so soon. And what is true for expositions in limited fields is just as true for "world's fairs."

But what is true for expositions is not necessarily true for the exhibits. An exhibit can be made permanent under normal conditions and should be made permanent, if this is possible. It is true, a fine exhibit can be set up quickly by the right man; Dr. Doremus showed this in arranging single-handed in a few days the really pretty little historical and technical exhibit for the American Electrochemical Society booth at last week's chemical exposition; it is a pity that this exhibit could not be made permanent because it had been obtained by loan from many sources. But most other exhibits can be made up with a view to permanency. It is unthinkable that the wonderfully instructive exhibit of the United States Steel Corporation at San Francisco should not be preserved permanently and used over and over again at different places as an almost inexhaustible source of instruction. What magnificent results can be obtained if an exhibit is built up with a view to permanency and gradually perfected, is shown by the exhibit in the Canadian Building in San Francisco which has elicited and will always elicit so much truly deserved admiration. This is a lesson which the average exhibitor at expositions has still to learn. The fine exhibit of the different government bureaus at the Chemical Exposition had been specially prepared for this occasion, but it could and should be kept together as a nucleus for future extension.

A New Agricultural Use for Sulphuric Acid

Is agriculture about to derive a new benefit from the application of sulphuric acid to alkali soils? And can the smelter foresee a partial outlet for a product, one of the constituents of which has caused him vexation and expense at the hands of the prospective beneficiary? And is chemical research on the eve of demonstrating another instance of the interdependence of widely different industries, through the conversion of a waste product of the one into a substance useful to the other? An affirmative answer to these queries is suggested by the results of two years of investigation by Dr. C. B. Lippman, of the University of California.

At one of the sessions of the recent San Francisco meeting of the American Institute of Mining Engineers, Dr. Lippman explained the nature and results of his investigations, and illustrated by photographs the ap-

parent beneficial results obtained by applications of sulphuric acid to alkali soils. The views showed crops growing on test plots that had received from 2½ to 7½ tons sulphuric acid per acre, the ground being otherwise unfit for agricultural purposes on account of the concentration of alkali salts. One effect of the acid is to cause a shrinkage of the colloids, giving a better opportunity for aeration of the soil and circulation of moisture, and creating more favorable conditions for the activity of nitrifying bacteria.

An important feature of the work from the metallurgical standpoint is the quantity of acid used, running into tons per acre. From the agricultural side there is prospect of rendering useful a vast acreage of ground in the Western States, now lying waste and shunned by the farmer. Here is prospect of co-operation for mutual good between interests that have regarded each other with suspicion and enmity. The smelter may yet prove to be one of the agents for making the desert blossom as the rose.

By-Product Coking

The rapid substitution of the retort for the beehive process of making coke in the iron industry that is occurring at this time may be looked upon as a metallurgical triumph, but it is really a financial achievement. Success from a technical standpoint occurred years ago in the manufacture and use of retort coke as the iron blast furnace fuel, and the building of by-product coking plants at the present time is proceeding chiefly in accordance with the quantity of funds available. In the circumstances the increase year by year in the proportion of by-product coke manufactured is slow rather than rapid. The growth is a function of the earnings of the iron and steel producers rather than of the economies assured by the process. Probably it would be difficult to find an engineer in any industry who would not insist that his employers or prospective clients were particularly slow in investing their capital in improvements promising economy, but the whole history of the iron and steel industry shows how it is continually demanding more and more capital. At the present time the industry is investing more of its funds in by-product coking plants than in any other single item.

The growth in by-product coke production is really slow. Last year was no criterion, as iron production was small and slightly less by-product coke was made than in 1913, while there was concurrently a large decrease in the beehive production, whereby the 11,219,943 net tons of by-product coke made in 1914 comprised 32.5 per cent of the total coke output, while the 12,714,700 tons of by-product coke made in 1913 comprised 27.5 per cent of the year's coke output. One-half as much by-product coke was made in 1909 as in 1913, one-fourth as much in 1905 and one-eighth as much, approximately, in 1902, showing successive doublings in three, four and five years respectively.

Of the total coke produced, as reported by the Geological Survey, which does not take account of gashouse coke, fully 80 per cent is consumed in the manufacture of pig iron, and thus the matter of replacing the beehive oven with the retort oven is chiefly the concern of the blast furnace. In view of the fact that the gas can be profitably employed in the steel works it is at the blast furnaces of the steel works more than at the merchant blast furnaces that by-product ovens are being built. A further differentiation can be made, that the consumers who have beehive ovens have been less disposed to build by-product ovens than those who have had to purchase their coke in the open market. Connellsville coke has frequently sold at very low prices, but it has always advanced to a very high level when there was a heavy demand, often doubling in price. The buyer has therefore paid more than the apparent average price, because he bought more high priced coke than low priced. Of late the building of by-product ovens has proceeded more rapidly than the erection of blast furnaces, a circumstance that has prevented the coke market from experiencing its usual sharp advance at this time when the production of pig iron has become very heavy.

It may be estimated that there are now being built, or definitely projected, by-product ovens having an annual capacity of about 4,000,000 tons, and as it is usually not far from a year from the inception of the enterprise to the actual production of coke the rate of growth in output is at the moment at the rate of not far from 4,000,000 tons annually. The present capacity seems to be somewhat under 15,000,000 tons, while as closely as can be approximated the coke requirements of the existing blast furnaces, if they were required to operate at capacity, would be about halfway between 40,000,000 and 45,000,000 tons. Even with the completion of the present new construction, therefore, the iron industry will not have accomplished one-half its task of arranging to supply itself with by-product instead of beehive coke. The remainder of the operation will be carried out largely as funds become available. The incentive to invest capital in this manner will in general be less in the future than it has been in the past, for the reason that thus far by-product ovens have been built chiefly by interests that had been buying coke, or were building blast furnaces in excess of their present coking facilities. In a short time there will be few blast furnaces using beehive coke except those that produce it themselves, or detached merchant furnaces to which the capital outlay would be somewhat disproportionate to the size of the present investment. It is to be expected, however, that even the furnace interests that have beehive ovens will gradually abandon them in favor of retort ovens located alongside the furnace.

Of course, the principal single stimulus which has caused this rapid development in by-product oven construction is the cutting off by the war of the importations of the coal-tar distillation by-products for which there is such an urgent demand by the chemical and allied industries. Just now it pays very well to invest in by-product coke ovens not for the sake of the coke, but for the sake of the by-products. But this is another story which may be reserved for another time.

Readers' Views and Comments

The Electric Furnace in the Foundry

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I have read with considerable interest the paper entitled "The Electric Furnace in the Foundry," written by Mr. Wm. G. Kranz and to be presented at the San Francisco meeting of the American Institute of Mining Engineers, which appeared in the Sept. 1 issue of Metallurgical & Chemical Engineering. I have forwarded a copy of this discussion to the secretary of the American Institute of Mining Engineers for presentation at the San Francisco meeting (Sept. 16 to 18).

I agree perfectly with Mr. Kranz that steel for castings made in an electric furnace is not because of that fact all necessarily good steel, and also that the qualities which he mentions, such as absence of segregation, elimination of sulphur, great tenacity, etc., can be obtained in an electric furnace if operated under proper metallurgical conditions.

An unusually low content of sulphur in steel for castings is not, of course, an absolute necessity and the range of this element usually obtained in steel made in basic open-hearth furnaces is sufficiently low to meet all physical requirements.

The main factor in making steel for castings regardless of the process is the complete deoxidation of the bath to prevent the formation of segregation and also increase the physical qualities of the steel. Such complete deoxidation is accomplished in basic electric furnaces by holding the metal sufficiently long in the presence of a blanket of carbide of calcium, as in the Heroult or Stassano process or by the addition of 50 per cent ferrosilicon, as in the Girod or induction furnace process. However, if steel is as completely deoxidized in the furnace that when, as pointed out by Mr. Kranz, an addition of aluminium or titanium is made the added metal will not oxidize but will be found in the metallic state in the steel, there can be no doubt that such steel will reoxidize during the tapping of the furnace and also during the teeming from the ladle into the molds.

While Mr. Kranz has undoubtedly through inadvertence failed to mention the fact, it is probably the practice at his plant to add aluminium in the ladle during the tapping of the furnace to completely deoxidize the steel.

If, as I assume, it is therefore a necessity under any circumstances to complete the deoxidation of the steel in the ladle, while appreciating the fact that an electric furnace properly controlled must give a more completely deoxidized product in the furnace than it is possible to obtain in such oxidizing processes as open hearth and converter, I still question its great advantage if it is still necessary to complete the deoxidation in the ladle.

In the schedule below I have reproduced Table No. 1 showing the comparative properties of electric and basic open-hearth steel as printed in Mr. Kranz's paper, and also the results of samples from six heats of basic open-hearth and converter steels of approximately the same chemical composition.

These six analyses are representative of the quality of thoroughly deoxidized steel produced under good foundry practice, and it will be noted that the physical properties compare very satisfactorily with those of the electric steel reported by Mr. Kranz.

Mr. Kranz mentions that "absence of segregation and oxides has been firmly established by a great many investigations in our chemical and physical laboratories," and states as a proof of this fact that when ferrotitanium or aluminium is added to their electric steel either of these metals will be found as much in the steel, indicating that no oxides were present which would cause their oxidation.

Table I.

	Elastic Limit	Ult. Str.	Elong.	Red	C	Mn	Si	S	P	
Electric steel..	36,400	65,300	36%	55%	.24	.52	.25	.019	.010	Referred to by Mr. Kranz
O. H. Basic....	34,800	63,000	29.5	35	.23	.53	.24	.038	.011	
O. H. Basic....	40,900	70,400	35.9	56.3	.24	.55	.30	.020	.020	
O. H. Basic....	36,200	64,200	35.9	61.3	.23	.51	.35	.020	.012	
O. H. Basic....	35,800	68,300	35.9	61.4	.23	.77	.34	.027	.012	
O. H. Basic....	38,700	61,600	35	54.0	.19	.56	.22	.027	.014	Test piece unannealed
Converter Steel	38,000	69,200	32	53.6	.21	.76	.37	.055	.041	
Converter Steel	40,500	71,000	32	52.8	.21	.68	.34	.052	.044	

I am inclined to believe that many metallurgists will be interested to obtain full details in reference to this particular point made by Mr. Kranz. Personally, I have made hundreds of heats of steel in the same type of furnace which he is using. In many of these heats 0.10 per cent titanium was used, and in no case have ever traces of titanium been found in the finished casting.

At other times I have used aluminium in the ladle and occasionally adding it into the stream of steel as it flowed from the ladle into the folds, particularly at the end of the operation, because this addition of aluminium was judged necessary to insure the soundness of the castings. In no case has aluminium been found in the finished casting, but in every case where an examination has been made for it the presence of alumina, the oxide of aluminium, has been established both by chemical and microscopical means.

I am of the opinion that what Mr. Kranz has reported as aluminium in the steels which he has treated with that metal, is in reality alumina, and I believe that more complete information on this particular point will interest metallurgists generally.

N. Petinot.

Britannia Linings for Hardinge Mills

To the Editor of Metallurgical & Chemical Engineering:

Sir:—In the interesting article in your August issue by H. C. Parmelee, on the Caribou mill in Boulder County, Colorado, he refers to their experience with Britannia lining for Hardinge mills, which seems to have been wholly unsatisfactory. A later experience with the same material at the Mary Murphy mill suggests that the condemnation at the Caribou mill may have been premature.

Having adopted the use of 2-in. manganoid steel balls instead of pebbles for our 4½-ft. mill, because of the increased capacity thereby obtained, we soon found that the life of the silex linings which we had been using theretofore was unduly reduced by the use of the steel balls.

We planned to try chrome steel lining, but as this would take a long time to make and deliver, we decided to use a Britannia lining in the meantime.

We obtained some of the discarded pieces of rail from the Caribou plant, which on arrival proved to be considerably worn and smooth at the edges, showing that when formerly used the mills had been run for a long time

after the lining had given way. The pieces of rail were, furthermore, encrusted with cement in places, which could not be completely removed by chipping without unwarranted expense. Owing to these conditions, the lining hardly had a fair chance.

The pieces of rail were embedded in a mixture of two parts sand to one part cement, fitted as closely as possible, and left to harden seven days. The work of lining occupied five days, as only one section could be completed at a time.

After being in use, the portion around the manhole gave some trouble at first by becoming loose. To overcome this we drove in worn balls into the interstices between the rails, hastening the process of wedging with balls which would no doubt have taken place naturally sooner or later.

Since that time the mill has been in operation ninety days, during which it has ground approximately 2500 tons of very tough ore, and it looks as if the lining will last from thirty to sixty days yet. Had the rails furnished to us been hardened as Hardinge recommends, the life of the lining would have been still greater.

In our judgment, apart from the loss of time in lining, the Britannia lining answers very well indeed. Its installation would be considerably facilitated by bolting rings around the manhole and at both ends, to which the rails might be wedged tight. If this were done, we believe there would be no difficulty whatever, with ordinary care, in getting the lining to stand. Another improvement would be to use progressively shorter pieces of rail to line the conical ends.

In our opinion, the principal drawback of the Britannia lining is the wasted space, because of which, and of the time required for lining, we do not expect to adopt it for the Hardinge mills at the Mary Murphy.

The difficulty at the Caribou mill, as to the 6-ft. Hardinge, may have been due to the very heavy balls in use there (5 in. in diameter).

Denver, Colo. GEORGE E. COLLINS.

Niagara Falls Section of the American Electrochemical Society

(From Our Special Correspondent)

The organizing meeting of the Niagara Falls Section of the American Electrochemical Society commenced with reasonable promptness at 8 h. 0 m. 30 s. p. m. on Sept. 16. Mr. F. A. J. FitzGerald, whose protests were drowned by cries of "Oh, go ahead, be a sport!" was railroaded into the office of temporary chairman which he filled in a more or less desultory manner throughout the evening.

The minatory tones of the secretary, Mr. A. T. Hinckley, prevented any opposition to his proposal that his own minutes be accepted without reading, and Mr. Acheson Smith reported the minutes of the organizing committee, and asked for comments or criticisms on the proposed by-laws. As everybody likely to protest had been put on the organizing committee, no one, naturally, had any to offer, and Mr. Acheson Smith then reported the following nominations on behalf of the nominating committee: President, F. A. Lidbury; vice-president, L. E. Saunders; secretary, A. T. Hinckley. Someone moved that Hinckley cast one vote for himself and the rest; he blushed and did.

At this point the chairman got so fidgety that it was thought advisable to adjourn the meeting, and, the president and vice-president elect arriving at this junction, a "business session" was thereupon held at the Hotel Imperial, where the executive committee might have been seen at one end of the long table fixing plans for raising the wind—and other things.

The following telegram was sent to President Addicks of the American Electrochemical Society at San Francisco: "The Niagara Falls Section at the conclusion of its organizing meeting sends best wishes to the parent society for as lively and successful a meeting as its own sessions promise to be."

On Tuesday, Oct. 12, the section will get down to business. Operating men, power-plant engineers and, as is hoped, some eminent designers of transformers will, under the seal of the confessional, speak to each other on the subject of "Transformers for Electric Furnace Work" with as much politeness as is consistent with frankness and truth.

The Western Metallurgical Field

State Licenses for Colorado Ore Buyers

In accordance with the provisions of a bill passed by the last Colorado Legislature, effective Nov. 1, all individuals or companies engaged in ore-buying in the State are required to take out a license at a cost of $100 per annum. The bill had its inception with Cripple Creek operators who have long sought some effective means of preventing "high-grading" by alleged assay offices and other places for disposing of stolen ore. By requiring all ore buyers to take out licenses and keep accurate records of their purchases, it is hoped that illicit buying of rich ore will be minimized. Legitimate reduction works already keep careful records of the source of the purchases, and the additional requirement of a $100 license fee is probably cheerfully accepted by them in the interest of the mining industry. As in most cases of such legislation, some individuals buying ores and similar materials in a legitimate way will find the annual fee a burden. Annual losses from the stealing of rich ore in such camps as Cripple Creek run into enormous sums which the present legislation hopes to divert into legitimate channels.

Heavy penalties in the nature of fines and even of prison sentences can be imposed for convictions under the law.

Safety and Efficiency Engineering at Colorado School of Mines

The opening of the Colorado School of Mines for the regular fall session was marked by the dedication of the Joseph A. Holmes chair of Safety and Efficiency Engineering, a new department established in memory of the late director of the Bureau of Mines. Governor Carlson made the dedicatory address and the exercises were attended by members of the State Industrial Commission, which is charged with the administration of workmen's compensation in Colorado. State officials and engineers have evinced a keen interest in the establishment of this new chair through the initiative of Dr. William B. Phillips, president of the school. It stands not only as a fitting memorial to a man who devoted the best years of his life to the promotion of safety and efficiency in the mining and metallurgical industries, but also as an active means for training young engineers in those two paramount features of modern industrial work. No appointment has yet been made to the new professorship, but it is expected that Dr. Phillips will shortly recommend a suitable man for election by the trustees. The necessary equipment will be purchased and the courses of study correlated with those of the other departments. In addition to the work of instruction at Golden, it is expected that subsequent developments will bring the new department into close relations with operators, miners and millmen throughout the State.

New Club House for Employees of Nevada Consolidated Copper Company

The accompanying illustration shows the new club house under construction at McGill, Nev., for the employees of the Nevada Consolidated Copper Company. The building is being erected and furnished by the company, and when completed will have the usual club features. In the basement there is a large swimming pool and shower baths, bowling alleys and locker rooms. The first floor will be devoted mainly to a general lounge, reading room and library, with one large room set apart for a gymnasium. On the second and third floors there are thirty-three living rooms that will be furnished and rented to single men in the company's employ, exclusive of the members of the technical staff for whom quarters have already been provided. The average monthly rental will be about $10 per room. A few of the rooms have private bath, but on each floor there is a large bath and toilet room for general use.

The club will be for the use of all employees without distinction or restriction except as to hours designated for certain groups of men and members of their families. The establishment of this club is an evidence of the growing sentiment in favor of welfare work among the employees of large companies, especially in isolated places where opportunity for recreation is limited.

EMPLOYEES' CLUB HOUSE, NEVADA CONSOLIDATED COPPER COMPANY

Weidlein's Copper Process

Some interesting experimental work in copper hydrometallurgy is in progress at the Mason Valley smelter at Thompson, Nev., under the direction of Dr. E. R. Weidlein. Particular novelty rests in the method of precipitating copper from solution and in the concentration of sulphur dioxide from smelter fume or other dilute sulphurous gases.

The method of treatment is applicable to either carbonate or sweet-roasted sulphide ores of copper. Sulphuric acid is the solvent used. Ore that is readily leachable is treated in vats; but for finer material a six-step Dorr classifier has been used with countercurrent flow of solution.

Before precipitation the solution is neutralized with lime and treated with sulphur dioxide until it has dissolved a percentage of gas equal to that of the contained copper. Precipitation of metallic copper ensues instantly when this solution is brought to a temperature of 160 deg. C. under a pressure of 100 lb. The precipitated metal is finely crystalline and when melted assays over 99 per cent pure. In the process of precipitation, sulphuric acid is regenerated in twice the quantity originally present in combination with copper:

$$CuSO_4 + SO_2 + 2H_2O = Cu + 2H_2SO_4.$$

The mechanical arrangements are such that the processes of dissolution and precipitation are continuous. Heat is conserved by returning the hot precipitated solution through a heat exchanger in counter current to the flow of fresh solution to the precipitator. The latter is a lead-lined cylinder through which the solution flows from bottom to top. The necessary temperature is obtained by circulating oil of high flash-point from a heater through the jacket surrounding the lead lining. Precipitated copper is discharged through a bottom gate into a receptacle from which it is periodically removed, washed and melted.

An interesting development of Dr. Weidlein's research, and one of prospective economic importance, is a process of concentrating the sulphur dioxide from smelter fume or other gases weak in that constituent. The details of the method are not now available, but it depends on the principle of selective absorption in a tower packed with the absorbent. The gas can be driven from the absorbent by heat and used as desired.

Some of the research work in connection with this process has been conducted at the Mellon Institute, Pittsburgh, in conjunction with the large-scale experimental work at Thompson, Nev. The investigations have been carried on in a careful and scientific manner, and the announcement of results will be awaited with interest, in view of the probable future importance of hydrometallurgy for low-grade, oxidized ores of copper.

First-Aid Field Meet at San Francisco

The contests in first-aid and rescue work held at the Exposition grounds in San Francisco, Sept. 22, 23 and 24, formed an interesting feature of "Mining Week" at the Exposition. Twenty-six first-aid teams and fifteen mine-rescue teams were entered, representing eighteen States. The contest events were selected by the judges from lists that had been previously placed in the hands of the teams for practice purposes. In first-aid there were events for one man, two and three men and full team. For coal-mine rescue events an explosion was simulated in an improvised gallery. The meet was financed by the California Metal Producers Association, which subscribed $1,500. Prizes for successful contestants included silver cups, silver and bronze medals, and miscellaneous donations from numerous manufacturers.

American Mining Congress

The eighteenth annual session of the American Mining Congress was held at San Francisco, Sept. 20-22, to receive reports of important committees and discuss topics of interest to the mining industry. Mr. Van H. Manning, director of the Bureau of Mines, outlined the past services of the Bureau to the mining industry and suggested a number of lines of metallurgical research in which work will be done in the near future. Among some of these problems are the recovery of platinum and allied metals, the improvement in recovery of zinc from low-grade ores, and the development of our resources in tin, chromium, manganese, antimony and molybdenum, by improving methods for handling low-grade material. Dr. George Otis Smith addressed the Congress on the subject of "Plain Writing," with a plea for fewer razor-edged words in technical writing, suited only to hair-splitting technicalities. The subject of mining and metallurgical education also received attention in a paper by Prof. Charles F. Willis of Tucson, Ariz. The balance of the program was devoted to business and economic aspects of mining.

Memorial exercises in honor of Dr. Joseph A. Holmes, late director of the Bureau of Mines, were held at noon, Sept. 21.

The Iron and Steel Market

Another month's developments in the course of the iron and steel market has indicated still more conclusively that the backbone of the steel demand is the requirements for war purposes. The war demand has continued to increase, and as fresh orders for large tonnages are placed from day to day, while purchases formerly made were for extended deliveries, the output of war material is steadily increasing.

The general alignment of demand has become more clearly defined. In no finished steel product is there a large domestic demand. For war purposes there is a very heavy demand for wire products, for large steel rounds and for forging billets. Inasmuch as the large rounds are rolled on rail mills, enabling the rail mills to consume more steel than for many years, while the large tonnage of forging billets demanded requires no finishing operation by way of rolling, a condition has arisen by which there is great pressure for tonnage upon the steel-making departments, and only occasional pressure upon finishing mills. At the same time it develops that there is ample pig iron for the requirements of Bessemer converters and open-hearth furnaces. There results what is called in trade parlance "a scarcity of steel." Rolling billets are scarcely to be obtained at $26 at mill, per gross ton, when bars, plates and shapes are quoted at $27 per net ton, and forging billets have brought $35 and more. Between basic pig iron at valley furnace and basic open-hearth billets at valley mill there is a spread of fully $11 per ton while last December the spread was only about $5.

The entire open-hearth steel-making capacity of the country is in full employment, and practically the entire Bessemer capacity. The small Bessemer plant at Columbus is idle, and at a few Bessemer plants operations are not at the fullest rate possible, but such instances are exceptional. The steel trade has thus far supplied itself with pig iron without drawing nearly as much upon the merchant furnaces as in 1912 or 1909, periods in which the pressure for steel was scarcely as great as at present. Upon coke there has been no pressure at all, doubtless by reason of the large increase in coke-making capacity of late through the erection of retort plants. The demand in the market for scrap is not heavy and scrap is selling at lower prices than are usually current when billets bring their present prices. The situation doubtless is a reflection of the large ingot cropping required in the filling of many of the war orders.

All the consuming industries in the United States show a better demand for finished steel products than two or three months ago, but in no instance is the demand up to previous high levels unless the industry is engaged more or less in the production of war material. In a general sense export and war orders are synonymous, for the purchases of neutral countries are still below normal. Agricultural implement exports, while heavier than six months or a year ago, are distinctly below normal. In the machine tool and automobile industries there is feverish activity as, of course, is the case at munition factories. Exports direct and indirect are probably now consuming finished steel at the rate of more than 5,000,000 tons annually.

Pig Iron

Pig iron prices advanced about one-half as much in September as in August, and the September advances were due more to the sold-up condition of the furnaces than to any large demand. There was very little buying by foundry interests, and no general buying by steel works, though a few large blocks were taken. The condition at the close of September is that consumers appear to be well covered against requirements through the remainder of the year, with the furnaces now in operation equally well sold up, and neither buyer nor seller anxious to force conclusions as to deliveries in the first half of the new year. A buying movement for that delivery is hardly expected before late October or early November. While the steel works are producing more steel than ever before, and the steel interests are making more pig iron than ever before, the merchant blast furnace output is considerably less than the capacity. The idle merchant furnaces are not finding occasion to blow in as rapidly as was expected and thus buyers of pig iron feel fairly well insured, at least for the present, against a runaway market.

Shipments of Lake Superior ore down the lakes amounted to 26,806,420 tons for the season to Sept. 1, or less than in the corresponding period of several preceding years, but estimates of the movement for the remainder of the season are made as high as 22,000,000 tons and if such expectations are realized the year's movement will closely approximate the record. There is no danger of anything like a general ore shortage, though buyers seeking particular descriptions of ore, especially for the open-hearth furnace, have lately had a little difficulty in effecting purchases. Pig iron is quotable as follows: No. 2 foundry delivered Philadelphia, $16.25 to $16.75; f.o.b. furnace, Buffalo, $15.50 to $16; delivered Cleveland, $15.25; f.o.b. furnace, Chicago, $14.25 to $14.75; f.o.b. Birmingham, $11.50 for prompt, $12.50 for first half 1916; at valley furnaces, 95c. higher delivered Pittsburgh: Bessemer, $16; basic, $15; No. 2 foundry and malleable, $14.50 to $15; gray forge, $14.25 to $14.75.

Steel

To the insistent demand for rolling billets that characterized August, with a moderate demand for forging billets, there has succeeded a very heavy demand for forging billets. Billets are so scarce in general, and prices that can be secured for special steels are so attractive, that the market for ordinary soft steel rolling billets is scarcely quotable at all. There is no question that $26 at maker's mill, Youngstown, would readily be paid for ordinary open-hearth billets, and Bessemer billets might easily bring $25, prices delivered Pittsburgh being $1 a ton higher, as no steel to speak of is being offered by Pittsburgh mills. Sheet bars would not be sold except at the full billet price or a trifle more, but there is no demand whatever. The sheet and tin mills are covered by contracts, and in any event the selling prices of their products are such that they could not afford to buy steel at prices that would be asked. Wire rods are quotable at $30, Pittsburgh, but sellers can scarcely be found at any price.

Finished Steel

Wire products were advanced $2 a ton Sept. 20. Effective Sept. 28 the American Sheet & Tin Plate Company advances its prices $2 a ton on blue annealed and black sheets, to 1.6c. for blue annealed, 2c. for Bessemer black and 2.05c. to 2.1c. for open-hearth black. Bars, plates and shapes for delivery at mill convenience have been 1.35c., for 1.40c. has been quoted and done on first quarter contracts and the mills have little left to sell for earlier delivery so that the market promises shortly to be squarely on the basis of 1.4c.

Current quotations, f.o.b. Pittsburgh, unless otherwise noted:

Rails, standard section, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.35c. to 1.4c.

Shapes, 1.35c. to 1.4c.

Steel bars and bands, 1.35c. to 1.4c., base; hoops, 1.5c., base.

Iron bars, 1.45c. to 1.5c., Pittsburgh; 1.509c. to 1.559c., Philadelphia; 1.35c., Chicago.

Sheets, blue annealed, 10-gage, 1.55c. to 1.6c.; black, 28-gage, 2c. to 2.1c.; galvanized, 28-gage, 3.5c. to 3.6c.; painted corrugated, 28-gage, 2.2c.; galvanized corrugated, 28-gage, 3.55c. to 3.65c.

Tin plate, $3.10 to $3.20 for 100-lb. coke.

Steel pipe, ¾ to 3-in., black, 79 per cent off list; galvanized, 63½ per cent off list.

Steel boiler tubes (less than carloads) 72 per cent off list.

Structural rivets, 1.6c.; boiler rivets, 1.7c.

Railroad spikes, 1.5c., Pittsburgh; 1.65c., Chicago.

The New Director of the Bureau of Mines

Mr. Van H. Manning has been appointed Director of the U. S. Bureau of Mines, as successor of the late Joseph A. Holmes. During Dr. Holmes' administration of the bureau, Mr. Manning was Assistant Director. Before entering the Bureau of Mines he was connected with the U. S. Geological Survey. The good wishes of the profession and the industry are due to Mr. Manning on his entrance into a position of grave responsibilities and great opportunities.

San Francisco Meeting of American Electrochemical Society

The twenty-eighth general meeting of the American Electrochemical Society was held in San Francisco from Thursday to Saturday, Sept. 16 to 18. The attendance was comparatively small on account of the scarcity of local members and electrochemical industries in California, but it came up to expectations, and those who were present enjoyed the meeting immensely.

At the Board of Directors meeting routine business was transacted and it was decided to hold the Spring meeting, 1916, at Washington, D. C.

The technical session of Thursday morning was opened by President Addicks and the papers by Wills and Schuyler, Snyder, Mott, Aldrich, Betts, Bennet, Rose and Tinkler, Frederiksen, Bancroft, and Bosworth were read and briefly discussed.

On Friday two sessions were held as planned. In the morning session held jointly with the American Institute of Mining Engineers, the papers by Lyon and Keeney, Clevenger, Addicks, Wile, Boeck, Davy, Goodrich and Pyne were read and discussed at some length.

The afternoon session was held in conjunction with the American Institute of Electrical Engineers and the papers by Foster, Sebast, and Beckman were read and discussed.

We reserve a full account of all the papers and discussions for our next issue.

A pleasing feature of the meeting was the session at which the Exposition medal was presented to the Society. Mr. Chas. Butters presided on this occasion. Mr. Chas. A. Vogelsang presented the medal.

President Addicks accepted the medal with a short address in which he referred to the westward trend of electrometallurgy. He traced the historical development from the invention of the dynamo with its effect on mechanical and electrical engineering and on chemistry and metallurgy to the ultimate birth of electrochemistry as a distinct science and industry which necessitated the formation of a new society for growth and expansion. Electrochemistry has played an important part in the industrial progress of recent years, which the San Francisco Exposition expresses on such a magnificent scale. The presentation of the medal was followed by special visits to the exhibit of the Bureau of Mines and the Norway exhibit of nitrate products.

All social functions were carried out according to the program and greatly enjoyed.

San Francisco Meeting of American Institute of Mining Engineers

The 111th meeting of the American Institute of Mining Engineers, held in San Francisco from Sept. 16 to 18, was most successful. The attendance was large in the technical sessions as well as at all social functions. Great credit is due to the different committees and their chairmen, Merrill, Hanks, Shockley, Clevenger, for the excellent arrangements made. An elaborate souvenir program with artistic illustrations of California and the Exposition had been prepared. All meetings were held at the Bellevue Hotel.

At the opening meeting on Thursday morning in the Palm Room of the Bellevue Hotel, C. W. Merrill presided. An address of welcome to California was made by Arthur Arlett. President Saunders replied for the Institute. Dr. L. D. Ricketts then presented his address on some problems of copper leaching. A. J. Clark spoke on Homestake metallurgy, and F. L. Bosqui on gold metallurgy in the Witwatersrand district. The latter paper brought out considerable discussion of a reminiscent nature from former Rand operators.

In the afternoon session on gold and silver F. Lynwood Garrison presided, and papers by C. W. DeWitt, W. P. Lass, E. E. Carpenter, N. Herz, E. B. Thornhill, J. A. Carpenter, W. J. Sharwood and A. H. Jones were read. Simultaneously a session on geology and mineralogy was held, Andrew G. Lawson presiding.

On Friday morning a joint session was held with the American Electrochemical Society, Lawrence Addicks presiding. Simultaneously there was a session on petroleum and gas, with Arthur F. L. Bell in the chair. In the afternoon there was a session on mining, milling and non-ferrous metallurgy.

Abstracts of the papers and discussions are reserved for our next issue.

On Friday afternoon the Exposition medal was presented by the Exposition authorities to the Institute. President Saunders accepted the medal with a felicitous speech.

The banquet on Friday night at the Palace Hotel was a brilliant affair, attended by some three hundred members and friends of the Institute. The occasion was graced by the presence of many ladies. Mr. E. H. Benjamin acted as toastmaster and speeches were made by Benjamin Ide Wheeler, "An Engineer"; W. L. Saunders, "California"; Van H. Manning, "Co-operation"; George Otis Smith, "The Outlook," and T. A. Rickard, "The Ladies."

On Saturday morning a boat trip was made around San Francisco Bay on the private yacht Cyprus, by courtesy of Mr. D. C. Jackling. A stop was made at the Selby Smelter, where the blast furnaces, the Parkes refining process, the Cottrell process for precipitation of sulphuric acid fume from parting vats, the filtration of smelter gases in a bag house and the manufacture of special lead products were shown. For Sunday afternoon Mr. and Mrs. Charles Butters had invited the Institute to their Oakland home for a lawn reception and tea, and inspection of laboratories and testing plant.

The Institute may be proud of the great success of this meeting.

Metallurgy at International Engineering Congress

San Francisco, September 20 to 25, 1915

The International Engineering Congress, held at San Francisco from Monday to Saturday, Sept. 20 to 25, 1915, was a great success from start to finish.

At the opening session on Monday the attendance was 800, with a good representation from foreign countries.

Mr. W. F. Durand, chairman of the organization and managing committee, opened the Congress with a review of the four years of work, the object of which was now being realized. The local committee had corresponded with 250,000 engineers and 250 engineering societies. Although the European war had threatened to impair the success, the value of the Proceedings of the Congress has not been impaired in any way. Two hundred papers have been printed in advance; thirty more papers are yet to be printed. The Proceedings of the Congress will fill eleven volumes of 7000 pages, and the authors will represent eighteen countries. Mr. Durand concluded by introducing the Honorary President General Goethals, who, after acknowledging the honor, introduced the Mayor of San Francisco.

Mayor James Rolph, Jr., welcomed the Congress to San Francisco and paid a high tribute to all classes of engineers for constructive work on the Panama Canal, of which San Francisco is the chief beneficiary.

President Charles C. Moore of the Panama-Pacific Exposition said this Congress was by far the most important of 880 different conventions held in connection with the Exposition and expressed the hope that the deliberations of the Congress would result in vast good for humanity.

General Goethals then made his formal address on the Panama Canal and the Panama-Pacific Exposition. The completion of the canal was possible only through the coöperation of all classes of engineers and scientists. Incidentally it proved that engineers are fitted for great executive administrative work when politics is eliminated.

Brief responses to the address of welcome were made by the delegates of Sweden, Switzerland, France, Cuba, China, Japan, Netherlands, Nicaragua, Spain, Canada and Guatemala.

The presentation of the John Fritz medal to Dr. James Douglas, which was to conclude this session, had to be postponed on account of the illness of Dr. Douglas.

The real work of the Congress was carried out, of course, in the different sections. In the following we report the proceedings in the Section on Metallurgy:

TUESDAY SESSION

The first session of the Metallurgical Section was held on Tuesday afternoon, Prof. Richards presiding. It was almost completely devoted to the Symposium on Iron and Steel.

Symposium on Iron and Steel

The Symposium on Iron and Steel had been arranged and edited by Dr. Henry M. Howe.

The first paper presented related to **iron and steel castings,** the author being Mr. John Howe Hall of the Taylor-Wharton Iron & Steel Co. of High Bridge, N. J. Iron and steel castings may be made either of steel or of malleable iron or of cast iron. According to the general nature of the three metals, the castings have distinct fields of usefulness.

The variations in the properties of steel castings are due (1) to variation in the composition of the steel, (2) to the annealing or heat treatment to which the steel is subjected, and (3) to the soundness of the casting.

The soundness depends on the degree to which blowholes or shrinkage cavities can be avoided. As to composition the effect of carbon, silicon, manganese, phosphorus and sulphur was discussed, also the effect of annealing and heat treatment on steels of different composition.

The method by which the steel is made influences its properties largely by its effect upon the composition that it is possible to secure and upon the tendency of the steel to unsoundness. The extent to which the steel is subjected to oxidation during its manufacture influences the tendency to unsoundness. In general, the Bessemer process oxidizes the steel to the greatest extent, the open-hearth process to a less degree, the crucible process to a still less degree, and the electric furnace process least of all.

The process by which the steel is made is, in many cases, of less importance that the skill and knowledge of the workmen, so that the purchaser is better protected by calling for metal of good properties as exhibited by tests than by buying castings made by some particular process that he supposes to be the best. Even electric-furnace steel is subject to this statement. The growing use of the electric furnace in steel foundries is due as much to the fact that it possesses certain technical advantages for the manufacture of high-grade small castings as to the superior excellence of the steel made in it. "The electric furnace, so far, has been used in competition with the Bessemer and crucible processes in making light work, for which it has certain marked advantages. One may hazard a guess that its chief application in the future will be in this field, and that its use for heavy work will be confined to a limited number of cases where steel of very high quality is required."

Malleable iron castings and cast iron castings were finally briefiy discussed.

"The best way to secure satisfactory castings is to prescribe the tests that the metal must meet—such as strength, ability to withstand a certain hydraulic pressure without developing leaks, machinability, etc.—and leave the composition to the maker, who can generally be depended upon to choose the composition best suited to the requirements. The maximum sulphur, and sometimes phosphorus, content, may be specified, but the engineer should be careful not to go so far in this line as to unnecessarily embarrass the foundryman."

In the discussion which followed, Mr. Bechman said the trade term "semi-steel" should be eliminated, as it offered a chance for imposition on the consumer by suggesting something better than the actual product. The possibility of including radiographic tests of castings in the specification was pointed out.

Metallography and the Hardening of Steel was the subject of a paper by Dr. Albert Sauveur of Harvard University. The influence exerted by metallography on the elucidation of the still much debated question of the causes underlying the hardening of steel was pointed out. The author discussed the phlogiston theory, Percy's explanation, Akerman's compression theory,

Howe's explanation in 1890, early tension or stress theory, Osmond's allotropic theory, the stress theory again, Le Chatelier's theory, Arnold's subcarbide theory, McCance's interstrain theory, Humphrey's amorphous theory, and Carpenter's and Edwards' twinning and amorphous iron theory.

The many recent attempts at arriving at a satisfactory explanation of the hardening of steel are based on one or more of the following conceptions (1) existence of a hard allotropic variety of iron, (2) existence of solid solutions involving the occurrence of so-called "hardening" carbon, and (3) existence of strains in quenched steel causing or not an amorphous condition in the iron. No theory so far presented fully satisfies our craving for a scientifically acceptable explanation of the many phenomena involved.

"It would seem as if the methods used to date for the elucidation of this complex problem have yielded all they are capable of yielding, and that further straining of these methods will only serve to confuse the issue, a point having been reached when this juggling, no matter how skillfully done, with allotropy, solid solutions, and strains is causing weariness without advancing the solution of the problem. The tendency of late has been to abandon the safer road of experimental facts and to enter the maze of excessive speculations, in which there is great danger of some becoming hopelessly lost. The conclusion seems warranted that new avenues of approach must be found if we are ever to obtain a correct answer to this apparent enigma."

The discussion of this paper showed that the consensus of opinion was in favor of Le Chatelier's theory, although it was admitted that it would not explain all varieties of steel. Radiography was again suggested as a possible new method of attack to distinguish between different steels.

The Recent Progress and Present State of the Technical Application of the Case Hardening of Steel was the subject of a long paper by F. Giolitti, Director General of the Steel Works, Gio. Ansaldo & Co. of Genoa, Italy. The author first discusses the present condition of our theoretical knowledge of the process of case-hardening of steel. He then deals with the characteristics of the various carburizing substances and their use. He favors "gradual" agents, the activity of which is due exclusively or in absolutely preponderant degree to the specific action of carbon monoxide, as distinguished from "abrupt" agents (nitrogenous organic substances, hydrocarbons, cyanides and ferrocyanides).

"Gradual" agents are powdered or granular charcoal, calcined lampblack and calcined bone charcoal; further mixtures of powdered or granular charcoal with carbonates which are dissociated at high temperature ("Caron's cement"; sixty parts of powdered wood charcoal mixed with forty parts of pulverized carbonate of barium); further granular wood charcoal through which is circulated a more or less slow current of carbon monoxide. With the last agent the action of the carburizing substance may best be regulated.

The author then gives illustrated descriptions of the arrangement for the use of various types of carburizing materials and finally discusses the treatment and the characteristic properties of cemented parts.

There was no discussion of this paper.

The Duplex Process of Steel Manufacture was the subject of a paper by Mr. F. F. Lines of the Maryland Steel Company, Sparrow's Point, Md. The author discusses the combination of the acid Bessemer and the basic open-hearth. The acid converter oxidizes the silicon, together with the manganese and a certain portion of the carbon, the exact amount depending upon the practice. The blow metal is then transferred to the basic open-hearth furnace where the phosphorus and the remainder of the carbon is removed. The duplex process shortens the open-hearth purification by more than five-sixths of the usual period, giving a steel of the same quality as the straight open-hearth process. Some details of operation in practice and results are given in the paper.

In the discussion of the paper, Dr. Richards said that this process was only one of many possible variations of duplexing. He expected a wider use of combination methods, using the most economic features of the Bessemer, the open-hearth, and the electric processes in combination.

Methods of Preventing Piping in Steel Ingots was the subject of a paper by Mr. Emil Gathmann of Baltimore, Md. After a brief discussion of Hadfield's and Kennedy's methods, the author said that an ingot with its larger horizontal cross-sectional area at the top is without question the best shape for obtaining the important so-called "lag" in solidification of the steel, and whenever such large-end-up ingots can be conveniently used, it is the best practice to do so. Another method of the author is now being tried at one plant of the U. S. Steel Corporation. He uses ordinary big-end-down ingots, but designs the mold so that the lower 70 or 80 per cent of the metallic mold in which the ingot is cast has a much greater degree of heat absorptive quality than the upper 30 or 20 per cent. (Fig. 1.) A metallic mold with heavy lower body walls and thin upper walls, *per se*, properly designed, will produce a sound homogeneous ingot with about a 20 per cent top crop in split ingots of dead killed steel, which is about 15 per cent less than is usually necessary in cropping cold ingots made in the old type of mold of like grade of steel.

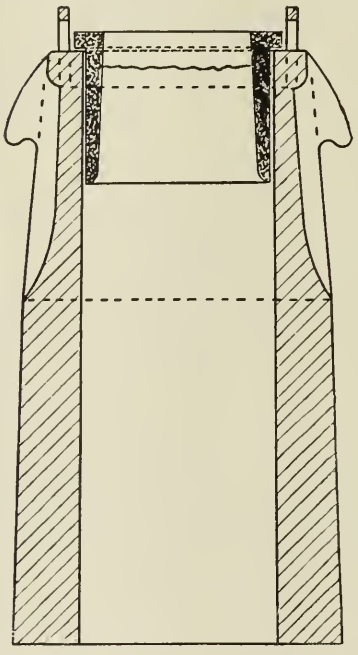

FIG. 1—GATHMANN MOLD

In the discussion of the paper the importance of following sound metallurgical principles in thorough degasification of molten steel regardless of the method of producing the ingot was pointed out.

Steel Alloys was the subject of a paper by George L. Norris of Pittsburgh, Pa. The paper gave compositions and special uses of steels alloyed with manganese, silicon, nickel, chromium, vanadium, tungsten, and cobalt.

Steel Making in the Electric Furnace was the subject of a paper of Mr. James H. Gray of the U. S. Steel Corporation. The electric furnace is a new instrument for steel-making, as it has a neutral and even reducing atmosphere as distinguished from the oxidizing atmosphere of all other steel furnaces.

Upward of 150 electric steel furnaces have been installed in many different countries. The largest unit so far is twenty tons.

"Electric steel is now extensively used for products as tires, axles, seamless tubes, and small castings. The

fact that electric steel lends itself to heat treatment more readily than other kinds of steel, both as regards greater range of temperature and absence of cracking in the quenched piece, and that there is less loss due to defective material after machining in the machine shop also gives this steel a preference even at a higher price.

"Many have doubted if electric steel can ever be made for such low-priced products as rails and structural material so as to compete with open-hearth steel. I believe that the solution of this problem depends upon the adoption of the proper combination process by which the roughing down work will be done by one or several of the older methods using cheap fuel, and the finishing or final refining done in the electric furnace. Both the acid and the basic Bessemer and the open hearth have been used to supply molten metal to the electric furnace. The finishing has been done in both basic and acid electric furnaces.

"In the basic electric furnace both dephosphorization and desulphurization can be performed, and it can be supplied with a metal only partially refined, while the acid electric furnace should be supplied with a metal from which both phosphorus and sulphur have been removed, requiring greater preliminary refining—going back even to the blast furnace.

"During the last two or three years rapid strides have been made with the duplex or Bessemer open-hearth process, and costs are being obtained which compensate for the excessive metal loss in the Bessemer part of the process. It may be that the duplex process in connection with either the basic or acid electric furnace will give us the solution. However, enough has already been done with the manufacture of the heavier or lower priced products to indicate that, provided it is turned out in producing units of equal size, the total cost of electric steel will be near enough to that of open hearth steel, so that the manufacturer can afford to stand the difference in order to give the consumer quality, the requirements for which are constantly growing more rigid.

"The possibility of bringing the cost of the two steels near together will appear more feasible if we consider such incidental savings as the use of cheap pig iron at the beginning of the process and the smaller discard of rolled product due to having an ingot free from segregation.

"In Germany, Luxembourg and eastern France, the electric furnace is the best apparent solution of a condition which is a menace to the steel industry of those countries.

"While the high phosphorus ores of Luxembourg and Lorraine, together with the basic Bessemer process, made possible the great steel development of Germany, the quality of basic Bessemer steel does not to-day give it a standing with open-hearth steel, while the demand for better quality is daily growing. On the other hand, basic Bessemer steel, after refining in the electric furnace, is superior to open-hearth steel. The manufacture of electric steel by this method was began in Germany several years ago, and has in moderate quantities been made into all kinds of steel products. It seems probable that the American steel manufacturer will find it necessary to adopt electric steel to meet the competition which he will meet in the world's markets.

"It has been remarked that the progress of electric steel manufacture in America has been slow as compared with that in Europe, but the indications are that this relation will soon be reversed. It was natural that the invention of the electric furnace should be made in countries where cheap hydro-electric power was already in extensive use for other electro-chemical processes, but it was only a couple of years before the first electric furnace was installed in the United States. We must also remember that the first large furnace, namely, one of fifteen tons' capacity, requiring electrodes 2 ft. in diameter, a then unheard of size for steel furnace use, was built here; also that this furnace was the first to use three-phase electric current, which adapted it to utilize the kind of current in general commercial use.

"There are now either built or building over forty electric furnaces in America, of which there are twenty-seven of the Heroult type alone. The average size of these furnaces is also greater than the average size in Europe.

"If the electric furnace be used for the further refining of steel made in present installations of the older processes, as now seems probable, the amount of electric steel produced should then eventually be commensurate with that now being produced by those processes; and it follows that electric steel production in the United States will exceed that of any other country."

In the discussion Mr. Beckman said that the manufacture of electric steel castings is possible at the Pacific coast, while duplexing is not possible in view of the lack of open-hearth and Bessemer plants. One hydro-electric development at the Pacific coast is able to supply 600,000 hp. continuously.

Mr. Babcock questioned the cheapness of hydro-electric power on account of the expense of the first installation and the fluctuation of the available water. He thought steam power to be cheaper but too expensive for electric furnace operation.

Mr. Beckman replied that castings are now made in the electric furnace in San Francisco, Portland, Seattle, and Los Angeles, and that four new plants are projected.

Electrometallurgy was the subject of the last paper of the session, the author being Dr. E. F. ROEBER, editor of "Metallurgical and Chemical Engineering." The author first deals with electric furnace processes, giving the fundamental principles and a classification, and discussing the chief metallurgical applications of electric furnaces for melting and refining (steel) and for reduction processes (ferro-alloys, iron, zinc). The second chapter deals with electrolytic processes; after a statement of the fundamental principles and a classification, the author discusses commercial applications of electrolytic processes with soluble anodes (electroplating, electrolytic refining of copper, silver, gold, lead, nickel, zinc, iron, tin, bismuth, cadmium) and of electrolytic processes with insoluble anodes (electrolytic precipitation of gold in cyanide process and of copper in copper leaching processes). The third part of the paper deals with electrolytic furnace processes (aluminium, sodium, magnesium, calcium, cerium, zinc).

In the discussion of the paper the possibilities of electric smelting of California complex ores was suggested.

THURSDAY SESSIONS

Symposium on Copper

The second and third sessions of the Section on Metallurgy were held on the morning and afternoon of Thursday, September 23, Dr. L. D. RICKETTS presiding.

Both sessions were devoted to the Symposium on Copper, arranged and edited by Mr. E. P. MATHEWSON, of the Anaconda Copper Mining Co.

The first paper on the program was a general statement of **Progress in Copper Metallurgy**, by THOMAS T. READ. The author reviews the shifting changes that have occurred to meet new conditions, and the resulting interest in different phases of copper metallurgy at different periods. Blast-furnace smelting developed

to its height when the mines were producing suitable high-grade sulphide ore in lump form. With the development of low-grade ore bodies and the methods of concentrating them, roasting and reverberatory-smelting furnaces became improved, and the advance in this art left blast-furnace smelting in the background. With this came the successful use of the basic lining for converters, which improved and simplified general smelting practice as well as converting itself. Later, hydrometallurgical processes received a great deal of attention, with resulting notable progress in the wet treatment of low-grade ores and tailings. This work is still in progress and, in the opinion of the author, may exert a profound effect on the metallurgy of copper.

In the discussion of this paper Dr. RICKETTS said the dust losses in reverberatory smelting likely increase with the treatment of fine flotation concentrates and must receive attention. The increase of leaching processes raises the problem of the disposal of waste acid liquor.

Advances in Copper Smelting was the subject of a paper by FREDERICK LAIST of the Anaconda Copper Mining Co. The author regards the rapid growth in favor of reverberatory as compared with blast-furnace smelting as the most notable difference between practice in the past ten years and the ten years preceding. He assigns the following reasons: The lengthening of Anaconda reverberatories together with the semi-continuous method of operation, and the reduction of cost of reverberatory smelting to the level of blast-furnace smelting; introduction of oil firing; success of pulverized coal firing; and the remarkable success of the flotation process in making high recoveries, so that concentration followed by reverberatory smelting is more profitable than direct smelting, even on comparatively high-grade material. At Anaconda, for example, the direct smelting of first-class ore is to be stopped, and all ore will be concentrated and smelted in reverberatories. This will result in economies due, in part, to the fact that reverberatory smelting with pulverized coal will be cheaper than blast-furnace smelting, and, in part, to the elimination of barren flux which must be used in blast furnaces.

Basic lining for converters has revolutionized converter practice, and it has been demonstrated that practically any size or shape of converter shell can be successfully lined and operated as a basic converter. Many of the refinements originally considered essential are not considered of vital importance. The main considerations for successful operation are (1) avoidance of too high temperature, and (2) the maintenance of a coating of magnetite over the bricks.

No radical changes of importance in blast-furnace smelting have occurred, except the building of the long furnaces by E. P. Mathewson. The use of hot blast has been abandoned. The development of the turbo blower for pressure up to 16 lb. per sq. in., may result in the displacement of the Root type of blower for blast furnace and converter air.

The McDougall type of roaster holds its place as a roasting furnace as well as a preheater for reverberatory charges where the quantity of sulphur is low and a hot-fry material is desired.

Bedding systems are growing in favor, especially where materials of diverse character are being smelted.

More attention is being paid to dust losses and the purification of smelter gases. Bag houses and the Cottrell system of electric precipitation are successfully used.

The author gives a bibliography of copper-smelting literature and brief comment on details of the foregoing general statements.

Dr. Cottrell spoke of the effect of temperature on electrostatic precipitation and fractional separation of fume constituents by regulation of temperature. Lower voltage is used at high temperatures since the dielectric strength decreases with increase in temperature.

Dr. Ricketts said that unaccountable losses in smelting suggested the necessity of studying possible constant errors in sampling which would explain such losses.

Mr. A. E. Wells mentioned an instance of faulty moisture sampling of concentrates at a smelter, which resulted in an apparent increase of the plant copper loss by 40 per cent.

Mr. E. A. Hersam pointed out the need of more data on converter slags and linings, on the temperature of slag formation, and the composition of the acid material added to the converter.

Replying to questions Mr. Laist said that basic converting could be successfully carried out in small plants since converters could be used only for one shift daily if necessary. The basic converter stands hard usage with surprisingly little cracking of the lining due to expansion and contraction. The prospective shortage of Austrian magnesite caused the Anaconda experiments with other materials. California magnesite was found fairly satisfactory giving half the life, while chrome brick gave one-fifth the life of Austrian magnesite.

Mr. R. H. Bradford inquired concerning the possibility of sintering raw concentrates and leaving enough sulphur for blast smelting.

Mr. Laist explained that it was rather difficult to sinter high-sulphur material, on account of the clogging of the grates and distillation of sulphur. But even if Mr. Bradford's suggestion could be carried out, the cost of sintering plus blast smelting is greater than the cost of roasting and reverberatory smelting.

Metallurgy of Copper in Japan was the subject of a paper by Mr. R. KONDO, Director of the Furnkawa Co., Tokyo, Japan. It reviewed the progress of copper metallurgy in Japan since the earliest days of the Mabuki converting process. The present Japanese copper plants use modern processes of sintering, smelting, and electrolytic refining. The smoke problem is acute in Japan on account of the congested population and the bad effect of the sulphur fumes on rice.

Copper Metallurgy of the Southwest was the subject of a paper by Dr. JAMES DOUGLAS, reviewing the history and development of copper metallurgy in the southwestern states. Evidences of copper metallurgy in prehistoric times in this part of the country may be seen in the copper hammers found in shallow pits on carbonate mines. Later, adobe furnaces were used, the remains of which still stand near the Hanover mines. Apart from these primitive efforts, the first important copper mining and reduction occurred about 1872 when the Longfellow and Coronado mines were opened at Clifton and the ores smelted in furnaces of different types; first, reverberatories; then adobe stacks, and finally copper-jacketed furnaces. The latter were still used as late as 1881.

Work at the Copper Queen began in June, 1880, with a 36-in. iron-jacket furnace for smelting. A second stack of this type was erected and the plant turned out for the original Copper Queen Mining Co., from 1880 to 1885, a total of 34,536,000 lb. copper from ore averaging 11.5 per cent copper. Fortunately the mines of the Bisbee district yielded an oxidized ore of fusible composition, and slag losses were low, being about 2½ per cent. In the Clifton and Globe districts, on the other hand, where the ores were silicious and required as much as 50 per cent barren flux to render them fusible, the slags ran from 3½ to 4½ per cent copper. The introduction of Bessemer converting at the Copper

Queen in 1893 was necessitated by the increased sulphur in the deeper ores. The furnace yield increased 1½ per cent and the grade of Bessemers to 99 per cent, fitting them for electrolytic refining.

When the new Copper Queen works were erected in the Sulphur Spring Valley, many changes and improvements were made. The blast furnaces were enlarged; basic-lined converters were adopted; a roasting and reverberatory department was added.

The most notable change in copper smelting in the southwest, as elsewhere, has been the substitution of reverberatories for blast furnaces, in order to smelt the increasing quantity of concentrates offered. At the new plant of the Arizona Copper Co., Clifton, and the American Smelting & Refining Co., Hayden, reverberatories are used exclusively. The new plant of the International S. & R. Co., a flow-sheet of which is shown in Fig. 1, will also have reverberatories for treating the concentrates from the Miami and Inspiration mines. These furnaces will be 21 ft. by 120 ft., and the concentrates to be smelted will contain approximately 40 per cent copper, so that their production will exceed that of any other Arizona smelter. In conclusion, Dr. Douglas gives an outline of the equipment at Arizona smelters.

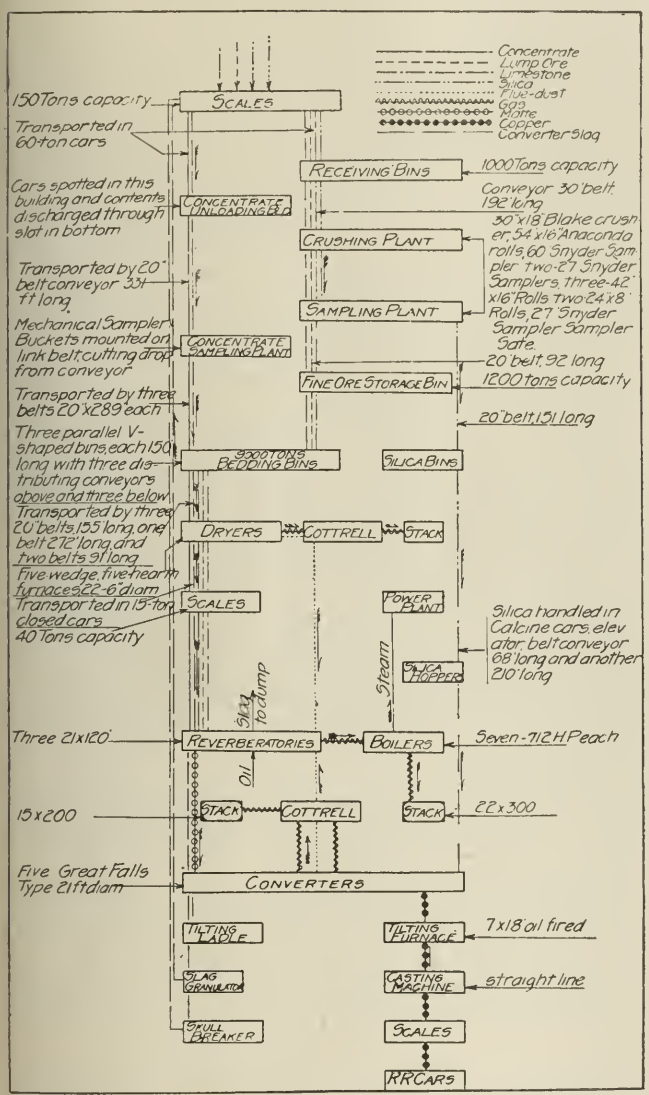

FIG. 1—FLOW SHEET OF NEW PLANT OF INTERNATIONAL SMELTING & REFINING COMPANY

The Copper Queen Consolidated Smelter was the subject of a paper by Mr. FOREST RUTHERFORD of Douglas, Arizona. The plant was started in 1904 with five blast furnaces and four converters, and was immediately enlarged to ten blast furnaces and seven stands of converters, being completed in 1907. Although larger, it still contained no reverberatories. The furnace charges were quite fine, 40 per cent passing a ¼-in. screen, and as a consequence dust losses were high. An investigation resulted in correcting the trouble by enlarging the dust chamber, diverting converter gases from the main chamber through a separate flue and header to the stack, and finally, after experiments with the Dwight-Lloyd sinter-roasting process, adding six McDougall roasters and two reverberatories. Changes in ore supply necessitated the later construction of one more reverberatory and three roasters. Again, on account of an increase in sulphide ores, seven more roasters were added to partly roast the material for the blast furnace and give better control over the sulphur content, and consequently the grade of matte. The old barrel-type of converters were replaced with 12-ft. Great Falls vertical type, and acid lining gave way to basic. Where the old plant in 1904 could treat with difficulty 2000 tons per day, the present plant can easily handle from 4000 to 5000 tons and can be run in such a manner that metallurgy and costs can receive careful attention.

The method of fettling the reverberatory furnaces is different to that found in other plants. No barren silicious material is used, as with the basic slag made it is too expensive to keep the furnace properly fettled with this material, and it has a tendency to blanket the charge. At present the front half of the furnace is lined with magnesite brick and is not fettled; in the back half ore is used for protecting the lining, running as high as 35 per cent iron, as low as 25 per cent silica, with sulphur from 15 to 18 per cent, and copper about 5 per cent. It is essential that the ore contain enough sulphur to matte the copper, or it will be carried out in the slag in the form of prill.

Progress in Copper Metallurgy in the Globe District, Arizona, is briefly outlined in a paper by Mr. L. O. HOWARD of the Old Dominion Copper Mining Co. Prior to the present decade different small smelting plants had been operating in the district, and the Warrior Copper Co. had made an unsuccessful attempt to leach oxidized and silicate ores with sulphuric acid. The United Globe and Old Dominion smelters remained in operation, but they were poorly equipped and were operated intermittently on account of uncertain supplies of ore due to poor railroad facilities. With improved transportation facilities conditions improved; but it was not until Phelps Dodge & Co. obtained control of the Old Dominion that a betterment in metallurgical practice began. The furnace equipment has been increased until the plant has a capacity of 1500 tons of charge daily. No reverberatories have ever been built, and the fine concentrates are mixed with coarse ores, relying on adequate dust chambers to recover the flue dust. Improvement in converting practice began when the usual barren silica and clay lining was replaced by silicious copper ores with aluminium slime from the concentrator for a binding. Later, blast-furnace flue dust was added to the mixture to the extent of 25 per cent without materially shortening the life of a lining. Finally, the Great Falls type of basic-lined converter was adopted. With this installation, using only one shell at a time, it has been possible to produce more than three and one-quarter million pounds of copper per month from a 42 per cent matte. One converter has been in continuous use for over 18 months, producing more than 45,000,000 pounds of copper without expending one cent for repairs to the lining.

The existing concentrator was remodeled in 1912, its capacity being increased by 500 tons. Oil flotation is used for the recovery of the fine material.

The Design of Modern Copper Plants is ably reviewed in a paper by CHARLES H. REPATH of Los Angeles, Cal., who has constructed some of the most modern copper smelters. The author speaks of the necessity of an organization of experts in order to secure the best results in design and construction of a copper smelter. The Washoe smelter of the Anaconda Copper Mining Co. is cited as the first of the great modern plants that was built by a corps of trained specialists. The design was based on experimental work in older plants; but as larger units were required new designs were made either by the company's engineers or by manufacturers, with the result that many innovations were made, such as large roasting and reverberatory furnaces, blast furnaces and converters. The segregation of the different departments was adopted because of the magnitude of the operation and to provide room for extension.

The author reviews the general principles in design and construction that are now followed in copper smelting plants. An accurate sampling and weighing plant is a necessity if metallurgical operations are to be conducted intelligently. The modern sampler delivers 1.6 lb. of ore to the sample bin for every ton that passes through the equipment. Automatic-recording belt-weighers record the weight to within 0.5 per cent. Belt conveyors are used for transportation of ore between different departments, displacing intermittent methods by means of cars. Bedding plants are used to secure proper mixture of ores for the furnaces. The weight and analysis of the bedded materials are known, and when the bed is partly completed calculations are made to determine its constituents and see what additions must be made to give the desired mixture. The beds are uniformly built by automatic trippers and reclaiming is done by Robins-Messiter machines, which remove the material simultaneously from all parts of a cross section of the bed and deliver it to conveyors.

In the design of roasting furnaces concrete hearths are proving satisfactory and are likely to displace the ordinary brick hearth. The furnaces are of the McDougall type, with superimposed hearths, large central shaft, and air-cooled rabbles and arms. In the Herreshoff furnaces installed at the Calumet & Arizona and the Arizona Copper Co., air is delivered to the furnaces under pressure, and is positively circulated through the vertical shaft and rabble arms.

For the recovery of flue dust, the author is of the opinion that combinations of the flue system, with baffle plates, partitions or wires, and the Cottrell electric precipitation system, may be adopted. Chimneys are built of reinforced concrete, common brick, special brick, and steel plate lined with brick or unlined, depending on conditions. The United Verde has a steel chimney with a 4-in. lining of brick, 30 ft. inside diameter and 400 ft. high. Smoke damage is a problem receiving a great deal of attention, and is being solved by building acid plants or by using high chimneys to diffuse the gases over as wide an area as possible.

Improvements in reverberatory construction have been in the length and width of the furnaces, the use of a larger brick and heavier roofs, the application of fettling material at the sides of the furnace, and the utilization of waste heat for steam generation. Fuel oil and pulverized coal have supplanted direct coal firing. Large furnaces 175 ft. long are being designed, using pulverized coal for firing, and charging the ore along the sides of the furnace. There will be a continuous flow of slag as in blast-furnace practice.

Blast furnaces have been increased both in length and width. They have been built up to 87 ft. long and 7 ft. wide, but the trend of furnace building indicates a length of about 40 ft. and a width of 4 ft. Such a furnace will treat over 1000 tons of charge in 24 hours. Jackets are being made in one length instead of two. 17 ft. long and 3 ft. 4 in. wide. Furnaces are being built with air-cooled tops of structural and plate steel and no brick work. The use of hot blast has not proved satisfactory, although in theory it should be economical; but the first cost of the furnace is greater and the repairs may be more due to greater complication. Mechanical systems are used for delivering ores to the blast furnaces. Charges are usually made up at storage bins, weighed into scale hoppers and dumped into charge cars. The latter are then hauled to the furnaces by electric motors and dumped by air hoists.

"At the Calumet and Arizona plant the method of charging the furnace is new and unique. The ore and coke bins are located on the charging floor, and above it, so that the material will drop through openings in the bottom of the bins into the charge cars. These bins are filled by means of conveyors from the bedding system where the ores have been properly mixed ready for charging the furnaces.

"The gates in the bottom of these bins are air operated, and so are easily manipulated. The large charge cars stand on scales located in the floor, and the man who has the work in charge loads into them the ore or the coke, as may be required. These cars have four compartments, so that the amount placed into each compartment will be the amount required in the section of the furnace that it is supposed to serve. After the car has been loaded, it is moved forward and dumped into the furnace. The bottom of the car is on a 45 deg. slope, so that as soon as the doors are released by the operator, the charge drops into the furnace. There are four cars to each 40-ft. furnace and they are alternately loaded with ore and coke. The car is electrically propelled. There are four large doors to each furnace and they are operated by compressed air.

"Another unique feature in the construction of these furnaces is the method of supporting the side and end jackets. The side of the furnace is supported by a built-up plate girder which becomes the lower side of the bustle or main air-pipe, thus using a minimum of space for supporting the jackets and permitting their removel when necessary for repairs. From this heavy girder, and also from the girders at the top of the furnaces, screw jacks are provided, and they are connected to the top and center of the jackets, the screw adjustment permitting the securing of the jackets in a strong and substantial manner."

Slag disposal is accomplished by hauling to the dump in ladle cars holding from 20 to 25 tons. Under certain appropriate conditions the slag can be granulated in water and sluiced to a dump. The recovery of the heat in the slag has been the subject of much experiment, but little has been accomplished in a commercial way.

Large cylindrical and vertical converters with linings of magnesite brick are now generally used. Cylindrical converters are built up to 10 ft. in diameter and 25 to 30 ft. long. The vertical type is built as large as 20 ft. diameter. The method recently adopted for disposing of converter slag is to carry it by cranes to reverberatories into which it is dumped. The furnaces act as settlers which permit the matte to separate from the slag. Where converter slag is to be used in the blast furnace it is cast into a mold arranged on a machine such as a Walker casting machine. The breaking of ladle skulls is now done by the McGregor skull breaker in which a drop hammer on a traveling crane breaks the skulls into pieces small enough to pass a grizzly with 6-in. or 8-in. openings. Copper is handled in casting machines of two types, round and straight-line. While

more power is used about a modern smelter, it is produced cheaper than formerly. Costs have been greatly reduced in every department of a modern copper smelter.

The Physical Properties of Copper was the subject of a paper by Prof. CARLE R. HAYWARD of the Massachusetts Institute of Technology. The paper gives electric and thermal conductivities and an account of the effect of gaseous and metallic impurities. Accurate equilibrium diagrams are a great aid in choosing elements to produce a certain effect. The heat treatment of copper alloys is of greatest importance and needs systematic research.

Mr. Addicks discussed the effect of oxygen on copper and suggested the casting of ingots on end as in steel practice.

Electrolytic Copper Refining was the subject of two papers on this subject, covering the development and progress in the art of electrolytic refining.

The first, by Mr. A. C. CLARK of the Raritan Copper Co., Perth Amboy, N. J., states that commercial electrolytic refining of copper did not begin until 1860, when batteries were used as a source of current. The dynamo came into existence in 1866. The Welsh process of copper refining had been developed to a high state of

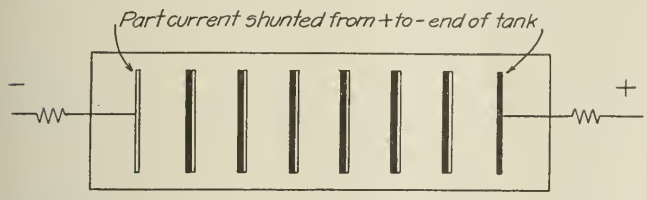

FIG. 2—SERIES SYSTEM

perfection, but failed to produce copper of high electrical conductivity. Gold and silver could not be parted from copper by this method, and in 1883 electrolytic copper refining began to be widely considered. Two refineries were established in 1887, and from that time the growth in electrolytic refining was enormous. The present output is about 1,500,000,000 lb. per annum.

Two systems of electrolytic refining are in use, the series and the multiple, each having advantages and disadvantages. The arrangement in the two systems is shown in Figs. 2 and 3.

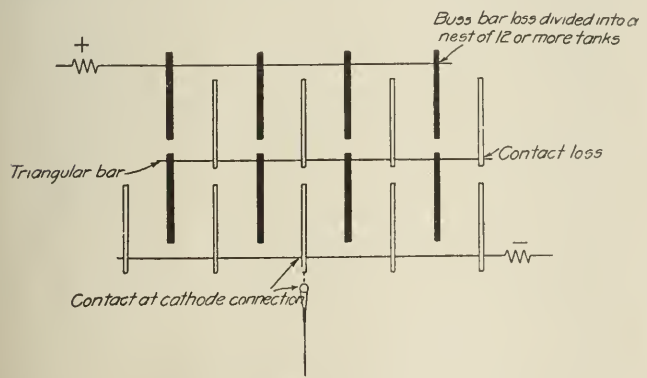

FIG. 3—WALKER MULTIPLE SYSTEM

The series system probably found favor in early days owing to lack of a suitable generator. Standard generators having a normal ampere output were satisfactory for use in this system, while it was necessary to use a number of generators connected in parallel to generate sufficient ampere current for the multiple system.

The multiple system has been greatly improved in recent years, and the former difficulties simplified by Walker's arrangement. Instead of using one tank subdivided into two cells, with heavy copper bus-bars on each side of tank and individual connecting contact strips between the electrodes of each cell, Mr. Walker groups his cells in batteries of from 10 to 17, requiring only one heavy bus-bar for the first and last cells, and by using small triangular copper bars on the intervening partitions of cells, he effects a two-fold saving in voltage, due to a shorter electrical circuit and to a lower resistance due to the sharp contact between the anodes and cathode rods and the triangular bars. This system also largely decreases the cost of installation. The internal electric circuits—namely the rod supporting the cathode and the clips between the cathode and cathode rod, the copper resistance of the anode itself, and the three electrode contacts—still form a serious loss in the multiple system that is not in evidence at all in the series system. However, the potential of the multiple system is so extremely low that it is easy to obtain an ampere efficiency of 90 per cent, while with the series system the current leaking from the first positive to the last negative electrode in the tank effects a power loss which fully equals the loss by the voltage drop in the copper circuit and contact resistance of the multiple system.

The quality of electrolytic copper has greatly improved. Early production was irregular in quality, due to impurities, and sold at a discount from the price of Lake copper; and this unjust discrimination has continued to the present day. At present electrolytic copper is uniform in quality and far superior, by analysis, to Lake copper. The early irregularities in quality were due to engine or generator troubles, insufficient circulation of electrolyte, undue variations in temperature, irregular chemical composition of solutions, etc. At present, however, electrolytic cathodes are hard and smooth and assay 99.96 per cent copper. As showing the high degree of purity of electrolytic copper now produced, its conductivity is frequently 102 per cent and over, based on Matthiesen's standard on supposedly pure copper in 1865. Arsenic is the most deleterious substance in refined copper. If 0.01 per cent is present, the conductivity is reduced about 3 per cent. The maximum quantity of arsenic permissible in first-class electrolytic castings is 0.002 per cent in oxide form.

Electrolytic solutions are generally circulated by centrifugal pumps invented by F. L. Antisell, of Perth Amboy. The pump is made of hard lead, without packing glands or wearing parts being subjected to corrosion. Charging machines are used to charge the furnaces, which have capacities up to 500,000 lb. Furnaces are partly or wholly lined with magnesite or chrome brick instead of the old silica brick, thus effecting a saving in slag production and cost of repairs. Casting machines are generally used. In the Clark & Clark casting wheel used at the Raritan works, the copper is tapped from the furnace into a ladle and six bars poured simultaneously, the molds being set radially on the casting wheel.

In the paper by LAWRENCE ADDICKS, the author points out that the development of the dynamo provided a suitable source of current for electrolytic refining and at the same time made possible the development of many electrical industries and thereby created a demand for high conductivity copper which can be produced only electrolytically.

If we say that electrolytic refining costs ½c a pound over fire refining and that copper sells for 15c a pound, it will take but a 3 1/3 per cent gain in conductivity to pay for the refining, when electrical uses are involved. Further, it is quite impossible to make a clean separation of silver and gold from copper by fire methods, while the "values" in cathode copper run but a few cents a ton. Copper is nearly always associated with silver and gold and our ½c a pound increase in cost calls for but $10 a ton of either or both of these metals to justify electrolysis from this standpoint.

The author divides the development of copper refining into three stages: That of early development; that of tonnage extension, and that of efficiency work. The first period ends with the introduction of mechanical ladling and the general use of cranes for handling electrodes; the second period covers about six years and witnessed the construction of the first really large plants; the third period covers the ten years just closed, with plenty of work in sight to put refining on a finished basis.

As a result of the construction of large furnaces, up to 600,000 lb. capacity, refining is done for less than half the cost in the best of the old hand-ladled furnaces.

Furnace charging is now done mechanically at the rate of 300,000 lb. an hour. Melting has been accelerated by forced and induced draft, and the modern furnace has waste-heat boilers. Hand-firing, combined with what is practically a gas-producer fire-box, holds its own as against mechanical stoking, oil firing or the use of pulverized coal. Coal consumption has decreased with the increase in size of furnaces, from about 20 per cent at 40,000 lb. to 10 per cent at 600,000 lb. Hand-rabbling has been displaced by blowing with compressed air. Skimming is done by rabbles, but the proportion of slag made has been reduced from 4 per cent to less than 1 per cent by keeping silica from the furnace lining, or from coal ashes, away from the cuprous oxide formed while melting and blowing. Crushed low-sulphur coke or anthracite coal is used to blanket the bath instead of charcoal. Poling is still done with green hard-wood poles. Ladling is done mechanically at as high a rate as 90,000 lb. an hour. Fettling is practically eliminated in basic-lined furnaces.

The only obstacle remaining to making furnace refining a continuous melting process, is sulphur brought over as sulphates from the tank-house or absorbed from the products of combustion.

The characteristics of the power requirements are high amperage, low voltage direct current, with a 100 per cent load factor. As individual circuits are limited to about 1500 kw., the reciprocating steam engine is at its best under these conditions, and up to date a high-economy, slow-speed, compound- or triple-expansion engine, generating a kilowatt-hour for about 15 lb. of steam at 150 lb. pressure sq. in., 100 deg. Fahr. superheat, and 27-in. vacuum, has been favored.

In the tank-house the Walker system of connections mentioned above has been adopted. The size of anodes has been increased to 3 ft. square, and even to 4 ft. in one leaching plant. The number of anodes in a tank also has been increased from 26 to 32. Current densities have risen to nearly 20 amperes per sq. ft. A current efficiency of about 90 per cent seems to express the economical balance between labor and power. Lead-lined wooden tanks are still used, but much experimenting is under way with various types of tank construction. With anode copper of 99 per cent or over, an electrolyte with 2.5 to 3.0 per cent copper and 12 per cent free sulphuric acid will give good results with almost any quantity of arsenic, nickel, etc. The electrolyte is generally purified by daily diverting the necessary portion and removing copper and arsenic as a cathode sludge, using insoluble anodes. The resulting liquor is concentrated by steam in lead-lined tanks and direct heat in iron vessels to a heavy liquor consisting of strong sulphuric acid and sodium sulphate, the sulphates of iron, nickel, etc., having fallen out as anhydrous salts. The sodium sulphate can be removed by chilling, and the sulphuric acid returned to the electrolyte. The addition of a small quantity of hydrochloric acid or salt causes antimony to slime as oxychloride. Glue or similar organic addition agents in small quantities aid in forming smooth cathodes.

The refining of anode slime is still in a transitional stage. Wet processes are being experimented with on account of metal losses in fire processes. A simple fusion of raw slime will give bullion, matte and slag. The bullion will contain lead, copper and the precious metals; the matte, copper, silver, selenium and tellurium; the slag, arsenic, antimony and the more easily oxidized metals. If the slime is roasted to oxidize copper, and that metal then dissolved as sulphate in suitable tanks, the remaining slime will form little matte when fused. After fusion in a small basic reverberatory the bath is skimmed clean and the base bullion refined to a high grade, done by blowing and nitreing. The slag is sorted, part sent back to the anode furnaces, part desilverized by a quiet fusion to free it from prills and part charged back into the silver furnace. The silver and gold are generally parted electrolytically and the resulting gold slimes treated for recovery of platinum and palladium. Selenium is recovered from the silver refinery flue dusts by leaching and reduction with sulphur dioxide.

One of the great difficulties in the way of devising a comprehensive wet process lies in the great variation in composition of the slimes at different times and places and in the number of elements present. The strong solvent action of ferric sulphate upon copper and the purity of silver chloride precipitated from foul solutions give a foundation for a wet process. The progress in electrostatic fume recovery is helping out the older process.

Leaching of Copper Ores was the subject of a paper by Mr. W. L. Austin, Riverside, Cal. This is an elaborate compilation, correlating important data collected from the recent extended experiments of different companies. The process is applicable under different conditions as at Chuquicamata, Anaconda and Calumet & Hecla Sulphuric acid is the choice of lixiviants. As to precipitation, local conditions determine the choice between scrap iron or chemical or electrolytic precipitation.

Friday Sessions

The two last sessions of the Section on Metallurgy were held on the morning and afternoon of Friday, Sept. 24. The morning session in which Mr. Chas. Butters presided was devoted to the symposium on gold and silver, arranged and edited by Mr. C. W. Merrill. The papers by G. O. Bradley on a coarse crushing plant of 1000 tons capacity, L. D. Mills, and M. H. Kuryla on crushing and grinding, M. H. Kuryla on solution of gold and silver, L. D. Mills on filtration or separation of metal-bearing solution from slime residue, and G. H. Clevenger on precipitation were read and discussed.

The afternoon session in which Mr. E. B. Braden presided was devoted to the papers on zinc (symposium arranged by Mr. W. R. Ingalls), lead, and fuels.

Limitations of space force us to reserve accounts of all Friday papers and discussions for our next issue.

All the social functions of the Congress and the excursions were carried out according to the program. The whole congress was a great success.

Canada Mineral Production.—The value of the mineral production in all Canada in 1914, according to revised statistics, was $128,556,268, as compared with a total output valued at $145,634,812 in 1913. In the Province of Alberta the 1914 production was $12,684,234 as compared with $15,054,046 in 1913. Coal is the leading product in this province with about ten and a half millions in 1913 and nine and one-third millions in 1914. No gold is recorded as having been produced in 1913 and only to the value of $992 in 1914.

The Aniline Dye Situation*

BY I. F. STONE

In rising to speak of the aniline dye condition in the United States at this time, it is perhaps needless to repeat what is already known to those who are interested in aniline colors either as merchants or consumers, and in fact, known to many of the public through the newspapers; that there is a very great shortage in supplies owing to the fact that goods, which formerly came from Europe upon which we depended largely for our supplies, are by reason of the war no longer sent over; therefore, American consumers are not able to get anything like the supply to which they have been accustomed and upon which they depended.

Eighty per cent of the colors consumed in the United States were brought over from Europe, principally from Germany, so that upon the stoppage of the imports from Europe, 80 per cent of the supply would naturally disappear. The other 20 per cent had been furnished largely by American manufacturers, but even this 20 per cent of the supply has not been maintained by the American manufacturers because they have been depending upon Europe for a large part of their intermediate or raw products, and when they were no longer able to get these products from Europe, naturally they could only run their factories as long as their stock on hand would enable them to do so. Their only chance, then, to continue running their factories was to make these raw or intermediate products themselves, and while this has been done to some extent, as I will explain later, it has not yet reached a stage where they can get full supplies of every raw material they need to produce the full line of colors which they have been manufacturing. Consequently they are unable to furnish some of the colors which they formerly supplied.

This leaves the consumer in a very critical position, as if he wishes to run his factory he must do so without his usual colors, meaning that he would have to make a different class of goods as far as colors are concerned, or else only operate part time, or close down altogether for lack of these dyes. Most of the factories have adopted the part-time method, in that they are manufacturing such goods as require little or no dyestuff, or else manufacturing such goods for which they can secure colors in America to manufacture. In some lines, for instance the hosiery and possibly the leather manufactures, this can be done to quite a large extent, as they use mostly blacks and other dark colors which are manufactured comparatively largely here; that is, for hosiery, direct and sulphur blacks, and for leather, blacks, nigrosines and logwoods, which can be obtained here almost in the necessary quantities. Other lines of manufacture, however, requiring fancy shades—such as silk manufacture, or manufacture of goods requiring indigo, alizarines, and other fast colors, paint and printing ink manufacturers, requiring special colors for their lakes to make their paints and printing inks, paper manufacturers requiring large quantities of blue to manufacture white paper and fancy shades, and many other industries not mentioned—are unable to obtain anything like their requirements and are accordingly not doing their usual volume of business, and many employees are therefore working only part time at a consequent great loss to themselves and to their employers.

The reason for this acute situation is manifestly, of course, the present European war, but, as a matter of fact, it could have been avoided largely by what I might call better judgment of two nations, viz., Germany and the United States. In explaining the situation I shall perhaps have to say something which will reflect upon the business methods of one nation—the German—and the political methods of the other nation—the United States. But whatever I do say will be without animosity, and simply a plain statement of facts, and should be taken as such.

*An address delivered before the National Exposition of Chemical Industries, New Grand Central Palace, New York City, Sept. 22, 1915.

The Attitude of the German Color Manufacturers

At the beginning of the war it was, of course, impossible for the German factories to ship their usual quantities over here because of the fact that the German Government had taken charge of all the railroads and other means of transportation for moving their troops and war supplies, and the German factories could not therefore get their colors to seaport for shipment; but after a couple of months this condition changed so that they were able to get their goods to the seaport, and did commence to make quite good size shipments to the United States, owing to the fact that they were able to do so on neutral or American vessels, and there was then no interference with these shipments on the part of England. The first large shipment, for instance, was made on the SS. Matanzas, which was chartered by American firms and sent over specially for the bringing over of dyestuffs, and this vessel subsequently made several other trips.

After this followed many other chartered vessels, and comparatively regular shipments were made until the spring of this year, when they ceased completely, for the reason, I believe, partly of the action of England in taking measures to prevent such shipments, and partly because the Germans were disinclined to make shipment when they could not get anything in return from this country, cotton and foodstuffs for instance. Had, however, the German firms taken advantage of the time when they could make shipments and had sent to this country a large supply of their products, their agents here could have accumulated large stocks which would have carried them over a long time and so largely prevented the acute shortage of the present time. But for reasons best known to themselves, they decided to ship to this country each month only about 75 per cent of their regular normal shipments, consequently a shortage of at least 25 per cent, and perhaps more, continued in spite of the German shipments. When I say that the German factories could have made large shipments, I say this for the reason that normally only about 20 per cent of their production was shipped to the United States, while the other 80 per cent was used in their own country and shipped to other parts of the world, and as at the time of the war they were barred from shipping to other parts of the world, a large percentage of this 80 per cent was available for shipment to the United States, and they could therefore have shipped to us many times the quantity they did ship, and if they had done so their American agents might have acquired a stock which would take care of their customers for perhaps a couple of years or more on some, if not all, of the colors. I say, therefore, that the German firms are responsible for the difficulty and the acute position of the American consumers. Their primary reason for this holding back of shipments was probably due to the fact that they did not want American consumers to get an oversupply of colors so that they could make up extra quantities of goods which they might use for export to customers in other countries who had formerly bought the same goods from Germany, but who could no longer obtain them. Therefore, they restricted as far as they could the American supply so that they would only have enough goods to supply what might be called their normal trade and could not increase their production.

On the intermediate or raw products which they had formerly shipped to American color factories an embargo was immediately placed by the German Government, so that they could no longer be shipped, the embargo being apparently for the reason that many of these materials were for the use of manufacturing explosives which were required by the German Government in their war movements; but as a matter of fact many of them, like aniline oil, beta naphthol, paranitraniline, naphthalene, and such articles, were not so necessary for this purpose, and large quantities of these could easily have been shipped over here and used in the manufacture of colors by American factories, and also in many cases by consumers themselves, as, for instance, aniline oil for blacks, and paranitranilin and beta naphthol for manufacture of colors by paint manufacturers.

The movement of German colors and intermediate products and chemicals was really controlled by a committee called "Verein zur Wahrung der Interessen der Deutschen Chemischen Industrie," the chairman of which, I understand, was a director of one of the large German color factories, and the reason then that larger quantities of various products were not sent when they could have been sent was evidently due to the judgment of this committee in reducing and finally stopping, because they considered it to the best interests of their manufactures to do so, for reasons already partially explained, and they therefore are really responsible for the present acute condition of the aniline dye supply in this country.

Whether or not it was really to their advantage to take this position it certainly was not to the advantage of American consumers, therefore in the future it seems to me they should bear in mind the position taken by German manufacturers in that the American consumers' position was not considered, and in the future ally themselves as far as they can with American manufacturers who are developing or about to develop the manufacture of aniline dyes in America to as large extent as may be possible, or to a comparatively small extent if the American Government does not come to their support by fixing a new and higher tariff on these goods so that American manufacturers can compete with Europe under normal conditions, but to a large extent if such protection is given.

The Situation of the American Manufacturer and the Necessity of a Tariff

This is really the crux of the whole situation as far as American manufacturers are concerned, viz., whether or not they will be given proper protection, and if so, as I have said, the business will develop to a large extent and in the course of time be practically independent of foreign supplies. I made this same statement in a circular which our company issued on Sept. 1, 1914, just a month after the war started, that is, that the American manufacturers could not make much progress without such protection, which I again repeated in an address before the American Chemical Society of New York on Oct. 9, 1914. As a result of this address, a committee was appointed by the American Chemical Society to look into the matter, and this committee subsequently reported on Nov. 6, 1914, that such protection was necessary, and advocated that the present duty of 3 per cent ad valorem be continued with an additional duty of 7½ cents per pound specific on finished colors, and an ad valorem duty of 15 per cent and 3¾ cents per pound specific on the intermediate or what might be called half-finished products.

This necessity was so apparent that it was even signed by one of the committee, Mr. H. A. Metz, who is the American representative of a large German color factory, whose personal interests naturally lie in the importation of colors, and who would not have signed it had it not been absolutely a necessary action if the development of the color business were to be largely increased in the United States.

This resolution, or report, was duly sent to the proper authorities in Washington, and has been on file there since that time. It is a reflection, I think, on the American Government that no action whatever has been taken in this matter, but here comes a question of politics, the present administration having been elected on the platform advocating reduced tariffs, and therefore will not apparently go back on their platform, even under the present unusual and unexpected conditions, even though American consumers are suffering for relief, in that many thousand employees of manufacturers requiring colors are reduced to only part time and, in fact, some of them laid off entirely by reason of their employers not being able to secure the necessary amount of dyestuffs to continue their regular productions.

In other words, the position of American consumers at present is not a political one, but one of cold fact, and should in my opinion have the attention of the administration irrespective of previous policies. Except that they have had practical example of the workings of a low tariff on aniline colors and coal tar products, and its flat failure as connected with this line of business, the result of which is the present deplorable condition, the present administration is no different from previous administrations for the last twenty-five or thirty years, both Republican and Democratic, none of them having given this necessary protection, and as a result not allowing the business to develop as it would have developed had they done so.

It is perhaps some excuse that they did not realize how large a part in the success of the manufactures of textiles, leather, paints, and many other lines, depended on their supply of dyestuffs, in that the business itself was perhaps not large enough to demand their careful attention, and they did not take into consideration the fact that so many other great lines depended on their supply of these goods. This fact was also not realized by many of the American consumers themselves, as is evidenced by the fact that during the many years that the tariff matters were before successive administrations many American consumers of dyestuffs fought an increase of duty thinking that it might increase their costs and evidently preferring to buy foreign goods at what they considered lower prices than to support the manufacture in America at a possible increase in cost to themselves by reason of a higher protection.

The fallacy of this position is now absolutely apparent in that the consumers are now not only not able to get sufficient supplies for their wants, but on what they do get are forced to pay fabulous prices, and certainly the extra cost of their supplies and their losses through failure to run their factories regularly will far exceed a slight possible advance in the cost of dyestuffs by reason of their being made in America under a protective tariff.

As an instance of prices which they are forced to pay when they do get goods I might mention a few products:

Sulphur black, which is used very largely by the hosiery and cotton trades, and which sells normally at about 20 cents per pound, has brought as high as $2.75 and even $3 per pound.

Indigo, which sold formerly at about 15 cents, has been sold as high as $1 per pound, even more.

Aniline oil, the normal price of which is about 10 cents, as high as $1.75 per pound.

Beta naphthol, with a normal price about 12 cents, sells as high as $1.50.

Paranitraniline, normally about 15 cents, sells as high as $1.75.

I might continue this list indefinitely, showing where all products for which consumers depended on European supply, that is, which were not manufactured here, are now selling at anywhere from five to twenty times their normal value.

I might call attention in this connection to the fact that these enormous advances do not apply on colors and products which were made regularly in America; for instance, such products as direct black, Bismarck brown, chrysoidine, nigrosine and any number of other colors, have not been advanced by American manufacturers more than two or three times their normal selling price, and this advance was only caused by reason of the fact that their raw materials are also used in the manufacture of ammunition and explosives and are now in large demand for this purpose, so large a demand, in fact, that American manufacturers of colors have been unable to get adequate supplies, and so for what they do get pay abnormal prices; benzol, for instance, having advanced from a normal price of about 20 cents to as high as $1.25 for immediate shipment, and on contract to about 65 cents at the present time, while toluol, with a normal price of about 25 cents, has been sold as high as $6 for immediate supply and on contract at this time about $4.25. Had these advances not taken place by reason of their demand for other purposes the manufacture of American colors could have continued on almost normal lines, so they are not to blame for the necessity for advancing prices to the extent they have, which, however, is no comparison to the advance in the prices of European colors which have not been made here.

I might say that the one American manufacturer of aniline oil before the war, even in the face of these enormous advances, continued to fill contracts at the old contract prices, and when they arranged to increase their production to a large extent only advanced the price in proportion to the advance in raw materials, and had it only been able to manufacture enough aniline oil to supply the country, which it was not at the time, the price on this article would not have soared to $1.75 as it has, but would have been held to some reasonable figures. This shows the policy of real American manufacturers, which is to protect their customers as far as possible under unusual conditions, and has also been the policy of color manufacturers.

The matter of tariff being so important a factor in the development of the color business in the United States, I might call your attention to an article recently written by Dr. B. C. Hesse, a well-known aniline expert, and published in pamphlet form, headed, "Who Killed Cock Robin?" and which gives the United States tariff history for the past thirty years. He calls attention to the fact that there was from 1880 to 1883 a duty of 35 per cent ad valorem and 50 cents per pound specific on aniline colors, which gave ample protection to the industry, and as a consequence there were then nine or ten factories in the United States, and the prospect of becoming independent of other nations for our supply of these aniline products was bright indeed. But the passage of the tariff act of July 1, 1883, which abolished the specific duty of 50 cents per pound, leaving only the ad valorem duty of 35 cents, and fixing a 20-cent duty on the intermediate products, which left only a net protection of 15 per cent, immediately checked the industry here. No new factories were started, and within one year after the new tariff took effect five of those already established were forced to succumb and go out of business, leaving only four to continue the work, who have since stayed in business but have not been able to develop to any extent. I might say that a specific duty of 50 cents at that time was not exorbitant, as the prices of aniline colors then manufactured were very much more than they are to-day, colors, for instance, selling at $4 to $5 per pound now sell at only 50 to 60 cents per pound, so that the 7½ cents specific duty now recommended by the American Chemical Society would not be very far out of proportion to the 50 cents per pound at that time.

Had a proper duty been kept on these aniline products, say from 1883 to about 1900, during what might be called the golden progress of the industry, when so many new colors and products were brought out, the business might be here to-day in the same prosperous condition as it has been in Germany, where, as everybody knows, enormous factories have been erected and the business of the world practically controlled by them. It is, of course, due to the Germans to say that many of their new products were patented colors produced through the careful research work of their chemists, but no one can say that American chemists would not have been equally diligent in research work had they had the same opportunities. Moreover, had the United States at that time had a proper patent law which would compel the manufacture in this country of all goods patented by foreign residents, it would have protected the industry and insured its great success. Our legislators, however, did not appreciate the importance of the business, and so failed to give us the proper protection and proper patent laws, and therefore the business has drifted away from the United States and resulted to the great credit and prosperity of the German manufacturers.

However, these patents have now practically expired, and the American manufacturers are free to manufacture practically everything that is needed, so I must emphasize again that it is now only an insufficient tariff which prevents the development of the American industry in the future. This pamphlet of Dr. Hesse's also shows that in the various tariff negotiations in Washington during the various administrations, fights against an increased tariff were made not only by foreign manufacturers and their representatives, but were actually supported by American manufacturers and consumers whose names are given and who are now, I think, very sorry that they took this position and did not rather favor a protection and development of the American industry.

The American Consumer

To show you the lines of manufactures which are dependent on their supply of dyestuffs to continue their regular production, I would say the most important, perhaps, are the textile manufacturers, comprising cotton, wool, carpets, knit goods, silk, cordage, shoddy, dyeing and finishing. The following figures are taken from the census of 1909:

	Establishments	Employees	Capital	Salaries and Wages	Value of Product
Cotton ...	1,324	387,771	$822,237,529	$147,270,903	$628,391,813
Wool	985	175,176	430,578,574	82,523,776	435,978,558
Carpets ..	139	34,706	75,627,010	17,745,092	71,188,152
Knit goods	1,374	136,130	163,641,171	52,431,680	200,143,527
Silk	852	105,238	152,158,002	46,097,364	196,911,667
Cordage ..	164	27,214	76,020,366	10,995,545	61,019,986
Shoddy ..	88	2,320	6,886,825	1,196,376	7,446,364
Dyeing and finishing	426	47,303	114,092,654	26,261,634	83,556,432
	5,352	915,858	$1,841,242,131	$384,522,370	$1,684,636,499

You will see that there are over 5000 of these establishments with over 900,000 employees, with a capital invested of $1,841,242,151, who are paying in wages annually $384,522,370 and the value of whose product is $1,684,636,499.

Then there are the leather manufacturers and tanners, of which there are over 900 establishments, with a capital of $322,726,952, employing over 62,000 people and the value of whose production is $327,874,187.

Then again there are the paper manufacturers, numbering over 750, with over 81,000 employees, with capital invested of over $400,000,000 and the value of whose product is over $260,000,000.

Then there are the paint and color manufacturers, about 900 in number, with a combined capital of about $250,000,000 and employing 30,000 men.

As I said at first, these figures are taken from the census of 1909, and those who are interested in these particular lines tell me that there has been an increase in practically every industry averaging about 25 per cent, so that the figures should be something like 20 per cent more than those given. Add to these lines of business others which are not separated in the census, such as printing and writing ink manufacturers, shoe dressing manufacturers, and a hundred and one other lines which consume dyestuffs, and I think I could safely say there are upward of 2,000,000 people employed in industries which require the use of dyestuffs and who are now affected by the present shortage. Others affected, of course not so directly, are the public generally, who will soon find that they cannot get what they want, and will have to take what they can get, and if some changes do not take place very shortly a totally new scheme in colors will have to be presented to the American public.

The Attitude of the Administration

We have now come to a point where we are under unusual conditions, and the American industry again has a chance to develop, and it would seem a pity if the present administration would not take the opportunity to help manufacturers to do so.

The New York *Sun,* in its edition of Sept. 3, had a good article on the subject, and an editorial calling the attention of the President to the fact that while he might be engrossed in very serious affairs, such as the Mexican situation and the foreign wars, at the same time the new conditions and new complications arising from the present conditions should warrant his attention to see what prompt action and judicious protective legislation in the matter of the dyestuff industry might do for the country, saying further that the dyestuff industry is a single illustration only of the great trade advantages which the situation promises. This article and editorial were repeated and supported by many other American newspapers, and certainly represent a step toward accomplishing a revision of the tariff on aniline products to take advantage of present conditions.

I might at this time call attention to a popular belief which I consider a mistake, that an advance in the tariff on aniline products would necessarily result in advance of prices, but this is open to question, as while it is true that many of the cheaper colors might be advanced to some extent, on the other hand, the higher-priced colors, which have not been made in America and which are controlled by European conventions, would probably be actually reduced in price, so that the general average price on everything would not be possibly much different from what it is to-day under normal conditions. Then, again, there is the question of the so-called "anti-dumping clause," referring to the fact that it has been the habit of European manufacturers to sell in this country colors which were made here at lower prices than they sold them in other countries, so as to prevent their development here, while at the same time they held prices at good figures on colors which are not made here and so averaged up their profits. I am glad to say that some legislation against these proceedings is favorably considered by the present administration, and no doubt some law will be passed which will prohibit this so-called dumping in the future.

In view of the emphasis I have placed on the necessity of tariff legislation, it may interest you to know what I have discovered in my interviews with various administration officials to get their ideas on the subject.

Some months ago, Secretary Lane of the Interior Department called a meeting of the various chemical manufacturers to get their ideas as to the situation and what was to be done about it, and at that meeting what little I said was to the same effect as what I am now saying, viz., the necessity of tariff action. Mr. Lane made the observation that if this were done it would create in this country a great monopoly or trust, and he did not think it would be advisable; but as a matter of fact the lack of this legislation has simply resulted in a great trust or monopoly in Germany, so I could not see where there could be any reason in this point. Such legislation would not necessarily create a monopoly here, as any one would be open to go into the business; the only point being that it would put us on equal terms with foreign competition, and this is the only result desired—not monopoly.

Mr. Lane further said, however, that the matter would probably be put in the hands of the Department of Commerce, which eventually did take place. Some time afterward I called on Secretary Redfield of the Department of Commerce and found that he was very sanguine of the ability of American manufacturers, through their ingenuity and ability, to create this business without help of a tariff, and instanced a number of new concerns who had started in the business since the war commenced, giving me the names of parties in Elizabeth, N. J.; Chester, Conn.; Edison of West Orange, N. J.; Wappingers Fall, N. Y.; Newark, N. J.; Stamford, Conn.; Perth Amboy, N. J., and Lincoln, N. J., who were about to enter the business, but as I knew most of these parties through previous inquiry I told him they were not being established for the manufacture of colors, but simply for such intermediate products as aniline oil, carbolic acid, beta naphthol and paranitraniline, which are more easily manufactured, and while they might be profitable under war conditions, could not possibly exist under normal conditions, which I believe is true.

Mr. Redfield was very much interested in the matter, and said that his department was doing everything possible to foster the development of the business in the United States, but could not say that he was in favor of higher tariff, as it was against his policy and against the policy of the present administration, but that he was in favor of some anti-dumping legislation which would prevent the selling in this country of European colors at lower prices than to other countries, and he thought something would be done in this line to prevent it in the future.

Nothwithstanding the fact, however, that the administration as represented by Secretaries Lane and Redfield is apparently opposed to higher tariff, it is a fact that in the meantime Dr. Thomas H. Norton, special representative of the Department of Commerce, gave his views on a dyestuff tariff in the New York *Sun* and the New York *Herald* of Sept. 15. He admitted that in spite of the fact that he does not think the general line of colors need any more protection he does feel that some of them, like indigo, alizarine and others, which are on the free list should have some protection to be successfully made here, and if he were to go a little more carefully into the matter he would find that while 30 per cent duty on the ordinary aniline colors might

be sufficient if it were a clear protection, as a matter of fact the intermediate and raw products which are used in this manufacture carry a duty of 10 to 15 per cent, so that the real protection on aniline colors is not half what it apparently is in the bill. If it were possible to buy these raw materials made in the United States at approximately the same prices at which they can be bought in Germany, then the 30 per cent tariff would be more or less effective, but for reasons just mentioned, i.e., the duty on the intermediate products, it is not, and to show that this is a positive fact, without any theories, I would again call attention to the fact that since 1885 there have been practically no new color factories started in the United States, and the great business developed since that time all over the world has been practically controlled by Germany. If these colors had been properly protected, as I have already said, then a large part at least of this great business would have stayed in the United States, and now that we have again a chance to get to a quick development through the present abnormal conditions, certainly we should not throw away another chance to become a great factor in the industry and no longer be dependent upon foreign countries for our supplies.

Manufacturing Costs in Germany and in the United States

In the tariff pamphlet by Dr. Hesse already mentioned, there is a copy of a brief filed with the Congressional Committee who were working on a new tariff in 1908. This brief is dated Nov. 9, 1908, and is a complete statement of the cost and operation of an aniline color plant designated to manufacture 3,000,000 lb. annually. It was written and filed by Mr. J. F. Schoellkopf of the Schoellkopf, Hartford & Hanna Company, now called Schoellkopf Aniline & Chemical Works, and is confirmed and also signed by the Heller & Merz Company, one of the largest and oldest color manufacturers in the United States.

In Table A of this brief it is shown in detail that the cost of such a plant would be $104,000 in the United States and $70,000 in Germany, a difference of $34,000 in favor of Germany.

In Table B the number of employees needed to operate such a plant is given in detail, and shows that their wages would amount to $116,236 in the United States against $61,493 in Germany, again a difference in favor of Germany of $55,000.

In Table C a list of the cost of the material required for running this factory to a 3,000,000-lb. capacity is given, showing that the cost in the United States would be $443,000 for these materials, which are given in detail, while in Germany the same materials would cost only $317,000, a difference of $126,000 in favor of Germany.

In Table D is given the cost of producing the colors as a whole, adding together materials, fuel, labor, interest on investment, depreciation of plant, etc., the table amounting to $693,000 in the United States where it would only cost in Germany $480,000, a difference of $212,000 in favor of Germany.

The net result as shown by these figures is that it actually costs 44 per cent less in Germany to make colors than it does in the United States, and while, of course, these figures are now somewhat old, I think the same difference would still be true at the present time.

Take, however, the possibility that the present manufacturers are not correct in their statements as to this increase of duty being necessary, let us take the opinion of two possible new manufacturers; for instance, Mr. Thomas A. Edison, who when the war started found that he could no longer get the large amount of carbolic acid which he consumed, and which was formerly furnished from Europe, promptly started to manufacture it himself, first making an arrangement with a large steel works for the benzol to make it from. In making the carbolic acid he also decided to produce aniline oil, and has been a producer of these products for some time. It was rumored at that time that he also intended to take up the manufacture of aniline colors, and this same rumor has been repeated in the public press in the last few days. Now, in an interview with him, published in a recent edition of the *Journal of Commerce*, he is quoted as saying that we can only become independent of Germany in the dyestuff industry if Congress will allow a moderate tariff, confirming the opinion of older manufacturers, and showing that after looking into the matter he was convinced that colors or coal tar products could not be manufactured successfully here in competition with Europe unless they had the proper protection.

Then the Pearsite Company of Cannel, Ky., who had lately been extolled by Dr. Norton as having a marvelous new process for manufacturing aniline colors by which they could manufacture them cheaper than the Germans and would soon control the entire consumption of the United States, gave an interview in the New York *Times* of Sept. 9, by Col. H. P. Bope, who is its president and also vice-president of the Carnegie Steel Company. Mr. Bope states in answer to a question as to whether his company could continue to compete with Europeans under normal conditions that he believed that the men in charge of affairs at Washington would readily see the necessity for and would give them the protection in tariffs that comes to all American industries. So you will see that Col. Bope's mind was also running on the line of protection in spite of the fact that the supposed new method of manufacture would entirely alter the whole situation.

The Attitude of the Administration Toward the Present American Manufacturers

Now, to come back to what the Government, through the Department of Commerce, are trying to do to help the production of dyestuffs in the United States, aside from any question of tariff, we find that while they are working diligently to do what they can they are starting from an entirely wrong point of view in that instead of trying to help the present manufacturers in the way of, for instance, securing them very much needed raw material and other helps to their production, they seem to be paying more attention to possible new productions, and to the claims of people who think they have wonderful new methods for producing dyestuffs which will render us independent of Europe for all time.

The first reports sent out by the department were to the effect that many new concerns were entering the field, which I have already mentioned in the account of my interview with Mr. Redfield, but it turned out that these concerns were not intending to make aniline colors, but only intermediate products.

Then the next reports of any interest were to the effect that they were working on agreement with the Swiss manufacturers whereby we were to send over to their country raw materials and the Swiss manufacturers were to make them up into colors and return them to us. That this arrangement has failed of any result is very natural, because the United States did not have the raw material to send—in fact, its own manufacturers could not get enough for their own wants—and if there had been any raw materials available it would have been much better for us to have given them to American factories instead of sending them to Switzer-

land. My own firm has recently had correspondence with Swiss manufacturers relative to furnishing them such articles as benzol, aniline oil, acetate of lime and oleum (which is a concentrated sulphuric acid). They stated they were unable to obtain supplies abroad, and we were obliged to write them that we could not get supplies ourselves, therefore could not send them anything from here. Aniline oil and oleum are out of the question, owing to the immense demand for them from American consumers, and benzol is practically barred because of its extremely high price and the enormous transportation charges for carrying it to Switzerland, which brought the total up to more than they are willing to pay.

The next what we might call important or interesting news given out by the Department of Commerce was an announcement in the New York *Times* of Sept. 4, in which it was stated in an interview with Dr. Norton, that an American had solved our dye problem, in that he had invented a new process for manufacturing colors which was much cheaper than the old process, and which would allow his factory to revolutionize the business in the way of costs and production, and that production would begin within two weeks, with a possible production of 5 tons per day, or 35,000,000 lb. per year —the total consumption of the United States, by the way, being about 30,000,000. The name of the concern which was to make these new colors was not given, but the next day, in the *Times* edition of Sept. 5, it was stated that the firm which would manufacture colors by the new process was the Pearsite company, which had large works at Cannel, Ky., and again repeated, with Dr. Norton's approval, that it would be ready to produce dyes in a few weeks, again mentioning 5 tons daily as its probable production, and further interviews with Dr. Norton on the subject were continued for several days, all to the effect that these new colors would be in the market in a few weeks in the quantities mentioned and would revolutionize the dyestuff conditions of the United States and relieve consumers from the present shortage.

I immediately received letters from all parts of the United States asking if we knew anything about the process and if it were true that colors could be had from this new company in so short a time, to which I replied that I did not know anything about it, except the newspaper reports, but that I doubted if it were possible for such a marvelous change to take place so quickly. Later, however, I have been in communication with parties who have actually had dyed samples and tried out the new colors, but instead of having an unlimited line of complicated colors such as are required by the United States consumers, some 900 in all, and which would be needed, a good many of them, to relieve the present shortage, the new company really only had five colors to begin with. This was also confirmed by an article in the New York *Times* of Sept. 15, stating that this would be the number of colors to be produced and giving the names of the new selling agents for these colors. The point to this matter is simply that instead of a marvelous new discovery which would alter the present conditions and relieve the present shortage of colors, as announced by the Department of Commerce through Dr. Norton, we simply have an experimental proposition which will not relieve the situation to any particular extent.

I do not question but that this Pearsite company may have some method of making colors which will produce colors, but I do say that it is impossible for them to have a method which would enable them to make all of the complicated colors consumed in this country and which are made not only from their base—benzol—but many other raw materials which are combined with coal tar products, but which are not related to them at all, and which they could not possibly manufatcure from a coal tar process alone. I do not believe that the Department of Commerce should allow such exaggerated statements to appear in the public press through their intervention, as it simply results in great disappointment to American consumers, who were hopeful that something had been found at last to supply their wants.

Mr. Redfield now says in an article in the New York *Sun* of Sept. 16 that "home dyes will be plenty soon," which if one did not know the conditions would again build up the hopes of consumers, while unfortunately there is no immediate relief in sight, and it must be months before a full quantity of dyestuffs can be obtained, even after the war is over. American consumers must understand this and take it into their calculations in figuring on their future production, and such statements should not be sent out by the Department of Commerce.

What American Manufacturers Have Already Done

Up to the present time I have mentioned the cause of the present shortage, the reason for and hope for a development in the manufacture of colors in America through tariff corrections on the part of the Government, and the attempt on the part of the Department of Commerce to create a new supply through other than ordinary methods, which, however, up to date has failed to produce anything of importance. I will now tell you what actually has been accomplished by American manufacturers to increase the production of American products in the United States, and those who have aided in this development are firms who will continue in business after the war is over, no matter what the conditions may be, even though they may have to do so at little or no profit unless they have some help from the Government. I am glad to say, however, that the development of the coal tar product business in this country will continue to a large extent, irrespective of what the tariff decision may be, but the development will not be anything as large as it would be if the tariff were corrected.

Aniline Colors.—There were five factories actually engaged in the manufacture of these products before the war, the names and locations being as follows:

Schoellkopf Aniline & Chemical Works, Inc., Buffalo, N. Y. (National Aniline & Chemical Company selling agents).

The Hudson River Aniline Color Works, Albany. (Bayer Company selling agents).

Heller & Merz Company, Newark, N. J.

Central Dyestuff & Chemical Company, Newark, N. J.

W. Beckers Aniline & Chemical Works, Brooklyn, N. Y.

When the war started, and the shortage of foreign goods became apparent, these firms were overwhelmed with orders from American consumers for supplies. For reasons which I have already mentioned, viz., their inability to get raw material from Europe, they were not able in the beginning to increase their production, and were compelled to use only the raw material which they had on hand, and when this was exhausted had to give up some colors entirely. In the meantime, however, some of them have commenced to manufacture these intermediate products, and the rest will undoubtedly do so as quickly as possible. Although I cannot speak specifically for any other factory, I can say that our own factory, Schoellkopf Aniline & Chemical Works of Buffalo, by the first of January will be making largely its own raw material, and this, together with what raw material we can get from other manufacturers, has en-

abled us to insure ourselves of a supply of raw material, so that we have increased our regular aniline products to the extent that by the first of January we will be producing something like 800,000 to 1,000,000 lb. monthly, or, say, 10,000,000 lb. annually, which is about four times our former production. While, as I have just said, I cannot speak specifically for other factories, I have no doubt that they are making equal improvements and will show equal increase in production in the course of time.

It is my opinion that an immediate development in the aniline color business in this country will depend entirely on these five original makers, as they are all equipped with capable and experienced men, who are able to direct much larger production than they are now getting and to manufacture successfully, which is a great advantage they have over new factories which may enter the field, who have not had the experience and necessary scientific help to develop the business quickly; and these factories, while having no connection one with another and no conventions nor understandings of any kind, are a unit in declaring that they must have additional protection in order to develop their business to an extent which would take care of the consumption of the United States.

Other large corporations, like the E. I. Du Pont de Nemours Powder Company, the General Chemical Company and Thomas A. Edison, have been recently mentioned as about to enter the manufacture of aniline colors, but I question if they have any intention of doing so in the immediate future, as their present business is so large and the demands upon them so severe that they will hardly be able to entertain taking up new lines in the near future, another difficulty being the inability of any of us or them to secure at present enough raw materials to manufacture even the amount of colors we could manufacture if raw materials were plentiful For instance, one article, oleum, which is a concentrated sulphuric acid, and which enters largely into the manufacture of colors, is almost unobtainable owing to the enormous increase in its demand, due to present war conditions, which require large quantities of it for explosive purposes, and unless sufficient quantities of it could be secured the development of the manufacture of colors could not be carried on by anybody.

Of course, the present aniline works have arranged for their supply of this product now in advance, so have enough in sight to enlarge their production to the extent which I have mentionel; but for a new concern to start in at this time, I think it would be impossible for them to get this, as well as other raw material, which is absolutely necessary, and for this reason, as I said before, I think it rests with the original five color makers to develop the business for the relief of consumers, and while other concerns like those mentioned may enter the field later, it certainly will not be in time to improve matters much for a year at least.

Two other concerns have been mentioned prominently in the papers of late in connection with the actual manufacture of aniline colors, as distinct from those mentioned as manufacturers of intermediates, both concerns claiming to have new methods which are different from the methods used by the older manufacturers in their production. One of them is the Pearsite company, mentioned above, and the other is the American Cooperative Dyes & Chemical Company, Bangor, Pa., who claim to have a new method for making a hosiery black and some other colors of similar nature, and which is now in the course of formation. These two companies, however, are not known to the trade as manufacturers of colors, and the success of their new methods is, therefore, more or less problematical, and the future only will show whether or not they will be successful in their lines.

Aniline Oil.—Until about three years before the war this very important product for the manufacture of aniline colors, and for producing blacks directly through oxidation in dye houses, was not made in the United States, and was furnished almost exclusively by Germany and England, being in the hands of a convention which controlled the price and conditions. About four years ago the manufacture of this product was commenced on a fairly large scale by the Benzol Products Company, now at Marcus Hook, Pa., whose sales agents are the General Chemical Company, who began with a production of about 1000 tons, the whole annual consumption of the country at that time, by the way, being about 4000 tons. This Benzol Products Company did not make much progress financially, owing to the fact that even when a tariff of 10 per cent was placed on this product the foreign convention immediately reduced their price accordingly, that is, assumed this duty and still sold to their consumers here at the regular prices, and such prices did not leave the Benzol company any profit, for they could not manufacture as cheaply as the Europeans were willing to sell for.

At the beginning of the war, however, the imports from Europe stopped suddenly, and the demand for aniline oil became very acute. The Benzol company immediately took the situation in hand and arranged to increase its production as quickly as possible, and has recently completed a new factory, so that it has increased its production very materially, and eventually will reach about 5000 tons, which will be more than the entire consumption of the country under normal conditions, although the consumption will be increased very largely by the probable development in the manufacture of aniline colors, which is the largest use.

This is the concern I have mentioned as having been so fair in making contracts with its customers, that those who have bought from it have not had to pay the exorbitant prices asked by outsiders, and it is to its great credit, therefore, for working directly for the benefit of American consumers without the possible abnormal profit which it might have secured had it wished to take a different position.

In addition to the Benzol Products Company, there have a number of firms started up since the war to manufacture aniline oil, and some of these new factories have already started to deliver, but even at that the total production is not yet large enough to supply the demand. But the point is that in the end enough aniline oil will be manufactured in America to supply the demands of all consumers, so that if properly protected by tariff it will make this country independent of Europe for its supply of this product.

Benzol.—This is the basis product for the manufacture of aniline colors and products, being used, however, largely for other purposes as well as for explosives. Before the present war the normal production in the United States was about 3,000,000 gal. Since the war, owing to its suddenly increased demand, many steel companies and other similar industries who could recover benzol from their other operations immediately began to do so, so that now it is estimated that the production of benzol for 1916 will be upward of 15,000,000 gal., or about five times the original production. Owing to the enormous demand for it from explosive manufacturers, and for export to other countries, the supply in this country, in spite of the increase, remains insufficient, and very high prices are asked. But the important point is that this large production is now assured, and whenever the foreign demand ceases and the de-

mand for explosives ceases the United States will have ample production of benzol from which to build up her other industries which depend upon it; for instance, the manufacture of aniline colors and other similar products, and inevitably in view of the large supply the prices should not be any higher than those paid by foreign manufacturers for the same product.

Carbolic Acid.—This is an article which has a large consumption in the United States, some 8,000,000 to 10,000,000 lb. per annum, but which before the war was not manufactured here to any extent, because American manufacturers could not compete with the German and English. Since the war, however, many plants have been put in and practically all that is consumed here at present is manufactured in this country. Thomas A. Edison alone, who was an enormous buyer before the war, now manufactures 12,000 lb. daily, according to his interview given in the *Journal of Commerce* of July 30, most of which, however, he requires in his own works, so that he does not have much for resale. Other manufacturers are making it mostly for the making of picric acid for export, but after this demand for picric acid is over then the manufacture of carbolic acid will continue here in large quantities for domestic consumption, and the country should then be independent of Europe for its supply. This is another article which is also used in the manufacture of aniline colors, and will help their development.

Indigo.—There is now being built in Charleston, W. Va., a factory for the ostensible purpose of manufacturing caustic soda and chlorine products. It is, however, being built and controlled by a firm which is the agent for one of the largest indigo manufacturers in Europe, and who, I am informed, have all arrangements made to make indigo if it can be done successfully here, which it can in every way, except possibly not as cheaply as in Europe. With a proper protective tariff, however, this plant could be fully completed for the manufacture of indigo, and surely it would be a great relief to American consumers, who use about $1,250,000 worth annually, to have a plant in this country from which they could draw their supplies and be assured of them in the future.

Intermediate Products.—These products were practically all imported from Europe prior to the war, but since the war factories have been started for their manufacture, so are now produced in this country such articles as beta naphthol, paranitraniline, diphenylamine, dimethyl-aniline, H-acid, benzidine, chlor-benzol, and some others, with more to come, all of which being used particularly by the aniline color manufacturers, although incidentally in some other lines; so again, if these new factories are protected by sufficient tariff, the manufacture will go on successfully and we will again be independent of Europe for our supplies.

Naphthalene.—This is another coal tar product which has increased very largely by reason of the present conditions. Before the war the production in this country was about 2,500,000 lb., while now it has increased to something like 7,000,000, perhaps more, the normal consumption being about 9,000,000 lb., and the difference between what was produced in America and the total obtained from England and Germany, which hereafter they should be practically unable to ship over here by reason of the new large production here, and which should be sold in normal times at as low prices as could be sold by Germany and England. This is also a very important intermediate product for the manufacture of aniline colors, and again a help in this production.

Sulphur Black.—This is a color used largely for hosiery and cotton purposes, and which never before was manufactured successfully in this country, or rather could not be manufactured cheaply enough to compete with European products. The probable consumption of it is 4,000,000 or 5,000,000 lb. annually. Since the war our own concern has taken up the manufacture of this color successfully and is now furnishing the goods to consumers. We are rapidly increasing our production so that we will probably produce 2,000,000 lb. or over in 1916, all of which is practically sold on contract. Two other manufacturers have also taken up its manufacture, and are making contracts over the same period, so that it is probable that in 1916 the total amount of sulphur black manufactured in the United States will equal the former import from Europe, and with a proper protection in the tariff this large volume of business could be retained in the United States against all foreign competition.

What Tariff Protection Would Accomplish

You will see from the above that there is something actually being done in the United States in the development of coal tar and allied products, and no matter what happens in the future a large increase in this production will be assured, but I must repeat once more that if it is to be developed to the extent of supplying the whole amount of dyestuffs needed in the country which have heretofore been imported, it must have help from the Government in the way of an increased tariff, and the help of every consumer should therefore be given to bring about this very desirable result.

I wish to impress upon you in connection with the above list of what has been done, that on many of the products we are already producing in this country the normal consumption of the country, and this production will be kept up if properly protected. A notable exception to this statement, however, is aniline colors, which are so badly needed, but which, owing to their variety and the complicated formulæ and range of raw material necessary to make them, as well as the large amount of capital necessary to manufacture them in a large way, have not been developed to the full quantity needed. But even with these disadvantages, my remarks show that all of the five factories mentioned are making every preparation for development to the best of their ability, and I believe, in spite of the difficulties against them, that by Jan. 1, 1916, when they will all commence to get the benefit of their new installation and increase, they will be producing anywhere from three to four times their former production, which is a very important increase in itself.

I make bold to say further that if these factories were assured of protection they would increase their production still further, and to such an extent that within a year they could furnish the entire amount of colors required by American consumers, and so relieve them once and for all of their dependence upon European manufacturers. When I make this statement I do not mean that they can make every color which has been imported in so short a time, as there are a number of specialties which have some particular advantage in application, fastness, or something of that sort, and require a special raw material, which they would not be able to take up so quickly, and again there are a few colors which are still patented. But what I do mean to say is that they could make the colors necessary to furnish consumers every quantity and every shade which might be required, that is, give them something which they could use in place of the specialties already mentioned, the latter being what we might call luxuries and dispensable until such time as they could again be resurrected or again imported from Europe, as there can be no question but that some colors would probably al-

ways be imported no matter what the American manufacturers are able to do.

Such an assurance of protection would also probably mean the establishment of branch factories in this country of the European factories, as they would not want to lose their business over here, but the establishment over here of such factories would be welcomed by American factories, because they would then have to work under the same conditions that we do, and would not have any advantage in the cost of manufacture. Again, this assurance of protection would probably stimulate the starting of new American companies who would then be willing to advance the capital necessary and take a chance of being successful. So that even if the five original factories mentioned could not live up to the statements I have made as to their ability, they would undoubtedly have lots of new help, and the result would be ultimately the same, viz., the manufacturing in this country of all colors which are needed for its consumption.

The Possibility of Government-Owned Factories

In closing, I might say, however, that there is one thing which might be done in lieu of an increased tariff protection and which has been suggested before in different forms, but which is so reasonable and simple that I do not suppose it will be considered by our political leaders and parties, and that is, the establishment by the United States of a factory or series of factories for the manufacture of the intermediate coal tar products needed by the color manufacturers, and an arrangement to sell same to them at the same prices which are paid by the German manufacturers, even though there might be no profit or even a possible loss to the Government in doing so.

In addition to this great relief to American color makers, the Government, however, would have the greater purpose in mind of having plants already established capable of manufacturing ammunition in case of war, the point being that the raw materials used by color makers are very much the same as those used in the manufacture of various kinds of ammunition and explosives, and certainly such a factory or series of factories would be a very valuable asset for the Government.

I believe it is true that other governments take an interest in and control to some extent their natural resources; for instance, Germany is interested in her potash and coal fields, Japan in her production of camphor and menthol, and other governments in other products. Therefore it is not out of reason that the United States Government should take a parental interest in its great benzol production, and the use of same for such purposes as the manufacture of aniline dyes for its American consumers and the manufacture of explosives for its own protection should it become necessary. Certainly such a matter is well worth considering by our administration if it is impossible to secure added tariff protection on the lines mentioned so many times in this address.

The South American Handbook, published by the National Foreign Trade Council of 64 Stone Street, New York City (76 pages, price 25 cents per copy), gives detailed information relating to government finances, railway development and foreign trade of the different South American countries. It also contains a report of the Latin-American trade committee on policy required for extension of our commerce and should prove of value to those interested in the development of United States trade with South American countries.

Slime Agitation and Solution Replacement Methods at the West End Mill, Tonopah, Nev.[1]

BY JAY A. CARPENTER

This paper deals with only one step in the treatment of ore at the West End mill; not because the other steps are repetitions of practice in other mills, but because in this particular step there is in use the Trent agitator. This device, although it has apparently failed in many mills, is here giving excellent service and has proved to be well adapted for making a thorough replacement of pregnant solution with a minimum amount of barren solution. The strong and weak points of this agitator, its present simple construction, and its use as a thickener for agitator or battery pulp are features of interest; but perhaps the point of greatest interest to the metallurgist in this day of continuous decantation is its use in a series of tanks for slime treatment by the replacement method.

The agitating department of the West End mill consists of six redwood tanks, 24 ft. in diameter, 18 ft. high, each equipped with a Trent agitator, a centrifugal pump, and a motor. The pulp is transferred by a pump from the top of a flat-bottomed tank to a set of arms and nozzles in the bottom of the tank, at just sufficient pressure to cause the arms to revolve. The streams from the many nozzles keep the bottom of the tank clean, and these streams, coupled with the effect of the revolving mechanism and the ascending current, keep the pulp in constant motion and of constant gravity.

These agitating tanks hold 90 tons of dry slime and 202 tons of solution with a 1.24 pulp, our ore having a specific gravity of 2.7. This capacity is about 10 per cent in excess of the standard 15 by 45 ft. Pachuca tank. The tanks are connected in one series for continuous agitation, the pulp for each agitator being drawn by its pulp through a branch suction from near the top of the preceding tank and delivered to the bottom of the tank by the agitator arms along with the regular pulp of that agitator. This method works automatically, since the flow through the branch suction varies directly with the difference in head of the two tanks. The chance for new pulp to pass out quickly is, therefore, much less than in many other systems of continuous agitation, since the new pulp is delivered at the bottom of the tank, and the discharge from the tank is near the top; the ascending current is uniform and slow.

The pulp is delivered to the first agitator of the series at a gravity of 1.26 by a set of diaphragm pumps, which raise the pulp to a height of 10 ft. above the top of the battery-pulp thickeners, whence it flows first in an open launder and then in a pipe to the suction of the first agitator pump. At intervals in the open launder are placed pieces of battery screen at an angle, which, with those placed at the lip of the diaphragm pumps, catch and remove nearly all the lime scale, wood pulp, and like material from the slow-traveling thickened pulp.

The pulp from the last agitator is raised by an air lift to a Dorr thickener, 28 ft. in diameter and 22 ft. deep, where the pulp it thickened before filtering.

The slaked lime and half the lead acetate are added direct to the scoop box of the tube mills, while the greater portion of the cyanide and the rest of the lead acetate are added at the lip launder of the diaphragm pumps; the remainder of the cyanide is added in the third agitator. For heating the pulp, live steam is introduced into three of the agitators, Nos. 1, 3, and 5, the purpose being to keep the temperature during agitation

[1] A paper presented at the San Francisco meeting of the American Institute of Mining Engineers, September, 1915.

around 100 to 120 deg. Fahr., in order to hasten extraction and obtain good extraction with the use of lower-strength cyanide solutions. These high temperatures are readily maintained in a Trent agitator and are not uncomfortable to the operators, since the heavy coat of foam on the agitators acts as an insulating blanket, keeping the pulp from radiating its heat or moisture, as it does in many other types of agitators. The condensed steam adds to the tonnage of mill solution, but it freshens the solution by dilution of impurities and it is needed to replace the solution that is mechanically lost from the filter.

Once a day, at 4 a. m., pulp samples are taken from agitators Nos. 1, 3, 5, and 6, which are thoroughly washed and dried and made ready for the assayer at 7 a. m. Normally, these assays show respectively 50, 25.5, 19 and 15 per cent of the valuable content of the agitator heads.

Air for the proper aeration of the pulp is compressed to 16 lb. in a compressor of 100 cu. ft. piston displacement, and is fed into the discharge pipe of the agitator pumps. By the time the air is discharged from the

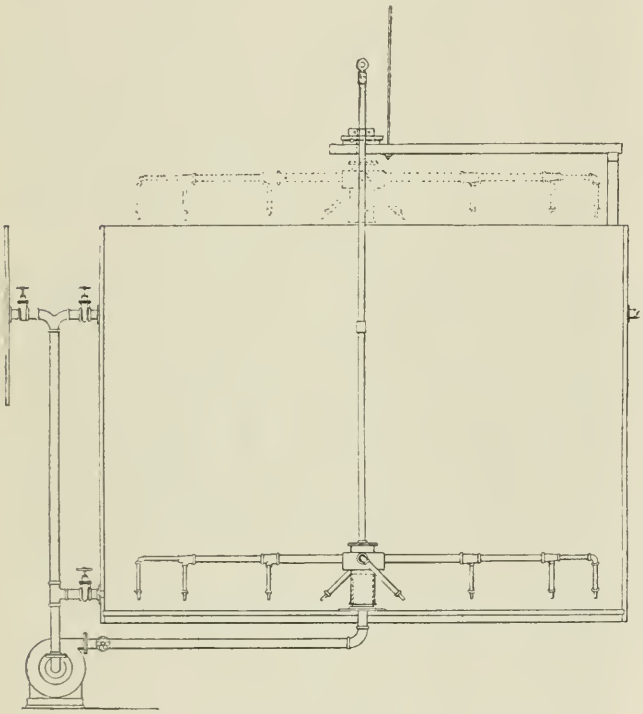

FIG. 1—TRENT AGITATOR, CARPENTER TYPE

nozzles it is thoroughly dispersed in the pulp as minute air bubbles. These air bubbles slowly make their way to the surface and escape into the foam. This well-distributed aeration, in contrast to the short contact of pulp with air in any air-lift type of agitator, is much in favor of the Trent. The pumps of the agitators can be made to suck their own air by throttling the main pulp suction, but in a large installation it is probably more economical to use an air compressor.

Modification of Original Trent Agitators

The original agitators as installed in 1911 were of the Trent underfeed type, with the large grit-proof bearing in the bottom of the tank and with the arms fitted with fifteen ¾-in. nozzles. While these agitators gave excellent service, there was a gradual wear, which necessitated repairs on the grit-proof bearing, due to absorption of the air in the air chamber and consequent rise of slime pulp to the ball race. An occasional cleaning of the nozzles was also necessary, due to their choking with bits of wood pulp, waste, and chips, as a nucleus, surrounded and packed tight by sand from the pulp. On a charge system these repairs could be taken care of easily when the tank was emptied, but when the continuous system was adopted it was necessary once in two or three months to empty each agitator into the following unit by the aid of the transfer pump, and make these repairs, to avoid the danger of an agitator stopping at a time when there was not room in the mill circuit to empty it.

The author, after seeing a Trent agitator suspended from a ball race at the Tonopah Extension mill, because the lower submerged ball race was worn out, conceived the idea and built a new type of this agitator which could be raised, cleaned, and dropped back into position without disturbing the pulp level in the tank. It consisted of a ball race, on timbers over the center of the agitating tank, from which the agitator mast, built of 3-in. pipe, was suspended, a collar clamped around the upper projection of the pipe resting directly on the ball race (Fig. 1).

At the same time, the large upper and lower castings, weighing 800 lb., were discarded, and castings weighing 300 lb. were substituted, which were fitted with extra heavy pipe nipples to serve for the slip joint between the stationary pump discharge and the revolving arms. The upper nipple was of 8-in. pipe, 12 in. long, and was made bell-shaped at the bottom. The lower nipple was of 7-in. pipe, 10 in. long, chamfered at the top. These nipples, after a skim cut in the lathe, have 1/64-in. clearance between them and about a 9-in. contact, which allows only a small flow of pulp to pass between them, but permits the agitator to be raised 9 in. before disengaging. An eye bolt was fastened in the roof directly over the center of the tank, and by means of a chain block the agitator is readily raised above the top of the pulp, where every part of the agitator, excepting the 7-in. nipple in the base casting, can be inspected, cleaned and repaired if necessary. Due to the balanced arms, the bell-shaped nipple, the plumbed point of support, and the guiding ball race, there is no difficulty in lowering the agitator and again engaging the nipples.

The first agitator of this type was placed in commission on Oct. 20, 1913. On account of its lighter weight, it traveled faster and put very little weight on the ball race, as the upward reaction from the nozzles nearly counterbalanced the weight. It was raised, cleaned, and lowered with ease. The tank was emptied at first every couple of months to examine the nipple wear, which was found to be very small. The original pair of nipples, after 19 months' service, are still in use and the wear has not affected the speed of the agitator.

After a thorough trial this new type of agitator was placed in all the tanks at convenient times. It has never been necessary to empty an agitator tank because of failure of the agitator of this type to revolve or keep the pulp agitated. The oldest agitator of this type had operated 10 months (on May 15, 1915) and three others nine months without lowering the pulp in the tank; and, judging from the speed of rotation and the feel of the bottom of the tank, they are good for months to come. When the agitator has been in operation for from four to eight weeks a rod drawn along the tank bottom will strike ridges, which are indications of choked nozzles. After raising the agitator and cleaning out an average of a half-dozen choked nipples, the agitator is lowered to within 6 in. of its usual depth until the cleaned nozzles have cut away the ridges. These agitators have been shut down for hours at a time and have started off after a few minutes' aid in making the first revolution.

This new type of agitator has now been adopted by

the Trent Co. as its standard design, adding to the previous good points of this agitator those of simplicity, durability and reliability.

The pump used on the agitator is a 4-in. centrifugal, driven by a 10-hp. motor. This pump, made by a local foundry, is lined, and has a white-iron open runner. The liners have given an average of eight months and the runners and shafts of six months; the cost of upkeep of the pump is about $5 a month. At first the pumps were driven at 525 r.p.m. and required 6.5 hp. At present the speed is 460 r.p.m., taking 5.8 hp. and keeping the pulp all of the same specific gravity with the aid of the 1.2 hp. used for compressed air. The speed can be dropped to 360 r.p.m. with good agitation, but not with the constant specific gravity desired for continuous agitation. There is often a false economy in cutting power costs of grinding or agitation a cent a ton, with a probable consequence of twice that loss in extraction. The actual power used, figured as motor input, is 7 hp. per agitator, or about 1 hp. for each 12 tons of ore or 42 tons of pulp. At the Goldfield Consolidated mill 200 tons of ore in a 1.5 to 1 pulp has been agitated for 7½ hp. or 1 hp. for 26 2/3 tons of ore or 66 2/3 tons of pulp.

Causes of Failure of Early Agitators

Several of the earlier failures of the Trent agitator were due to too small an area of nozzle discharge and to improper sizes and speeds of the pumps used. The following tests will illustrate some of the points governing the Trent agitator. With the agitator equipped with 15 ¾-in. nozzles, with the pump running at 450 r.p.m., and with 3 ft. of pulp in the tank, the pressure on the pump discharge was 7¾ lb. With the pump stopped, the pressure from the static head on the discharge was 1½ lb. The actual increase of pressure, due to the pump, was 6¼ lb. With the pump running and the discharge valve slowly closed, the pressure increased to 15 lb. and the power decreased one-half. With the agitator run under similar conditions, but equipped with 1½-in. nozzles, giving four times the discharge area, the pressure on the discharge pipe was 2½ lb., or only 1-lb. increase of pressure above the static head; yet the agitator turned at the same speed of 2 r.p.m. and the motor input of 5.6 hp. remained the same.

The reason for the power remaining the same is that a centrifugal pump, running at a given speed, takes approximately the same horsepower for a wide range of heads, but the efficiency, it is to be remembered, varies greatly within this same range. The reason for the agitator running at the same speed is that the greater volume pumped in the second case, acting under less pressure, exerted as much turning force as the lesser volume under greater head.

Figuring from nozzle formula, the quantity discharged in the second case was twice that in the first case, giving, therefore, twice the upward velocity in the tank. The stronger the upward velocity, the more uniform the specific gravity of the pulp. It is evident, therefore, that a large nozzle area, with a pump designed for handling a large volume at a low head and slow speed, is the best combination, and such a pump, made along the lines of the modern Traylor sand pump, should not need repairs for a period of a year. In both the above cases, as the agitator was filled from 3 ft. in depth to 17 ft., the pressure on the pump discharge increased, but nearly in the same amount as the static head, giving the same difference or actual working head, the same power, and the same agitator speed. Consideration of these points takes the successful installation of this agitator and its pump out of the realm of guesswork.

Replacement of Pregnant Solution

At times, when the mill heads were high, it became necessary to replace pregnant with barren solution. The battery-tank solution fed to the glands of the pumps acted as an increasing diluent in the continuous circuit, but did not remove pregnant solution. The top suction of the agitator is about 4 ft. below the top of the tank, and by cutting off the air to the agitator this top 4 ft. becomes a static thickener, ending abruptly in the moving pulp at the agitator suction line. The pulp in the tank from this line down will have a constant gravity without the aid of the air. A decanting pipe placed in this top 4 ft. of the agitator removed the pregnant solution direct to the silver tank. The decanting of a full 3-in. pipe stream can begin thirty minutes after the air is turned off.

With a crowding of tonnage for several months to over 200 tons a day, which was beyond the capacity of the thickeners ahead of the agitators, the overflow of the four 8-ft. Callow cones in the concentrating department was diverted from the thickeners direct to a well, 2 in. in diameter and 3 ft. deep, in the center of the above agitator, which was No. 2 in the series. This pulp was very thin and contained the lightest particles of the ore; yet, with all this pump flowing into the top, this agitator delivered the mill flow of ore in a thicker pulp and of a lower value of solution to No. 3 agitator than it received from No. 1, and, while keeping its pulp in constant agitation for 14 ft. of its depth, it delivered a clear stream of pregnant solution to the silver tank.

At another time for several months, with less tonnage but a higher grade of ore, No. 4 agitator was fitted with an overflow launder, and a well, 2 ft. in diameter and 4 ft. deep, to take the feed from No. 3 agitator. The agitator was run without air, with top suction closed, bottom suction open, and a bottom discharge to No. 5 agitator. The pump entered the agitator at 2½ to 1, and was discharged at 1 to 1 to agitator No. 5, where barren solution was added. The extraction in the tank remained the same as before, when it had air, which, in my opinion, was due to the fact that the greatest extraction had taken place by the time it reached this agitator, and the air included in the pulp was sufficient for extraction.

I have known a Dorr thickener, placed in the middle of a series of agitators, to make a greater extraction than the preceding agitator. However, when the air has been cut off No. 1 Trent agitator in our series, only half the usual extraction has been made. The No. 4 agitator pump on this work was cut to 340 r.p.m., taking 3.5 hp.; yet the agitator started up in its 1.45 pulp after a shutdown as rapidly as the other agitators with only 1.25 pulp. The reason for this is that as the gravity increases the viscosity also increases, hindering the settlement of the heavier sandy particles, which are further handicapped by a diminished difference in gravity between themselves and the surrounding pulp. On this basis, with a proper thickening of the pulp, pyrite concentrate can be readily agitated in a Trent agitator, as is being done at present at the Original Amador Consolidated Mines Company mill at Amador, Cal.

The next and final step in replacing of solutions was proposed to us by L. C. Trent, the inventor of the agitator. The idea was to feed to the agitator pump a ton of barren solution for each ton of ore fed to the tank, to overflow from the tank the whole tonnage of solution fed to it, and to discharge a 1 to 1 pulp from the bottom of the tank, the solution in which should be the barren solution fed to the pump.

This was to be secured by feeding the new pulp to a distributing umbrella on the surface of the pulp in order to feed it in a thin sheet, traveling nearly horizon-

tally, and by having the bottom suction draw pulp from all over the tank by means of a perforated bustle pipe inside the tank, these two doing away with all strong currents. A bypass between the discharge and the suction of the pump would regulate the speed of the agitator, and a series of manifold valves would regulate the flow of barren solution to the pump. A 1 to 1 pulp would be established in the bottom 6 ft. of the tank, and above this a sharp change to thin pulp, and then to clear solution at the top of the tank. The new pulp entering the tank would enter on the surface, only causing a ripple. The solid content would settle through the clear zone into the thick pulp below, but the solution would overflow into the launder, since there would be no downward current, due to the fact that as much solution was introduced at the bottom of the tank as was removed. For a similar reason, the solution fed in at the bottom would find no rising current, and, being mixed with the pulp, would be discharged as an integral part of the discharge pulp. By this method, the inventor reasoned that it would easily be possible to make a 90 per cent replacement of the dissolved silver entering the tank.

At the time of this visit, every agitator was needed for agitation purposes, the canvas-leaf filter was doing good work, and, lastly, we had little faith in making a high replacement of pregnant solution by this method, for all the many efforts along this line had been failures; and it was generally conceded that the diffusion of solutions of equal gravity took place so quickly and so completely that such a scheme was not practical. However, these replacers were installed at the Gold Cross and Imperial Reduction Company plants near Ogilby, Cal., and news of their successful operation came to us not only from the company headquarters, but from the traveling fraternity of millmen looking for a job.

In February, 1915, with a decrease in tonnage, No. 4 agitator was fitted up for a trial as a replacer. With the agitator filled with 1.20 specific gravity pulp, containing 203 tons of solution assaying 7 oz. silver, the feed of pulp and the air were cut off, and the bottom suction opened. Three hours later, when the pulp in the bottom of the tank reached 1.36 specific gravity, a flow of barren solution, assaying 0.13 oz. silver per ton, was admitted to the pump at the rate of about 3 tons an hour. At the end of twelve hours the gravity at 4 ft. from the bottom was 1.36, at 8 ft., 1.11, and at 12 ft., clear; and the solution assays were 3.94, 4.57 and 6.97 oz., respectively. In thirty-six hours there had been added a little over 100 tons of solution, and the specific gravity at 4 ft. from the bottom was 1.34; at 8 ft., cloudy; at 12 ft., cloudy, and the overflow clear; and the solution assays were 1.79, 2.52, 6.21 and 6.6 oz., respectively. Since there was no discharge from the tank, the addition of barren solution had to be slow to keep from thinning the pulp in the bottom of the tank. The replacing action is distinctly shown by the assays. At the end of this time pulp feed and pulp discharge were started into and from the replacer. The results of the next two days' work are shown in Table 1.

The sharp reduction in the value of the ore, due to the extraction made in the replacer, makes it difficult to calculate the efficiency of the replacement, but, since most of the ore is in the bottom 6 ft. of the tank in the barren-solution zone, it is probably true that most of the dissolved silver goes out with the discharged solution.

During the second day there was more solution discharged from the tank than barren solution fed into the pump, and the effect is shown by the assays.

On the third day the agitator slowed down, and shutting the bypass did not increase the speed; yet the turning pressure of a man's hands on the ball race would turn the agitator faster. It pointed clearly to a choked suction pipe, which, with an inventor's optimism, was submerged under 12 ft. of pulp. Not being able to continue the experiment, the top suction was opened and the agitator started off at 3 r.p.m. The result of the experiment demonstrated that a barren zone could be maintained in the bottom of the tank and a high percentage of replacement made, but it also showed that

the capacity of the 24-ft. tank was limited to 60 tons of ore per day at a 2½ to 1 dilution, in order to keep a clear overflow, and proved that the mechanical arrangement was defective.

Mechanical Defects Remedied

To improve the mechanical defects, the author designed both a new arrangement for the incoming pulp and a new suction for the replacer pump. Instead of the umbrella, a well, 2 ft. in diameter and 4 ft. deep, was placed at the center of the tank around the mast. The bottom was made solid and the sides perforated with ¾-in. holes. An arm was put on the mast, which kept the bottom of the well clear.

The suction of the pump was carried around the outside of the tank as a bustle pipe, with the diameter proportioned to the flow. Twelve 1½-in. branches entered the tank at the floor level and ended at varying lengths in upturned ells. Each branch suction was connected to the main pipe by a plug cock, and each had a ¾-in. connection for testing the flow and for connecting high-pressure water if it was choked.

On March 5, 1915, the replacer was started again with these changes. The new well still introduced the incoming pulp horizontally, but below the surface, giving a greater distance down to the slime line at the overflow launder. The new suction made it possible to test and keep open the twelve suction ports at all times, and left nothing inside the tank to give trouble. The agitator, being the new style, was capable of being raised out of the tank for cleaning the nozzles, and for repairs if necessary, and dropped back without affecting the solution zones in the tank. In starting the experiment, the introduction of the barren solution, as before, gradually established a barren zone, or, rather, in this case, a zone of low grade at the bottom, increasing value upward in the tank. This suggests a method for very small plants, such as used on old dumps, of using the replacer as a thickener first, an agitator second, and lastly as a replacer, discharging after making a second replacement with water. After establishing the barren zone, the feed into and discharge from the replacer were started, and the results obtained are shown in Table I.

A detailed study of the table brings out many interesting features of the replacer. A feed of replacing solution considerably in excess of discharge solution for the period of a shift results in a marked lowering of the solution value in the thick pulp and a decrease in that of the thin pulp, while the opposite condition of feed will increase the value likewise. The sharp change in the silver content of the solution is between the thick 1 to 1 pulp and the thin pulp above it, for the reason that the diffusion in the thin pulp is rapid. Hence, there is no advantage, in installing a replacer, in having any more depth above the 6 ft. of thick pulp than is necessary for the settling of the ore. It is possible to discharge the pulp thicker than 1 to 1, but it takes more power applied to the pump to turn the agitator. With a positive drive overhead, taking very little power, the pulp could be discharged as an 0.8 to 1 pulp or thicker with better replacing results.

In order to calculate the replacement of solutions in these tests, two methods are used as checks: First, dividing the ounces overflowed by the ounces fed; second, dividing the ounces discharged by ounces fed. However, before doing this, the ounces extracted from the ore and the ounces fed in with the replacing solution should be divided between the ounces overflowed and ounces discharged. These two items amount to considerable in our tests, because we were not equipped to add barren solution, and, secondly, the ore still lacked sufficient agitation to be ready for filtering. Since the replacing solution is fed to the bottom of the tank, and assays show that it remains there as a partly barren zone, and since over 90 per cent of the ore is in the bottom half of the tank and a large part of it in contact with the barren replacing solution, it is fair to presume that over 80 per cent of the replacing solution and ore extraction go out in the discharge and 20 per cent reaches the overflow.

In the first test, 27 oz. of silver was introduced with the replacing solution, and 112 oz. of silver was yielded to the solutions by the ore, or a total of 139 oz., 20 per cent of which is 28 oz. and 80 per cent 111 oz. Silver to the amount of 2345 oz. was fed with the pulp solution, and of this 2219 oz. less 28 oz. was overflowed, giving 93.2 per cent replacement. Figuring by the second method, of the 2345 oz. of silver fed, only 310 oz. less 111 oz. of it was discharged, giving 91.5 per cent replacement.

In the second test 43 oz. of silver was introduced with the replacing solutions and 158 oz. of silver derived from the ore. The silver fed with the pulp solution was 3708 oz. and of this 3416 oz. less 40 oz. was overflowed, giving 93.2 per cent replacement. Figuring by the second method, of the 3708 oz. fed, only 335 oz. less 160 oz. of it was discharged, giving 95.3 per cent replacement.

In actual practice there is always a little silver in the replacing solution, and, as has been found in the continuous-decantation method, there is always an extraction from the ore, no matter how long it has been treated before decantation. These items were not considered in the foregoing calculations, as they were exceptionally high under our conditions. Again, in the tests, 11 per cent more replacing solution was added than was discharged, which could not be done with the final water replacing, due to the building up of solution tonnage.

Conclusions Drawn from Experiment

However, it was established to our satisfaction:

1. That replacing with the Trent apparatus is practicable.

2. That it is easy to control and regulate the replacer; the one important factor being to regulate the solution fed to the pump and that discharged from the replacer. In a plant designed for this system this would be a much easier matter than in our case.

3. That on a quick-settling pulp it would handle a remarkably large tonnage as far as adding the necessary barren solution is concerned, but that on a pulp carrying a fair percentage of light, flocculent slime it is limited in tonnage to the rate at which the light, flocculent slime will settle in a neutral or no-current tank. In a Dorr thickener there is a downward current to aid settling. At the new mill at Aurora, Nev., the light slime hardly settled in a Dorr thickener, and practically remained in suspension in the Trent replacer.

4. That mechanically the replacer worked very satisfactorily, but that changes could be made to cut down the power consumed and yet make the rotating action more positive.

5. That with a mixture of Tonopah ores, 60 tons of ore in a 2½ to 1 pulp, with 60 tons of replacing solution, was all that a replacer 24 ft. in diameter and 18 ft. high could handle with a clear overflow and a 1 to 1 discharge.

The use of this agitator for replacer experiments necessitated by passing all but 60 tons past this agitator, and caused a loss in extraction that made it necessary to stop the experiment without a working test extending over a few weeks' time; but the author believes the same results would have continued, as everything about the installation was capable of easy adjustment and repair.

Before changing back to an agitator, the replacer was run as an ordinary thickener with a 1 to 1 discharge, all replacing solution and gland water being cut off the pump, and the speed of the agitator cut to one revolution in five minutes. Hose lines were strung to add a large tonnage of solution to the 60 tons of ore in a 2½ to 1 pulp. To run as a thickener and make 90 per cent replacement with a 1 to 1 discharge, the 60 tons of ore would have to be diluted to a 10 to 1 pulp by the addition of 450 tons of barren solution to the 150 tons of pregnant solution. About a 7 to 1 pulp was all that could be supplied without interfering with mill operations, but the slime line rose rapidly from 4 ft. below the surface up to the overflow launder. The 60 tons capacity of the replacer had appeared disappointing, but the test showed it to be a good tonnage on this particular ore compared with replacement by dilution; but it also confirmed the author's conviction that on an ore containing considerable flocculent slime the various replacing methods will have a strong rival in the older leaf and pressure filters that make an easily washed cake from the mixture of the flocculent and sandy components of the ore.

The great advantage of the replacer over the thickener-dilution method is in the smaller installation required, and the small amount of barren solution required compared with the large tonnage of barren and partly barren solution of the dilution method.

The main drawback to the replacer system has been, first, lack of faith in its principles, and second, lack of faith in its mechanical features.

To one that has operated the replacer it is easy to understand that in a 1 to 1 and thicker pulp, the pulp is so thick that the ore and solution are approaching a solid, and that the viscosity of the pulp is so great that the solution is not free to move above amid the ore particles, but, rather, is constrained to move with them; and that, once the barren solution is whipped into the pulp by the pump, it tends to remain locked up in it. The pump is of such a size that the difference in specific gravity between its suction and its discharge is only a couple of hundredths, so that the discharge pulp has no tendency to rise in the tank. This explains why the Trent method is a success and why other methods of adding the replacing solution directly into the bottom of a tank have failed.

The last year has brought about a marked improvement in mechanical simplicity and reliability in the mechanism of the replacer. One strong objection to it, compared with the dilution system, is the power required to operate it. However, this does not seem excessive when one considers the saving of the power that is consumed in handling and precipitating the large tonnages of solution required by the dilution methods. The author believes the power consumption of the replacer can be made nearly as low as that required by the equivalent number of thickeners, by the simple device of not depending entirely upon the pump to rotate the agitator, but to drive the agitator from overhead by a worm drive similar to that of the Dorr thickener and to use the pump more as a mixer and circulator of pulp, running it at a slower speed and with larger nozzles on the agitator. Our experience was that it required about 3 hp. on the motor to turn the agitator at only 1 r.p.m. in a 1 to 1 pulp, when a man with a 1-ft. leverage on the mast could turn it with ease. Why, then, should pump nozzle velocity be relied upon to turn the agitator when its proper function should be that of mixing the barren solution into the pulp and giving only the turning effect derived from that function? The pump, with a slower speed and lower working head, should need only annual repairs.

With these modifications, the author believes that the replacer will become an accepted machine in the treatment of slime that is not too colloidal in its nature.

Tonopah, Nev.

The Necessity of Tariff Reform for the American Chemical Industries

The necessity of tariff reform for the chemical industries was the subject of quite a number of lectures at the National Exposition of Chemical Industries, held in New York City, from Sept. 20 to 25. One phase of the problem, the necessity of a really strong and efficient Tariff Commission, was the subject of two addresses, made by Mr. Howard H. Gross on the afternoon of Sept. 21, and at the meeting of the American Chemical Society, in the evening of Sept. 24.

Mr. Howard H. Gross, a banker in Chicago in private life, is the president of the Tariff Commission League. He emphasized that tariff tinkering must stop. In thirty years of "tariff tinkering" we have had five revisions of the tariff and two attempts at revision. The result has been that nobody is satisfied, that business has been periodically upset, that hundreds of millions of money have been lost and millions of workers distressed.

The tariff must be taken out of politics. This is absolutely necessary. What is needed to accomplish it is a permanent nonpartisan tariff commission, a sane tariff policy and scientific adjustment.

The Tariff Commission League has been founded to inaugurate and carry forward a nationwide campaign of education, to create and crystallize a public sentiment that will demand of Congress the establishment and permanent maintenance of a nonpartisan tariff commission of the highest personnel, with long tenure of office and adequate salaries; the commission to have broad powers covering investigation, gathering of tariff data, making reports and recommendations to Congress, hearing complaints, etc., to the end that tariff enactments shall be in the interest of all the people from the standpoint of sound economics rather than political expediency. The final decision as to rates will, however, be with Congress.

It is proposed that this Tariff Commission be composed of seven members, to be appointed by the President and confirmed by the Senate. In the make-up of the commission, one member is to represent agriculture, one industrial labor, one manufactures, one trade and commerce, one is to represent higher education and have special training for scientific investigation and research, and one is to be experienced in tariff classifications and familiar with departmental rulings in tariff matters. No one political party shall have a majority of the members of the commission. No member of Congress, or one who has served in Congress within two years, shall be eligible to appointment.

Mr. Gross emphasized that public sentiment is the strongest force in the world. What the people really want and insist upon, they will get. That is the reason why they got civil service. And they will get a real strong Tariff Commission if they insist upon it.

* * *

Another phase of the tariff reform which is necessary for the aid of the chemical industries of this country—that is, a scientifically devised protective tariff, sufficiently high and for a sufficiently long time—was the subject of a number of speeches, especially of the elaborate address by Mr. I. F. Stone, on the aniline dye situation. This is printed in full on page 663 of this issue.

Applied Chemistry*

BY L. H. BAEKELAND

It is only three years ago that a Brooklyn alderman, who, in the absence of the Mayor of New York, had to welcome the visitors to the International Congress of Chemistry, addressed them as if they were druggists or pharmacists.

After all, he made not much greater a mistake than many so-called educated men who obtained a B.A. and yet are ignorant enough of elementary scientific knowledge to imagine that the main occupation of a chemist is to analyze substances and detect falsifications.

Even in England, a pharmacist is currently designated as "chemist," while a real chemist is called an "analytical chemist."

But the European war has done much to correct some of these mistaken notions of the public at large. Our daily press has now more or less acquainted this country with the fact that in our national make-up, there is such a thing as chemical problems. I doubt, however, whether the unthinking masses have begun to realize that aside of the so-called chemical industry, practically every other industry, in fact, every enterprise, has chemical questions to contend with, and that chemical industry itself is intimately interwoven with the great network of every modern industrial or agricultural state; that the economic welfare of our country, and the health of its citizens are largely dependent on the way we utilize our chemical knowledge.

CHEMICAL WARS

The present war has been aptly called a "chemical war" because efficient work of every department of the fighting armies, from the Red Cross service to the manufacture of guns and explosives, involves incessantly chemical knowledge—and still more chemical knowledge.

But do not imagine that this is the first chemical war. The art of killing and robbing each other became "chemical" the day gunpowder was invented; at that time, however, the existing knowledge of chemistry was just of pinhead size. Napoleon knew very well how to use adroitly exact knowledge and chemistry for furthering his insatiable ambition to dominate the world; so he surrounded himself with the most able chemical advisers and scientists, and for awhile at least, he placed himself at a decided advantage over his many enemies; incidentally, he thus helped to lay the foundation for some very important branches of chemical industry.

"Les chiens ont appris quelquechose," exclaimed the Corsican conqueror when he realized that his enemies began to adopt the same means which had given him temporary mastership over them; but those whom he called so contemptuously " "the dogs," finally beat him at his own game.

Ever since then, science, technology and chemistry in particular, have played a rôle of increasing importance in the armament of nations. This accounts, perhaps, for the strange fact that the really great military inventions have practically all emanated from civilians and from non-military nations like our own. If the men of the military class, essentially conservative in all countries, had been left to their own devices, they would probably still be fighting with bows and arrows—or perhaps, with the traditional sling. Nor should the pacifist blame the chemist if the latter's most beautiful conquests in science, if his proudest discoveries, have been turned into means of relentless destruction and human slaughter. Do not reproach chemistry with the fact that nitrocellulose, of which the first application was to heal wounds and to advance the art of photography, was stolen away from these ultrapacific purposes for making smokeless powder and for loading torpedoes. Do not curse the chemist when phenol, which revolutionized surgery, turned from a blessing to humanity into a fearful explosive, after it had been discovered that nitration changes it into picric acid.

As well might you curse written speech or language or the art of printing—by which the most noble thoughts of the human race have been expressed, disseminated and preserved—if it has been used also to distribute the vilest lies and the most damnable errors.

Knowledge is like a knife: In the hands of a well-balanced adult, it is an instrument for good of unestimable value; but in the hands of a child, an idiot, a criminal, a drunkard, or an insane man, it may cause havoc, misery, suffering and crime.

Science and religion have this in common, that their noble aims, their power for good, have often with wrong men, deteriorated into a boomerang to the human race. Our very successes will threaten to devour us as long as all of us have not yet become imbued with the truth that greater knowledge, like greater possession of wealth or power, demands a greater feeling of responsibility, greater virtues, higher aims, better men.

Let us hope, in the meantime, that war carried to its modern logical gruesomeness, shorn of all its false glamor, deceptive picturesqueness, and rhetorical bombast, exposed in all the nakedness of its nasty horrors, may hurry along the day when we shall be compelled to accept means for avoiding its repetition.

Will you take it amiss if I made a digression from my subject as an answer to some repeated attacks which have been made of late by men who blame our increasing scientific knowledge in general and our chemical science in particular, for the excesses of the present European war?

THE PEACEFUL WORK OF AMERICAN CHEMISTS

But let us turn our attention to more peaceful chemical pursuits and more particularly to the chemists of this country.

Their work is difficult to understand and still more difficult to be appreciated by the uneducated or uninitiated; nor do chemists court the plaudits of an ignorant public that cannot understand them; they feel fully compensated by the results of their work if it only meets with the approval of a few of their fellow-chemists, irrespective whether it brings them financial results or not; in fact, most chemists are so much in love with their work that very often they neglect the financial side to their own immediate detriment.

Unlike the physician, lawyer, clergyman, actor, writer, artist, or businessman, the chemist does not depend on the public at large; he is either engaged in some private enterprise or he acts in a consulting capacity for a few people, if he is not engaged as professor or teacher in some educational institution. Popularity in the usual sense has little or no value for the chemist.

No wonder then that the chemists of this country, numerous and active as they are, have hardly been noticed among the daily noise of newspaper sensation and shrieking publicity—no more than a skillful watchmaker would be noticed among the hammering of a busy steam-boiler manufacturing plant.

And yet, right here in the United States, the chemical profession has taken such a root, such a develop-

*An address presented at the meeting of the American Chemical Society at Seattle, Wash., and repeated before the National Exposition of Chemical Industries in New York City.

ment during the later years, that we have here assembled at this very meeting, the representatives of our national American Chemical Society, which counts over 7000 members, by far the largest membership of any chemical society in the world, with all due respect to England, France and Germany. A society which finds it possible to spend yearly over $100,000 on its three chemical publications, copies of which are to be found all over the world in every well equipped scientific library.

Nor is the study of the science of chemistry in this country a matter of recent occurrence. Our European friends are astonished when we tell them that as far back as 1792, there existed already the Chemical Society of Philadelphia, which was probably the first chemical society ever organized in the world; even today, some of the papers read at the meetings of that early scientific body furnish very interesting reading. Some of our American universities equipped chemical research laboratories for students as far back as thirty-five years ago, at a time when exceedingly few of the best known European universities possessed any such facilities.

Nor should we overlook the fact that notwithstanding the essentially pragmatic tendencies of our country, the United States has given to the world a Willard Gibbs, who out-theorized existing chemical theories and whose mathematical deductions are still after his death, furnishing food for profound thought to the most renowned physical chemists of Europe to whom they have opened entirely new fields in the study of chemical dynamics.

THE ANILINE-DYE SITUATION

I mention this more particularly because some of our aniline-dye consumers have taken the chemists of the United States bitterly to task and have made decidedly unfavorable comments on their abilities, because since the European war, dyes could no longer be imported from Europe. But Dr. B. C. Hesse, an American-born chemist, a graduate of the University of Michigan, has already ably answered this indictment of the American chemists. In a paper[1] full of information on this subject, which he presented at our last general meeting, but which, unfortunately, has received little or no attention from our daily press, he has clearly demonstrated that the aniline-dye consumers of the United States can have all the chemists and all the dyes they want; provided they are willing to make the necessary investments of capital and to submit to the risk of uncertain profits by starting their own dye-manufacturing establishments here in the United States instead of, as in the past, favoring imported dyes, either through personal choice, or by fostering legislation which forbids the home manufacturers to utilize such methods as selling agreements, "Kartels," or other consolidation of interests, dumping, so as to kill new competitors in the field, while making up the temporary loss by increasing the price of other products, and in general, any of the many other trade-arrangements and trading tricks freely and openly utilized by European manufacturers so as to stifle possible competition of our home aniline-dye producers.

The outcry which has been raised as to our shortage of artificial dyes is out of all proportion if we take in consideration that the annual importation of dyes and synthetic products from Germany amounts only to about $9,000,000. As our former president, Mr. A. D. Little, pointed out, this represents about the same sum of money as the amount of candy sold annually by the Woolworth ten-cent stores.

[1]Met. & Chem. Engineering, May, 1915, page 287.

LOCAL OPPORTUNITIES OF AMERICAN CHEMICAL INDUSTRIES

The development of any chemical industry is a matter of local opportunities; for instance, the manufacture of cellulose, as well as the industry of wood-distilling, has taken a greater development in the wood-covered sections of the United States than in Germany or any other country in the world.

The magnitude and earning capacity of the largest German chemical enterprise, however imposing they may be, look less astonishing if you take into consideration that some of these companies have been in existence for more than half a century. Much younger American chemical enterprises, which make American specialties—for instance, the Eastman Kodak Company, which sends its films and photographic papers throughout the whole world—have annual earnings decidedly greater than the most successful German chemical works of much older existence. Nor is the value of the output of our largest purely chemical companies much less important than that of the German concerns.

SULPHURIC ACID

This country is now the greatest producer of sulphuric acid, with an annual production of about 3,000,000 tons. Yet it is not so long ago that the first maker of sulphuric acid could not even find a purchaser for a triflingly small production of a few tons per week. It needed the opportunity of a home market; by and by this was created by the refining of petroleum after the discovery of our oil fields, the discovery of natural phosphates and the resultant industry of superphosphates, the use of dynamite for blasting, the development of the glucose industry, electrolytic copper refining. These and many other new industries all required large amounts of sulphuric acid, and gave this country an opportunity of developing sulphuric acid manufacturing to its present importance. In fact, the same reasoning holds good for all of our industries. I doubt very much whether the talented foreigners, who have now become proficient in chemical manufacturing, would have tied their initiative and enterprise by specializing in coal-tar-dyes manufacturing, if they had had the limitless opportunities of an immense undeveloped country like ours, to which to give outlet to their spirit of pioneership in mining, transportation, agriculture, and similar subjects, all beckoning for more urgent attention, and offering at the same time, more immediate rewards.

AMERICAN ELECTROCHEMICAL INDUSTRIES

In the meantime some of our other chemical industries better suited to our local conditions, have taken such an enormous development here as to make the United States an undisputed leader in at least some of them. Such products as the various acids and salts, aluminium, artificial abrasives, soda and caustic alkalies, bleaching powder, chlorine products, electrolytic copper, are decidedly more important in value and in economic importance than the few million imported coal-tar dyes.

F. A. Lidbury[2] pointed out rightly that if there had been a shortage in some of the products of our electrochemical industries in which the United States has been a pioneer, the consequences to our national economies would have been so serious that the present complaint of our aniline-dye users would have sounded like a timid whisper, compared to the bellowing lamentations of so many more important industries which would have become absolutely paralyzed. The fact is

[2]Met. & Chem. Engineering, May, 1915, page 277.

that few men realize how many industries are directly dependent on the work of American chemists.

If the aniline-dye industry has been somewhat neglected in this country, there are many other good reasons for it; not only was the possibility of reasonable profits too scant to offer special inducement to clever-headed businessmen to risk their capital in this branch of manufacturing when they had so much better choice in other channels of enterprise, but the first raw material, suitable coal-tar, was not abundantly available here as it is in Europe, for the simple reason that this country long ago discarded the older and more expensive methods of gas manufacturing generally used in Europe, and which give coal-tar as a by-product. The less expensive and simpler water-gas process, adopted in the United States, gives no suitable gas-tar; it is only of late, by the introduction of the by-product coke-ovens that we can look forward to an almost illimited supply of coal-tar.

In the meantime, the German manufacturers had every opportunity in specializing in these coal-tar industries and could afford to concentrate their efforts so as to supply not only their home consumption and that of the United States, but that of the whole world; in about the same way as the United States sends to the remotest corners of the globe, its sewing machines, its typewriters and its Ford cars.

Judging from the past history of the chemical industry in America, I have little doubt that the day it will be found profitable to manufacture all kinds of synthetic dyes here in the United States, instead of a few as is the case now, there will be little further delay in supplying the demand by a hustling and bustling home production.

In fact, it is quite possible that under present abnormal conditions, this branch of manufacturing may be stimulated to the point as to result in over-production after the war is over.

CHEMICAL RESEARCH IN UNITED STATES

If hitherto our chemists have been deficient in this special line, we can, with some satisfaction, point to better efforts in other chemical industries. For instance, it is not sufficiently known how many research chemists in our different American manufacturing establishments, are busily occupied in studying and improving manufacturing processes, nor what large sums of money are devoted every year to industrial chemical research. If we hear it constantly repeated that some of the largest German chemical companies employ hundreds of chemists and engineers, it is less known that right here in the United States, the number of chemists employed in some of our better organized chemical enterprises is scarcely less; but nobody finds it necessary to boast about it.

In fact, the most striking symptom is that so many engineering enterprises, for instance, some of our large electrical companies—although their field of action seems rather remote of chemical subjects—have now elaborate chemical research organizations, of which the record is well known by its excellent results.

Conditions were quite different some fifteen or twenty years ago; but this country has grown, and as the requirements and opportunities grew up at the same time new chemical problems arose thereby.

THE ANALYTIC AND CONSTRUCTIVE TURN OF MIND

The urgent nature as well as the magnitude of some of these new chemical problems, is shaking our chemists awake—is making new men of them. Professor Whitaker is probably right when he says that the chemists are thirty years behind the engineers as far as method and attitude of mind is concerned, but this same criticism holds good for chemists all over the world. The fact is that the engineer was called first, and he was born centuries before the chemist, but the latter is now making up for lost time.

New conditions, new problems, are compelling the chemist to learn to tackle a proposition in a true engineering spirit and—to hitch some business sense to it. He is learning to forget thinking or acting on the test-tube plan; he is thrown more and more in contact with businessmen; he begins to realize that too one-sided theoretical considerations are sometimes more dangerous than complete ignorance and that a sense of proportion and relative values is the first requirement for good practical effort.

Here, indeed, is one of the weakest spots of the chemist. Aside from the fact that the chemical profession seems one of those vocations which have fascinated a large number of intellectual freaks, it has generally attracted men of an analytical, rather than a constructive turn of mind. Successful engineering is essentially constructive. The most urgent work for the chemist of to-day, must be constructive—he must learn how to cement together the vast amount of data which already lie at his disposal, even if he, himself, has to provide this very cement by further research.

THE CHEMIST IN OTHER INDUSTRIES

The chemist of to-day is no longer confined to purely chemical enterprises; even the most stubbornly conservative manufacturers have learned, through competition, that every industry, however mechanical be its nature, has its chemical problems. Things have changed rapidly since the day Andrew Carnegie listened with a sly twinkle in his eyes, to the fun his competitors were poking at him when he first engaged a spectacled professor to investigate the chemical problems in his iron-works. Conditions have now become reversed; to-day a steel or iron-works without a competent chemist justly provokes contempt and distrust.

Nor is the time so far distant when even our biggest railroads had not begun to realize how they missed the constant services of a staff of chemists, so as to advise them in the endless chemical problems which present themselves in the operation of a well organized railroad.

Some time ago, I visited the plant of the National Cash Register Company, in Dayton, Ohio; one of its most interesting departments was its well-equipped chemical laboratory, where no end of chemical questions relating to the manufacture of purely mechanical devices have to be studied and solved.

No up-to-date motor-car works is complete without its chemical department and the same remark holds good for all well organized engineering concerns.

In this country, the importance of chemistry has been first appreciated in its relations to agriculture. So obvious was this, that we set an example to all other nations of the world by the number of our federal and our State chemical agricultural laboratories. This, more than anything else, was the entering wedge of applied chemistry in this country, which extended later on in the Government Service, Geological Survey, Bureau of Standards, and the Bureau of Mines. Nor did the useful effect stop there. Many of our federal-chemists, our State-chemists, have left public service, to accept better paying positions in private industries; but the men trained in public service, implanted their high aims and scientific ways in some of our commercial enterprises, which needed it badly. I know of some cases where this beneficial influence changed radically the whole spirit of the commercial organiza-

tion, from its manufacturing to its selling department, and introduced instead of reckless, sordid commercialism, a spirit of fairness and efficiency which soon proved the more profitable policy.

ETHICS OF THE CHEMIST

In this and similar directions, the chemist can exercise a valuable moral influence on the community. If you think it over, you will find that the quest of efficiency lies quite close to the path of honesty, justice, and equity.

Here also the chemist has much to learn. In some instances I have been astounded at the almost child-like attitude of mind of some of our chemists who are too ready to sell their services to anybody who has a temporary use for them, irrespective of the underlying motives or purposes.

Some lawyers tell me that they never have the slightest difficulty in hiring chemical experts to defend contradictory opinions. It is quite amazing how some chemists in their eagerness of pleasing their employers will overlook their own ignorance of the most elementary principles of patent law, as well as their superficial acquaintance with the many details of intricate technical questions while not hesitating to furnish cocksure opinions which encourage infringers or industrial pirates to trespass on the rights of intellectual property of others.

Much ruinous patent litigation would be avoided in this country, and invention would be better encouraged if we had more men of the type of some well-known British electrical expert, who never hesitates in court to tell the simple and direct truth, regardless whether it kills or saves the case of his client; his statements are so highly valued and respected that the judges accept them without suspicion, and the same expert is frequently retained by the two opposing parties, whom he serves impartially, and who gladly pay him higher fees than to a mere litigation-acrobat-expert, or a chemical "ambulance-chaser."

EMPLOYERS AND EMPLOYEES

The ethics of our profession have been dealt with by the American Institute of Chemical Engineers, and have been embodied in its recently adopted Code of Ethics, which may furnish a good guide for younger or less experienced chemists. And this leads me to state that many more manufacturers or businessmen would be induced to utilize the services of chemists, if they could feel confident that in so doing they are not putting themselves at the immediate mercy of a stranger, by confiding to him facts or processes which it has cost them many sacrifices of time and money to accumulate, and the undivided knowledge of which, constitutes sometimes one of their most valuable assets. On the other hand, a chemist can hardly be of any service unless his client or employer is just as frank with him as he would be with his lawyer or physician.

However, this mooted point is easily overcome by referring to the Code of Ethics to which I have just alluded, or better by making a preliminary agreement between the chemist and his client or employer, safeguarding the interests of both parties. But in such a case, the compensation to the chemist should be made commensurate to the occasion.

This same principle holds good in the employment of chemists in manufacturing plants, where the chemist is either engaged in research or in a manufacturing capacity. An employer should not expect an intelligent chemist to render him important services without proper compensation, and in as far as the practical value of the work of a chemist can seldom be determined in advance, it will pay the employer to offer special inducements or rewards for initiative; he can well afford to give his chemist some share of the increased profits he has received through his work; to do otherwise, would be narrow-minded, short-sighted, and detrimental to the direct interests of the employer.

The work of a research chemist cannot be performed nor measured like that of a bookkeeper or a laborer; the results of his work are uncertain; delays and obstacles beset him at every turn; sometimes luck plays an important role; but good will, enthusiasm, and persistent endeavor are indispensable factors and these may be encouraged or killed by the attitude of the employer. An employer who is unfair, or who cannot arouse the respect or the enthusiasm of his chemists, cannot get the best there is in them. He must make them feel that if their work turns out well for him, they will get some decent share of compensation. Therefore, a reasonable salary ought to be supplemented by the possibility of a bonus or some share in the profits based on the earnings brought about directly by the work of the chemist.

On the other hand, the chemist must not overlook the financial sacrifices and business-risks assumed by his employer. He should specially bear in mind that knowledge or experience gathered at great cost by his employer, or through expensive factory equipment, or other facilities, have in most cases enabled him to take up his own work at an advanced stage. It would be rather unfair, unless otherwise stated, that a chemist should be allowed during or after his period of employment, to divulge or take advantage of all knowledge or information gathered around the plant in which he is engaged; or patent for his exclusive benefit, any inventions he may make on those particular subjects for which he is engaged, as long as the stimulating ideas themselves have been gathered by the very means put at his disposal by his employer. All these questions should be provided for and embodied in an equitable contract which will necessarily vary with special circumstances. But here again, niggardliness, or too great cunningness of the employer, will hardly pay. Unless his chemist be a fool—and a fool of a chemist is not worth anything—he will lose the good-will and confidence of the very man whose work is primarily dependent on these factors.

Faithful and generous observance of these conditions has brought about the most excellent results in many instances; I know that the contract system, with a salary supplemented by a bonus, or participation in profits in special departments, has been used with great advantage to all concerned, by some of the most successful chemical companies in Continental Europe, and in some of the more progressive American enterprises.

It has been objected that a contract of the kind merely binds the employer who has tangible assets, while in most cases it would be difficult to enforce it against faithless employees. But even then, a clear and well defined contract will prevent many misunderstandings which will crop up in the course of time. It has been my experience that direct dishonesty and faithlessness are merely exceptions among chemists, whatever their other short-comings may be.

THE CHEMIST AS A RESTLESS PROSPECTOR

We know where the work of the chemist begins. We can never tell where it ends, and through what unexpected ramifications it may lead. It is just this fact which adds some zest to the life of the struggling, hard-working chemist, and brings to his work frequently as much excitement as the best of sports; his hopes and disappointments can be compared to those of the restless prospector.

Pasteur, while he was professor at the University of Lille, was consulted by a local alcohol distiller about some irregularities in the fermentation processes. Little did the great French chemist dream, when he tried to solve this purely industrial problem, that by doing so, he was going to establish such an amount of new and unsuspected scientific facts, destined to upset all formerly accepted notions, not merely on fermentation, but on life, disease, contagion and epidemics; that he was about to revolutionize surgery, sanitation and medicine, and create several new departments of medical science; that he was going to save millions of lives, reduce sorrow and misery.

So little were the men of that period prepared for all these stupendous revelations that this great benefactor of the human race had to suffer most from the gibes and violent attacks of some of the best-known men of that very medical profession into which he was going to infuse new life by placing it on a true scientific basis. The history of the stubborn polemics and angry discussions at the French Academy show that, at that time at least, the imagination even of men of science could not expand to the point of perceiving that medicine and surgery were to be remodeled by the hands of a mere chemist.

Notes on Reverberatory Smelting Practice of Nevada Consolidated Copper Co.

(Editorial Correspondence)

Conditions surrounding reverberatory smelting at the plant of the Nevada Consolidated Copper Co., McGill, Nevada, differ somewhat from those at smelters treating copper concentrates from the other large "porphyry" copper properties. While the copper content of the original ore, averaging 1.55 per cent for August, compares favorably with that of similar ores, there is a greater abundance of iron sulphide which lowers the concentration ratio. This results in a low-grade concentrate—7 to 9 per cent copper—and the conversion of a low-grade matte—about 27 per cent copper—and necessitates the treatment of an abnormally large tonnage for a given output of copper. The grade of concentrate fluctuates from day to day with production from different parts of the mine; and as the smelter treats the concentrates practically as fast as produced, there is no opportunity for mixing to secure uniformity of charge. Proper fluxing is effected by varying the feed of lime rock at the roasters in accordance with analyses of current mill production.

Mr. Pomeroy[1] has published the following analyses of charge components and furnace products:

Material	Per cent Cu	Per cent SiO_2	Per cent Fe	Per cent CaO	Per cent Al_2O_3	Per cent S
Concentrates roasted	6.48	28.4	27.0	...	5.2	28.4
Cold secondaries	9.37	19.9	43.4	...	3.4	8.4
Hot converter slag	2.01	27.2	46.2	...	4.5	1.2
Fettling slimes	3.32	65.8	7.3	...	8.3	7.6
Lime rock	...	2.1	0.8	51.1	0.8	...
Roaster flue dust	5.85	40.4	15.2	0.7	6.6	9.2
Reverberatory matte	27.46	0.4	40.8	...	0.5	27.2
Reverberatory slag	0.298	42.2	28.4	9.5	6.8	0.4

Under present conditions, when every department of the plant is being pushed to capacity, the lack of ample facilities for roasting is being felt. With insufficient means for eliminating sulphur, the grade of the resulting reverberatory matte is not as high as might otherwise be obtained, and this, in turn, places an additional burden on the converters.

The roasters, which have six hearths 18 ft. inside diameter, are making a creditable performance, considering that they were originally designed for the treatment of 50 tons each per day. They are now handling nearly twice that amount of charge. The daily average for August was 91 gross tons, consisting of 79 tons of ore and 12 of lime rock. Seventy-five per cent of the sulphur is eliminated, amounting to 15 tons per furnace day. In order to utilize the heat of the roasters as fully as possible in the elimination of sulphur, the practice has been adopted of introducing the lime rock on the fifth hearth, or next to the bottom. Some further changes are now contemplated at the roasting plant that will improve the draft and sulphur elimination, as a result of which it is expected that the grade of reverberatory matte can be raised to about 30 per cent copper.

Crude Oil for Smelting Fuel

Fuel is the main item of cost in reverberatory smelting at McGill. Here the furnaces are oil-fired, using California crude petroleum heated to between 175 and 200 deg. Fahr. There is no probability of a change from this practice to the use of coal dust, notwithstanding the excellent results obtained with the latter fuel elsewhere. A number of factors determine this decision at McGill. In the first place the cost of coal of any grade is high, while fuel oil is obtainable from California at moderate cost. Second, the excellent fuel ratios now obtained with oil, compared with those reported from other plants fired with coal dust, lead the management to believe that coal dust would show no advantage or improvement over oil. And finally, the capital and operating costs of a coal-pulverizing plant are eliminated by the use of oil, which requires no preparation other than heating. Compressed air, of course, is required for either method of firing.

The number of burners to each furnace has been reduced from seven to five, and sometimes only four may be in use. The oil is fed under static pressure of 34 lb. and atomized with air at 40 oz. Combustion is practically perfect. The maximum temperature is developed at the second side door, 21 ft. from the burners, ranging from about 2650 to 3075 deg. Fahr. The furnaces are charged through four holes in the roof, 20 to 25 tons at a time. The side walls are fettled in the usual manner, the openings being piled full of fettling material. Different fettling materials are used at various points for special purposes. Thus converter secondaries are charged along the firing wall or wherever it is desired to sink a heavy material below the slag line to act as a foundation for silicious fettling. Flotation concentrates, which are now being produced in the course of experimental work at the concentrator, are used extensively for fettling.

Recent Furnace Performance

In explanation of the following data, the term "total charge" indicates the sum of the "solid charge" plus converter slag. The "gross fuel ratio," expressed in barrels of oil consumed per ton of charge smelted, gives the total oil consumption. In order to get the "net fuel ratio," a credit must be applied for heat recovery at the waste-heat boilers. This credit is based on water evaporated, and is expressed as a percentage of a factor of 14 lb. water per pound of oil.

For the month of August, 1915, the average tonnage of total charge per furnace day was 645, of which about 15 per cent was hot converter slag. Oil consumption averaged 0.48 bbl. per ton of total charge. Applying a credit of 35 per cent for waste-heat recovery, the net oil ratio was 0.312 bbl. per ton of total charge. Furnace No. 2 had an average daily record of 671 tons and a gross fuel ratio of 0.45 bbl. of oil.

[1]New York meeting A. I. M. E., February, 1915. "Reverberatory Smelting Practice of Nevada Consolidated Copper Company." By R. E. H. Pomeroy, smelter superintendent, McGill, Nev. The supplementary data on furnace operations given in these notes were kindly provided by Mr. Pomeroy during a recent visit at the plant.

On August 31, 1915, furnace No. 2, measuring 18 ft. 10 in. by 132 ft. at the skim-line level, had been in continuous operation for one calendar year, and the campaign was not yet closed. During this period the furnace treated over 240,000 tons of charge, a performance which has encouraged the management to set a new goal of a quarter of a million tons in a single campaign. The exact data on this furnace are given below.

Furnace days	358.3
Total charge, tons	241,053
Solid charge, tons	213,223
Total charge per furnace day, tons	673
Solid charge per furnace day, tons	594
Oil ratio for total charge, bbl	0.565
Oil ratio for solid charge, bbl	0.640

Furnace No. 1 is now on an unfinished campaign, the current record of which follows.

Furnace days	150.7
Total charge, tons	93,618
Solid charge, tons	79,385
Total charge per furnace day, tons	621
Solid charge per furnace day, tons	526
Oil ratio for total charge, bbl	0.482
Oil ratio for solid charge, bbl	0.608

All factors and conditions considered, it is believed that these records are among the best in reverberatory copper smelting. Naturally, they are obtained only by careful study and close attention to detail, discovering the factors that make for high or low efficiency, and augmenting the former and diminishing the latter as much as possible. No small part of the success lies in creating a good organization and maintaining the proper spirit of interest and loyalty in the operating crew.

The Estimation of Aromatic Hydrocarbons in Cracked Petroleum[1]

BY W. F. RITTMAN, T. J. TWOMEY AND G. EGLOFF

In connection with the commercial production of aromatic hydrocarbons from petroleum a necessity has arisen for convenient and reasonably accurate analytical methods. Such methods may have as a basis either chemical or physical differences among the properties of the constituents of the mixtures which are produced by the cracking process. The present communication deals with the application of physical methods to the processes of separation and differentiation. Some experiments have also been performed on the chemical side of the question results of which will be published in a subsequent connection.

The following physical properties are suggested as of possible utility:

1. Solubility.
2. Melting point
3. Boiling point.
4. Specific gravity.
5. Refractive index.
6. Surface tension.
7. Viscosity.
8. "Molecular weights" (effect on boiling point or freezing point when in solution).

Of these properties the first three may permit an actual separation of the constituents of a mixture. The other can serve [at most] only as means of differentiation.

Several possibilities may be eliminated on the basis of previous knowledge. Surface tension is readily influenced by the presence of small quantities of impurities and in the absence of definite knowledge concerning the exact nature of this phenomena, is of little service. "Molecular weights"[2] have been shown to be unreliable even when determined for mixtures which are chemically more homogeneous than those obtained in the present work.

Refractive indices are related closely to specific gravity, and on account of that relation do not need special consideration. Viscosity is not an additive property. In actual fact, information is needed regarding only the first four possibilities of the list.

A consideration of actual conditions reveals the following state of affairs: The cracked petroleum oil is a complex mixture containing a series of aromatic hydrocarbons, of which the most important are benzene, toluene and xylene. "Xylene" represents a mixture of the three isomers, the properties of which are closely related. Higher aromatic hydrocarbons are likewise present and work is at present in progress for the purpose of studying methods for their separation and estimation. There are also present in the mixture considerable quantities of non-aromatic hydrocarbons of various classes and of almost all boiling points. From these facts it appears improbable that the desired separation and estimation may be accomplished through an application of any one property.

A method of separation which suggests itself as particularly attractive is that based on differences in solubility. Unfortunately, however, there are known few, if any, satisfactory differences of this sort. Certain asphalts are dissolved by aromatic and are unattacked by non-aromatic hydrocarbons, and this fact has been utilized for a qualitative test[3] for the former.

The use of liquid sulphur dioxide has many of the characteristics of a differential solubility method, but in the present connection has been classed as a chemical method.

One other solvent which is recommended as offering a satisfactory medium for separation by solubility is dimethyl sulphate. Experiments have been performed to discover the utility of this method when applied in the simple way practicable in the ordinary commercial laboratory.

A second possible method of separation depends upon differences in melting point. An examination of physical chemical tables indicates that benzene[4] freezes at about 5°.5 C., and that all the hydrocarbons which are associated with it in distillation cuts have considerably lower points of solidification. Experiments have been conducted to ascertain whether or not any simple and convenient laboratory method may be based on these differences.

The method of separation through differences in boiling point needs little discussion. That it is possible to separate benzene, toluene and xylene by the method of distillation is indicated by the differences in their boiling points:

Benzene[5], 80°.4.
Toluene[6], 110°.3.
Xylene[7], 138 to 142°.

While, however, the three aromatics may be separated from each other by the process of rectification they cannot be isolated from the aliphatic hydrocarbons which are present in the cracked oil, and which have boiling points approximately the same as those of the benzene, toluene and xylene.

A convenient fact appears in the wide differences

satisfactory method of differentiating compounds which are alike in the property of volatility.

Experimental

SOLUBILITY METHOD—USE OF DIMETHYL SULPHATE

Valenta[14] has stated that aromatic hydrocarbons are soluble in dimethyl sulphate and that open chain hydrocarbons are practically insoluble. This condition, however, he limits to compounds having boiling points between 240 deg. and 300 deg. C.

Since the publication of his results the utility of this reagent has been investigated by various experimenters. Perkins and Harrison[15] subjected it to a number of

Chapin[16] also arrived at the conclusion that dimethyl sulphate does not effect a quantitative separation, but believes that under certain conditions the results may be of value. Reeves and Lewis[17] have found the reagent of service and suggest that it may be of value if used in conjunction with a volatilization test. They believe, however, that more data must be accumulated. On the other hand, Sommer[18] has failed by the use of dimethyl sulphate to detect as much as 10 per cent of asphalt in oil.

Church and Weiss[19] have studied the behavior of the reagent under the exact conditions specified by Valenta[20] and find that with coal tar and water gas tar distillates boiling between 240 deg. and 300 deg. C. dimethyl sulphate failed to show indications of non-aromatic constituents when by the sulphonation methods, amounts varying between 1.2 per cent and 6.8 per cent were estimated.

Church and Weiss arrive at the conclusion that the use of the reagent does not attain any degree of accuracy, and that dimethyl sulphate is, in addition, undesirable because it is difficult to obtain in a pure state, is unstable, and on account of its poisonous nature is dangerous to those handling it.

In the present experiments the method of application was as follows: Five cubic centimeters of the sample were measured into a 25 c.c. stoppered and graduated cylinder and 20 c.c. of dimethyl sulphate added. The mixture was shaken for five minutes, heated for fifteen minutes and shaken again.

In no case did any separation occur, even when the mixture treated was known to contain a considerable proportion of non-aromatic constituents. This discrepancy may have been due to any one of the causes indicated above, and it therefore appears that dimethyl sulphate is entirely lacking in utility for the present needs.

FREEZING METHOD

The fact that benzene crystallizes at about 5.5 deg. C. and all other hydrocarbons which might be present with it in a distillation cut about 100 deg.[21] lower led to

[16]Bureau of Animal Industry Circular 167.
[17]*Jour. Ind. Eng. Chem.*, 5, 293, 1913.

the belief that this properly might be used as the basis of an analytical method. Some experiments were therefore conducted with known mixtures of benzene and a unrefined gasoline of specific gravity of 0.728. These mixtures were treated at three temperatures. Melting ice gave a temperature of zero degrees centrigrade. An ice-salt mixture gave a temperature of — 20 deg. C. A temperature of — 40 deg. C. was obtained by the admixture of carbon dioxide with an excess of acetone in a Dewar flask.

At zero degrees no solidification took place with any of the mixtures, except with the 90 per cent mixture, which gave a recovery of 20 per cent, within the time of a reasonable period of treatment. In all cases the mixture was kept at the required temperature for from fifteen to twenty minutes with constant stirring. Furthermore, inoculation of the solution yielded no different results.

At — 40 deg. results were obtained which show in Table 2.

From these results it appears that benzene crystals tend to include so much mother liquor that the freezing method for the estimation of this constituent is rendered unreliable. It also appears that in the presence of an excess of non-aromatic constituents the benzene crystals may be either prevented from separating out or dissolved as soon as formed. In any event the freezing method seems to have little to recommend it.

DISTILLATION METHOD

The approximate separation of benzene from toluene and toluene from xylene is not necessarily a difficult problem, as there are differences of about 30 deg. C. between the boiling points of each of the adjacent pairs of hydrocarbons. By the use of efficient and convenient still-heads of the Hempel type a satisfactory degree of separation may be attained in three successive distillations, which involves a time consumption of two to two and a half hours for one operator. This procedure, while approximately separating the three aromatics from each other, does not rid them of the non-aromatic constituents with which they are associated.

The largely empirical method which has been adopted is as follows: The original cracked oil is distilled and a cut made at 175 deg. C. A portion of this cut is redistilled and divided into three portions at the limits 105 deg., 130 deg., and 160 deg. C. These cuts are subjected to a further fractionation, the temperature limits this time being 95 deg., 105 deg. and 150 deg. C. The cut limit of 150 deg. is fixed by the fact that the distilling flask goes very nearly dry at this point. The figure 95 deg. is midway between the boiling points of benzol and toluol, and 120 deg. very nearly half way between toluene and the lowest boiling of the xylenes.

That the degree of fractionation is sufficient is shown by the results of the following experiment: A specimen of one of the final 95 deg. C. cuts was subjected to a further redistillation, and it was found that 94.3 per cent came over below the original limit. In consideration of the fact that a complex mixture was being distilled this may be considered as a very satisfactory degree of separation.

SPECIFIC GRAVITY

For this accurate determination of the percentages of the three aromatics in their respective distillation cuts by the method of specific gravity it is necessary to know the following three values:

1. The specific gravity of the aromatic constituent.
2. Specific gravity of the non-aromatic constituent.
3. Specific gravity of the cut.

Figures for the pure aromatics are obtainable in the literature.

The following values are given by Holde:[22]

Hydrocarbon	Purity	D 15°/15° C.
Benzene	95% boiling within 0.8°	—0.883 —0.884
Toluene	95% boiling within 0.8°	—0.870 —0.871
Xylene	0% boiling under 136°, 90% below 140°	—0.867 —0.869

Figures for the mixture of unknown composition are obtained from simple laboratory determinations. It is not as easy, however, to arrive at values for the non-aromatics. A scheme that has been used for approximate calculations in another connection (results to be published later) is to use the value obtained for a distillation cut between the same temperature limits obtained from an uncracked oil of the same type as that used in the transformation to aromatic hydrocarbons. This assumes that the properties of the non-aromatic constituents are unchanged by the cracking process. The extent to which this is true yet remains to be proved. Fortunately, however, conditions are such that an approximate knowledge of the gravities of non-aromatic constituents is sufficiently exact for present purposes. On the basis of general knowledge from various sources it has been assumed that the average gravity of these hydrocarbons in the benzene cut is 0.720, in the toluene cut 0.730, and in the xylene cut 0.760. These values are undoubtedly near the truth, but even if they are not their use permits the obtaining of results which are at least as reliable as those derived from analyses by chemical methods.

A specific illustration may serve to show the nature and magnitude of possible errors. The cuts, as obtained by the distillation method, generally ran between 60 per cent and 80 per cent benzene. The figures in Table 6 show the differences obtained by assuming for non-aromatics specific gravity figures respectively of 0.710 and 0.720.

Table VI.

Sp. Gr. (Measured)	Per Cent Benzene on Basis of 0.72 for Non-Aromatics	Per Cent Benzene on Basis of 0.71 for Non-Aromatics
0.816	60	62.5
0.832	70	72.0
0.848	80	81.0

The error, or rather variation, ranges between 1 per cent and 2.5 per cent on this basis. The lower values for benzene were obtained with the higher assumed gravity for the non-aromatic constituents. For the toluene and xylene cuts conditions are similar except

[22] Holde-Mueller, Op. cit., p. 260.

that the possibility of error in assumption is even less, due to the narrower range in boiling point of the cut.

To ascertain definitely the reliability of these assumptions concerning specific gravities an extensive set of supplementary experiments was conducted. First, the gravity results were verified by a series of chemical tests performed by the authors. Present experience has led to a preference for the nitration method for the determination of benzene, this being preceded by a removal of unsaturated open chain compounds. Procedure was as follows:

(*a*) *Removal of Olefines.*

A 100 c.c. sample of the 95 deg. distillation cut is measured into a 500 c.c. separatory funnel. To this was added 100 c.c. of conc. sulphuric acid (sp. gr. 1.84). During the addition of the acid and the subsequent shaking for five minutes the mixture is cooled with ice water. A reddish-brown sludge forms which may readily be separated by centrifuging for fifteen minutes, although it does not settle with long-continued simple standing. The acid-sludge mixture is drawn off and the residual oil subjected to nitration according to the method of Lunge.[23]

(*b*) *Nitration.*

The procedure for nitration is briefly as follows: The sample of about 100 c.c. of oil is placed in a 500 c.c. flask equipped with a dropping funnel and a tube which acts as an air-cooled reflux condenser. Into the oil is run dropwise and with constant shaking a well-cooled mixture of 100 g. of nitric acid (sp. gr. 1.4) and 180 to 200 g. of conc. sulphuric acid (sp. gr. 1.84). The flask is cooled during the addition by immersion in ice water. After the cessation of all tendency toward spontaneous heating of the mixture the flask and its contents are heated for two hours at a temperature of about 60 deg. C. The escape of vapors is prevented by the use of an efficient reflux condenser. After cooling, the contents of the flask are transferred to a separatory funnel, allowed to settle and the lower acid layer drawn off. The latter is diluted with several times its bulk of water, and any oily liquid separating is added to the nitrobenzene.

The crude nitrobenzene is washed three times with water, once with very dilute caustic soda and again with water. It is dried and weighed, then distilled up to 150 deg. and the distillate again treated with a large excess of the nitric-sulphuric acid mixture. Any liquid remaining undissolved in the acid is regarded as nonnitrifiable material.

Experimental Results

Nitration experiments were conducted upon specimens of the 95 deg. cut of such gravities that the benzene content was estimated at from 65 per cent to 99 per cent. Two or three determinations were made for each sample and results obtained which checked with variations of ½ to 1 gram in the quantity of nitrobenzene obtained.

Table VII.

Sp. Gr. of Sample	Per Cent Benzene on Basis of Sp. Gr.	Per Cent Benzene on Basis of Nitration Figures	Per Cent Difference
0.824	65.0	63.6	1.4
0.828	68.1	66.2	1.9
0.840	75.0	72.0	3.0
0.848	80.0	77.2	2.8
0.867	91.9	88.0	3.9
0.872	95.0	92.3	2.7
0.878	98.8	96.0	2.8

Results show in Table 7:

[23]Coal Tar and Ammonium, Lunge, 4 edit. (1909), Vol. II, page 765.

In each determination the per cent of benzene found by the nitration method is lower than that indicated by the specific gravity figures. That the results of the nitration method should be low is indicated by the fact that there are unavoidable errors due to losses in washing and transference, and that there is a possibility of the removal of benzene in the course of the deolefinization with sulphuric acid. Chemically pure benzene cannot be made to yield 100 per cent of the theoretical amount of nitro-product. The specific gravity figures are undoubtedly the more accurate and the assumption of the value 0.720 is hereby justified.

A second check on the reliability of the specific gravity-distillation method was obtained through the results of several analyses made in laboratories which specialize in the examination of hydrocarbon mixtures. These worked independently on samples of a cracked oil and a 200 deg. distillation cut from the same. The latter represented about 42 per cent of the cracked oil.

Results of the analyses show in Table 8.

Table VIII.

Analysis Number	Cracked Oil		Distillation Cut	
	Per Cent Benzene	Per Cent Toluene	Per Cent Benzene	Per Cent Toluene
1	10.50	11.50	29.00	26.25
2	11.68	11.33	23.20	26.20
3	.....	.....	39.91	23.55
4	9.60	6.60	30.20	24.80
5	13.00	10.70	26.20	23.80
Average 1-5	11.19	10.03	29.70	24.92

Analysis No. 1.—The method employed was distillation, followed by deolefinization and redistillation with subsequent determination of aromatics by the sulphonation method. Results show one slight discrepancy in that they do not indicate the same ratio of benzene and toluene in cracked oil and distillation cut derived therefrom.

Analysis No. 2—The oils were distilled and redistilled with efficient fractionating columns and subsequent determinations made by both sulphonation and nitration methods. The latter were given the preference. Results were submitted with the statement that they were probably 1 or 2 per cent too high. Here again there is a discrepancy between cracked oil and distillation cut, and it is in the opposite direction to that noted in analysis No. 1.

The results of both the preceding analyses are probably as reliable as could be obtained by laboratories working in ignorance of the exact conditions under which the cracked oil was produced and distilled.

Analysis No. 3 was made with a single separation by distillation, followed by duplicate determinations by the methods of sulphonation and freezing. The figure for toluene is near that obtained by other laboratories. That for benzene is high, probably because reliance was placed on the results of the method of freezing.

Analysis No. 4 was submitted without statement as to method. Results are in general low, which indicates a reliance on purely chemical methods.

Analysis No. 5 was made by the authors by the method of distillation and specific gravity indicated above. The results are similar to those of analyses No. 1 and No. 2, but have the advantage of agreeing as to the ratio of benzene and toluene in cracked oil and distillation cut.

Summary

The following conclusions have been reached through the results of a series of experiments performed with the degree of care and accuracy generally feasible in commercial laboratories:

1. Solubility methods for the separation and estimation of aromatic compounds in cracked petroleum do not seem to be satisfactory.

2. The freezing method for the determination of benzene yields at best only qualitative results.

3. (*a*) Results approximating those of the best chemical methods may be obtained by the method of separating aromatic hydrocarbons with three successive distillations and determining their percentage in distillation cuts by specific gravity relations.

(*b*) The method of procedure which has seemed most satisfactory on the basis of present experience is as follows:

Seven hundred grams of cracked oil are distilled from a 1 liter distilling flask through a fractionating column whose efficiency is at least as great as that of a 5-in. Hempel column of aluminium beads. Two successive redistillations are conducted, likewise with efficient fractionating columns. For these a 200 gram portion of the 175 deg. cut is taken. For the first redistillation fractions are separated at the temperatures of 105 deg., 130 deg. and 160 deg. For the second the cuts are made at 95 deg., 120 deg. and 150 deg.

Specific gravities are then determined by whatever method seems convenient. Measurements should be accurate to about one part in a thousand. The percentage of aromatics is then calculated from these values on the basis of the following gravity relations in the various cuts:

Temp. of Cut, C.	Sp. Gr. of Aromatic	Sp. Gr. of Non-Aromatic
95°	0.880	0.720
120°	0.871	0.730
150°	0.869	0.760

(*c*) The one assumption upon which this method is based is the gravity value assigned in each case to the non-aromatic constituents of the distillation cut. This need not be known with great accuracy, but with our present knowledge of the mechanism of the cracking process it is desirable occasionally to verify results obtained on the basis of these specific gravities by the application of chemical methods of determination.

Naval Advisory Board

The Naval Advisory Board announced by Secretary Daniels will consist of the following members:

Chairman—Thomas Edison.

American Institute of Electrical Engineers—
Frank Julian Sprague and Benjamin G. Lamme.

American Institute of Mining Engineers—
William L. Saunders and Benjamin B. Thayer.

American Society of Mechanical Engineers—
William LeRoy Emmet and Spencer Miller.

American Society of Civil Engineers—
Andrew M. Hunt and Alfred Craven.

American Chemical Society—
W. R. Whitney and L. H. Baekeland.

American Electrochemical Society—
Joseph W. Richards and Lawrence Addicks.

Inventors' Guild—
Peter Cooper Hewitt and Thomas Robins.

American Society of Aeronautic Engineers—
Henry A. W. Wood and Elmer A. Sperry.

American Society of Automobile Engineers—
Howard F. Coffin and Andrew L. Riker.

American Aeronautical Society—
Mathew B. Sellers and Hudson Maxim.

American Mathematical Society—
Robert S. Woodward and Arthur G. Webster.

Synthetic Phenol and Picric Acid*

BY DR. A. H. NEY

Under normal conditions the world's demand for carbolic acid or phenol is amply covered by the amounts produced by the coal tar industry and the by-products recovery of the coke oven. The recovery of carbolic acid, crude and pure, from the so-called "creosote oils," that is, from afterrun of the light fractions and the forerun of the heavy fractions of the coal-tar distillation and the alkaline washings of the naphthalene fraction, has been developed to a high degree of perfection and refinement in England, the true cradle of the organic chemical industry. Pure carbolic acid (or phenol) has found extensive applications in the arts since its discovery by Runge in 1834, who as the first isolated it from coal tar. The aniline color industry employs it as an important intermediate product; together with its homologues, the cresols, it is extensively used in recent times for the manufacture of synthetic resins, and it is the starting material for salicylic acid and picric acid.

Owing to the extraordinary demand for the latter product in war time, the supply of natural phenol is entirely insufficient; moreover the price of carbolic acid has been subject to considerable market fluctuations, while during the last decade, until the outbreak of the war, the price of benzol has remained remarkably stable. For this reason the synthetic production of phenol from a material always available in practically unlimited quantities has gained considerable importance. Chemical research, of course, has in time produced several ways for the preparation of phenol, synthetically from other materials. All these methods, however, possess no industrial importance, and I refrain from recounting them. They may be found in the literature, the references being contained in Beilstein and other reference books.

Faraday in 1826 prepared naphthalene sulfonic acid by the action of sulfuric acid on the hydrocarbon naphthalene. The technical importance of this operation, called sulfonation, was not realized until half a century later, when Wichelhaus introduced the alkalifusion of aromatic sulfonic acid in the industry, and since that time the stupendous development of the aniline dye industry has found one of its mainstays in the introduction of the hydroxy-group into aromatic hydrocarbons by sulfonation and subsequent alkalifusion. Beta naphthol, one of the most important intermediate products of the coal tar color industry has been produced during the last thirty years in enormous quantities by this method, which is prototype for the synthetic production of phenol. In Germany, synthetic phenol has been produced in insignificant quantities in the last decade of the last century, but when England, during the Boer rebellion, placed an embargo on phenol and a considerable shortage occurred on the continent, the chemical works of F. Raschig in Ludwigshafen engaged in the manufacture of phenol on a large scale and has maintained this whenever the price fluctuation of natural phenol permitted. The chemical works of Hoffmann-La Roche in Basle also produced synthetic phenol for many years and have always been able to compete successfully with the natural product for pharmaceutical purposes.

In this country, previous to the outbreak of the great war, synthetic phenol was never produced, however, not because of our inability, but for economical reasons. Thomas A. Edison, who was the first seriously to feel the consequence of the complete shut-off of the phenol

*A lecture delivered before the National Exhibition of Chemical Industries in New York City on Sept. 24, 1915.

supply, as he uses large quantities in the manufacture of his phonographic disk records, which contain the artificial resin prepared from phenol, as binder and are "faced" with a varnish of the same material, deserves credit for fearless and energetic action in quickly engaging in the manufacture of phenol from benzol. Already early last fall his plant in Silver Lake, N. J., produced synthetic phenol sufficient for his immediate needs, which are considerable. This most creditable achievement is only marred by the fact that the old and well known process was claimed as his own invention, and the appearance of exaggerated and foolish stories in the newspapers was permitted and countenanced.

With the arrival of demand for high explosives from Europe the demand for phenol increased enormously, and gradually other concerns began to prepare for the manufacture of phenol, and all of the many new organizations which were formed on the basis of often fictitious contracts for picric acid for the belligerent governments were compelled to consider the manufacture of phenol. While normally the price of synthetic phenol is about 9 cents per pound, with benzol at about 60 cents per gallon the cost price of synthetic phenol is about 18 cents. But when we consider that the price of picric acid is at present $1.50 to $1.75 for large contracts and that from one pound of phenol about 1¾ pounds of picric acid are obtained, we can see what enormous profits are theoretically involved.

The Manufacture of Synthetic Phenol From Benzol

The synthetic production of phenol from benzol comprises the following steps and operations:

1. Sulfonation of the benzol by strong sulfuric acid.
2. The conversion of the resulting mixture of sulfuric acid and benzol-sulfonic acid into the calcium salts by adding milk of lime to the diluted sulfonation mixture.
3. Separation of the soluble calcium salt of the benzol-sulfonic acid from the gypsum by filtration.
4. Conversion of the calcium salt of the benzol-sulfonic acid into the sodium salt (and separation of the solution of the latter from the precipitated calcium carbonate.)
5. Evaporation (to dryness) of the sodium salt of the benzol-sulfonic acid.
6. Caustic fusion of the sodium salt of the benzol-sulfonic acid.
7. Dissolving the fusion and acidulating the same to liberate the phenol formed and separating the same from the aqueous solution of the salts.
8. Distillation of the crude phenol.

(1) SULFONATION OF THE BENZOL

This operation is carried out in the customary sulfonation kettles, consisting of a cast iron kettle of perhaps 300-350 gal. capacity, having a jacket of any preferred material capable of being heated, either by water, steam or an oil circulating system, to about 80 deg. C. The kettle is in this case preferably provided with bottom discharge. The lid must close tightly, a soft lead casket having been found satisfactory. The lid is provided with man or hand-hole, thermometer pipe, 4-in. opening for running in the charge, an emergency opening, if desired, and connection to a spiral reflux condenser, water cooled, for condensing the benzol vapors. The kettles are elevated to permit gravity discharge into the limeing tanks.

The stirring device is of the greatest importance. Owing to the great difference of the specific gravities of sulfuric acid and benzol, the tendency to separate into two layers and rotate as such is very pronounced, and it is obvious that in that case chemical action is very much impeded. The ordinary horseshoe type of agitator is therefore entirely unsuitable. Two types of agitators have been tried out, and both give about equal satisfaction. One type consists of a pair of ordinary propellers mounted on the shaft, one pair, however, being set conversely to the other; proper speed being 120-180 r.p.m. The other type consists of one complete turn of a broad spiral round the shaft, the whole revolving in a cylindrical case, which is either mounted on the shaft, rotating with same, or is stationary, viz., suspended from the lid or otherwise, a screw conveyor in fact.

For the production of one ton of phenol per day a battery of two kettles is necessary, each kettle being charged and operated twice.

In the cold or slightly warm kettle 410 lb. of sulfuric acid 98 per cent is run in, preferably from a measuring vessel common to all units of the battery. The agitator remains standing. One hundred and fifty-three pounds of benzol are next run in the kettle, the agitator still standing. The operator now closes all openings, excepting that leading to the reflux condensor, and starts the agitator. The temperature soon rises to 62-68 deg. or even higher.

When the thermometer indicates no further rise, heat is admitted to the jacket, and from now until the end of the operation the temperature is maintained as closely as possible to the boiling point of benzol; care, however, must be taken to prevent too energetic ebulition of the benzol which would otherwise be thrown through the condensor.

The sulfonation requires from 5 to 9 hours (in the mean, 7 hours) and is finished when the odor of benzol is practically gone (it never disappears completely) and a sample of the sulfonation, when diluted with many times its volume of water does not separate any drops of benzol. No benzol di-sulfonic acid is formed under these conditions, and the amount of sulfon is negligible. With benzol of good quality and at least partially freed from thiophene, the color of the sulfonation mixture is light straw yellow; on cooling, benzol-sulfonic acid separates in fair quantities, occasionally in crystalline form.

(2) CONVERSION INTO CALCIUM SALT

After completed sulfonation, the resulting mixture of sulfonic acid and sulfuric acid is run into about an equal volume of water contained in the limeing tank. The limeing tank may or may not contain a certain amount of milk of lime or calcium carbonate paste (from the soda tanks).

The limeing tanks (two being necessary for the quantities assumed above, but will suffice for a much larger production) are wooden tanks, preferably, but not absolutely necessarily, lead-lined, with powerful wooden agitators of the "gate" type, all iron parts protected and having a lead steam coil or an open steam pipe. The capacity of each is 1200 gal.; 4-in. bottom outlet, flanged and "flush" inside, proper draining being assured by a slight tilt. Bottom outlet connected to filter press pump (or Montejus if used, which is not advisable).

The milk of lime is prepared in a suitable vessel, for instance a sheet-iron cylindrical tank with iron stirrer and a perforated cagelike basket, removable, in which the lime is placed. Suitable capacity 500 to 600 gal. A straining device should be attached to the outlet.

Suitable proportions for the milk of lime: 1 lb. of burned lime for 0.6-0.75 gal. of water.

The operation of limeing is carried out as follows: Milk of lime is run into the diluted sulfonation mixture, the latter being hot due to the hydration heat of the acid. Steam is turned into the coil when the milk

of lime begins to run in. The milk of lime is added just short of the point of alkalinity, viz., until all sulfuric acid and the largest part of sulfonic acid is neutralized; then sufficient calcium carbonate (chalk or from the soda tanks) is added to neutralize completely. The content has now begun to boil and is maintained boiling for about 20 to 30 min. If it should become too thick, a little water may be added. (Very little water is necessary to thin the mass.) The steam is then turned off and cold water equal to about 1½ volumes of the original volume of the sulfonation mixture is run in.

All these precautions serve the purpose of obtaining the gypsum precipitate in a form permitting rapid filtration and complete washing out of the press cakes with the least volume of water.

(3) SEPARATION OF SOLUBLE CALCIUM SALT FROM GYPSUM

Two filter presses are desirable, but one may do. The filter press with washing device made by Shriver & Co., Harrison, N. J., is probably the best, but when ordering, it should be insisted that two washing inlets, one at the bottom and one at the top of the plate are provided (which is done without extra charge). Open discharge! The lower washing holes should be worked first. Filter presses are best raised on a platform high enough to permit a dumping cart to be driven under it, into which the gypsum cakes are dropped through a chute.

The contents of the limeing tube are pumped into the press at a temperature of about 60 deg. C. and the filtrate collected in the soda tubs. The cakes are washed, by means of the washing attachments, with hot water, the first washing being added to the filtrate while the last wash water may be turned back into the limeing tub in place of pure water for diluting the sulfonation mixture. The amount of wash water necessary depends largely upon the state and form of the gypsum precipitate, that is, if the same has been properly prepared and treated, comparatively little washing will be required, while, on the other hand, if it has been allowed to become slimy, it is very difficult to completely remove the calcium benzol sulfonate from it. The economy of the process depends to a large extent on this factor. Generally speaking the volume of the solution should not be increased more than 50 per cent by the washing operation.

(4) CONVERSION OF CALCIUM SALT INTO SODIUM SALT

The filtrate and wash waters are run by gravity from the troughs of the filter presses into a wooden tub. Two are advisable, of a capacity of 1500 gal. They need not have a stirring device, but preferably have a light one, or may be agitated by air or even by hand. They may have a closed steam coil of good size, in order to evaporate while filling and to boil, which is necessary in order to obtain the calcium carbonate in the proper crystalline form. Soda ash (dry) is added until all calcium is precipitated, which point is recognized when further addition fails to produce more precipitate and by the slight alkaline reaction. No excess of soda should be allowed.

The calcium carbonate is allowed to settle, and the supernatant clear liquid is fed to the evaporator. After the layer of calcium carbonate has increased, say after three or four conversions, it is washed once with water and then withdrawn and used for neutralizing the sulfonation mixture.

(5) EVAPORATION

Evaporation of the sodium salt is obviously carried out most economically in a multiple-effect vacuum evaporator and the drying of the salt in a vacuum oven. However, the temporary nature of the proposition does not always warrant the large investment for installing this apparatus, and any means for evaporation and drying, such as tanks with steam coils for concentration and jacketed shallow pans for drying may be employed.

The dry sodium salt represents a dazzling white finely crystalline mass, which, for the fusion, should be pulverized to a coarse powder, any means to that end being suitable.

The yield of the sodium salt should be practically theoretical, any losses being mechanical and most probably due to incomplete washing of the gypsum cakes.

(6) CAUSTIC FUSION OF THE SODIUM SALT

The caustic fusion is carried out in open cast-iron round-bottom kettles, of about 300 gal. capacity, having an iron stirrer of the horseshoe type, which should as closely as possible approach the sides and bottom of the kettle.

Two fusion kettles are preferably set in brick, arch construction or sheet steel protector to prevent direct contact with the flame.

Heating means, preferably: Schutte & Koerting (Philadelphia) gravity oil burner, size ¼ in.

The kettle is charged with 480 lb. of caustic soda and 30 to 50 lb. water added, which facilitates the melting of the soda. The temperature is raised to 270 deg. C., and then 600 lb. of dry pulverized sodium salt of the benzol sulfonic acid are shoveled in. The temperature should not be permitted to fall, but should, during the throwing in of the sodium salt, rise, so that when all of the latter is in, about 300 deg. C. has been reached. This can be readily done by increasing the flow of the oil of the burner and by regulating the speed with which the salt is added. When all has been added the temperature of the fusion is raised to about 315 deg., whereupon the heat is turned off. The temperature rises a little further but should never exceed 330 deg. However, observation of the temperature is not very essential, as with a little practice the progress, etc., of the fusion can readily be observed and followed by the appearance of the same. A description of these visual indications, however, would help but little, and experience and a few trials in the laboratory will quickly enable the supervising chemist to determine the correct conditions. In general the fusion is completed, when all sodium salt has gone into solution, and the melt becomes thin. No separation in two layers takes place with the above proportions.

(7) DISSOLVING THE FUSION AND ACIDULATION WITH LIBERATION OF PHENOL

When still hot and liquid, the melt is ladled in shallow iron pans or trays and broken up after having solidified and cooled. A crusher might suitably be employed. The workingmen must be provided with rubber gloves and goggles and should be advised to protect their clothing with pieces of sacking. Clogs or wooden shoes, such as worn by the Lancashire mill hands, are also recommended.

The broken-up fusion cakes are now dissolved in water, two parts of water to one part of fusion. The best apparatus for this operation is a sheet-iron cylindrical tank with conical bottom, similar to a benzol washer; it need not be lead-lined as, in contradistinction to the separation of tar-phenol from the alkaline solution by mineral acids, no danger of over-acidulation exists, as acid is only added until bisulphite has been formed. The tank may be open, but should be provided with a hood.

A perforated false bottom, preferably arranged that it can be lowered and raised and entirely removed, should be provided in the tank, and agitation is prob-

ably best provided by air. A lead-pipe with perforated coil, a little above the conical end, serves for running in the acid, and the usual arrangement for withdrawing the liquid at the bottom and at different levels should be provided.

When the cakes are dissolved diluted sulfuric acid from a lead-lined storage vessel is run in until the beginning of copious evolution of sulfurous acid indicates the beginning of the decomposition of the bisulphite. Five thousand pounds of cakes require about 2500 lbs. of sulfuric acid 100 per cent in form of 40 deg. Be. The contents of the tank are now allowed to stand, the aqueous solution containing sodium sulphate and sodium bisulphite is subsequently withdrawn at the bottom, and the phenol freed from sulfurous acid by vigorously blowing air through it for some time.

(8) DISTILLATION OF CRUDE PHENOL

The resulting crude phenol is now distilled from a phenol still and gives, after removal of the forerun, pure crystalline phenol of the highest melting point.

The yield obtained should be one pound of phenol for one pound of benzol.

The synthetic phenol thus prepared possesses frequently a very disagreeable odor characteristic to organic sulfur compounds. Whether this odor is due to the presence of thiophene in the benzol or to compounds formed by the reducing action of the iron in the fusion kettle (or possibly sulfonation kettles) on the sulfuric acid or sulfites, the writer expresses no opinion. This odor, however, can be readily and completely removed by digesting the crude or distilled phenol with common wood charcoal or still better animal charcoal, or distilling it over the same.

Traces of diphenol (dioxy-diphenyl) appear in the after run.

As in all similar cases, when an old established method suddenly obtains greater importance than was the case before, inventors, real and otherwise, have become active. In the case of phenol no tangible result has been obtained. All methods suggested as "short-cuts" in the sulphonation and fusion phases of the process have proven futile. Of course, modifications of the different steps are always possible. So it is, for instance, possible to sulfonate benzol with fuming sulfuric acid of various anhydride contents, but it is then necessary to keep the temperature of the reacting mixture well below 50 deg. as otherwise considerable amounts of disulfonic acids are formed increasing, of course, with the concentration of the anhydride.

Another "invention" often submitted by would-be "phenol experts" is the direct production of the sodium salt of the benzol sulfonic acid by treating the sulfonate with solutions of common salt. This "invention" is based on the practice followed by certain beta naphthol manufacturers, but is unrational because of mechanical difficulties occasioned by the necessity of filtering strongly acid solutions. Furthermore, the "salt" thus obtained contains large amounts of glauber salt, which are a nuisance in the subsequent fusion and require the use of larger proportions of caustic soda. The suggestion centering in directly neutralizing the sulfation and digesting the mess with caustic is too ridiculous to be considered seriously, and only demonstrates the deplorable ignorance in such matters of those who advance it.

Chlorbenzol is a fairly readily accessible, cheap material, especially if use is made in its manufacture of the chlorine produced by the electrolytic alkali manufacture. The chlorine atom in aromatic compounds can be replaced more or less readily by the hydroxy-group by digesting the chlorinated compound with alkalies. When more substituents are contained in the kernel, especially negative ones, the chlorine atom can be replaced very readily, but chlorbenzol is very inert as regard to this reaction and very high temperature and dilute solutions of caustic soda are necessary to perform satisfactorily this conversion. For this reason, which necessitates the use of autoclaves for very high pressure and large volume, the industrial application of this elegant short method for preparing synthetic phenol is out of question.

The Manufacture of Picric Acid

Picric acid is the tri-nitro derivative of phenol, the product of an exhaustive nitration of phenol, many of its derivatives and to some extent of many organic substances.

It presents pale yellow crystalline leaflets of exceedingly acrid taste soluble to about 1 per cent in cold water, more readily in hot water, easily in ether, alcohol and the usual organic solvents. F. P. 122.5. Ignited it burns, without explosion; detonated by fulminates (Ag or Hg) or guncotton it explodes and is one of the brisantest explosives. The salts are very explosive and also a detonator for free picric acid. Specific gravity of fused picric acid is 1.64.

The technical production of picric acid is to-day carried out by two distinct processes:

1. The first and oldest method, which even to-day is employed almost exclusively, consists in nitrating the phenol sulfonic acid obtained by treating phenol with concentrated H_2SO_4 at about 100 to 110 deg. until the odor of phenol has disappeared and the reaction product is completely soluble in water, with an excess of nitric acid, preferably in the presence of an excess of sulfuric acid.

2. The second and more modern method employs as starting material chlorbenzol, which is dinitrated to dinitro-chlorbenzol; this product is separated from the spent nitrating mixture, the chlorine atom replaced by the hydroxyl by heating with caustic soda, and the resulting dinitro-phenol is nitrated.

The possibility of a third commercial method for the production of picric acid is suggested by an old publication by Hepp., *Ann.*, 215, 344 (1882), who claims to have obtained, with an excellent yield, picric acid by oxydizing trinitrobenzol in alkaline solution with potassium ferric cyanide, the possibility of the use of other mild oxydizing agents being implied.

In view of the difficulty in obtaining trinitrobenzol with anything like a satisfactory yield, the commercial feasibility of such procedure, is open to grave doubt, although the writer has private information that a small plant is at the present time producing picric acid to some extent by a process purported to be based upon this method, literature on trinitrobenzol, Kekule, *Ann.* 137, 167; Salkowski, Rehs, *Ber.*, 7, 371; Hepp. *Ann.*, 165, 18.

The chemical and technical literature contains many suggestions and several descriptions for the manufacture of picric acid, all of them, however, being obsolete. Chemically, the preparation of picric acid is very simple and easy and, as a matter of fact, it would seem almost impossible for anyone placing phenol and nitric acid together, in some form and manner, not to obtain picric acid. Technically, however, the manufacture involves several difficult problems, mainly due to the fact that the handling of straight nitric acid is a difficult and dangerous operation precluding the use of materials for receptacles, etc., usually employed in the chemical industry and the somewhat exaggerated fear of contaminating by inorganic salts, detrimental to the stability of the product. The drying and pulverizing of

the material is a very dangerous operation, which, however, is now seldom required in chemical factories, the ordnance works usually requiring delivery of the wet crystals with a moisture content of approximately 20 per cent.

The manufacture of picric acid is carried out as follows:

A large sulfonation kettle of the usual construction, preferably lead-lined, with steam jacket, bottom discharge and agitator, is charged with one part phenol and four parts sulfuric acid, 98 per cent. The mixture is heated under agitation until a sample appears completely sulfonate, that is, soluble in H_2O without turbidity and the complete disappearance of the phenol odor. The content of the sulfonation kettle is now divided into the nitrators which are receptacles, suspended in a space adapted to have hot or cold water circulated therein. To the content of each kettle an equal part of sulfuric acid is added, and after reducing the temperature to below 20 deg. the nitrating acid is run in. The nitrating acid is preferably the usual mixture of equal parts of HNO_3 (40 deg.) and H_2SO_4, but any other proportion is equally suitable. Instead of three molecules required by the theory, four molecules of HNO_3 are added, the temperature being kept below 40 deg., while the first 30 to 40 per cent nitric acid is run in and then gradually increased to 70 or 80 deg., hot water being circulated toward the end of the operation and one to two hours afterward. Proper ventilation must be provided. Air may be blown through the nitrators before removing their content in order to remove the nitrous gases formed.

The content is now removed into an acid-proof, nonmetallic receptacle and diluted with water, about equal volumes having been found to give the best results. After cooling, the picric acid, which separates usually in large crystals, is placed on filtering means, "nutches" or centrifuges, and washed. The formation of too large crystals and "caking" should be prevented. It is usually of sufficient purity for any requirements. To obtain it still purer it may be fused in steam-jacketed enamelled kettle, from which it is run, if desired, through a sieve of platinum or gold, into a wooden tank with water. It is then filtered again. The method suggested in the literature of dissolving in alkali and again precipitating is unrational and dangerous and has never been practised by manufacturers.

The material from which the nitrators are made may be cast-iron, if the strength of the acid is always kept above 82-85 per cent, otherwise earthenware or enamel receptacles are indispensable. After the nitration the mixture is diluted, and for all final operations, contact with metals, other than precious, must be avoided. Coatings of a pure asphaltum varnish have given satisfaction. Proper agitation devices and ready means for discharging the nitrators and filling the same open a wide field for the ingenuity of the construction engineer.

The largest manufacturers of picric acid in the world (Hauff in Fuerbach) use an interesting and highly efficient filtering device. It consists of a filtering box or "nutch," with vacuum below and above, and is adapted to be used as both filter and dryer. The crude picric acid is placed on the filtering surface (a porous stone plate) and suction is applied. After the bulk of the adhering waste acid has been removed, alcohol is sprayed on the material and received in a separate container, from which it is at once rectified and recovered. The filter box is then covered with a specially constructed lid and vacuum applied; the drying proceeds very rapidly and the resulting product is very pure, due to the fact that it has been washed with alcohol, which is an excellent solvent for the resinous products, always formed during high nitration.

First National Exposition of Chemical Industries

The National Exposition of Chemical Industries held in the Grand Central Palace, New York, from Monday to Saturday, Sept. 20 to 25, 1915, was a real great success, even greater than its promoters and most sanguinic well-wishers could have hoped for. Like every exposition, it was a little slow in starting, but by Monday night all the exhibits were well in place, and it was then evident that in spite of being the first exposition of its kind held in the country it was a surprisingly finished and thoroughly representative affair. It is true manufacturers in a few fields, such as chemical stone-ware, were absent, but these were exceptions which only emphasized still more the fact that otherwise the exhibition was truly representative of the industry. The exposition is planned as an annual affair, and the surprising success of the first trial promises even greater successes for the future.

The idea of this exposition originated with two American chemists, Mr. Adrian Nagelvoort and Mr. Charles F. Roth, to whom a great deal of credit is due not only for the origination of the idea but for the perseverance, energy and good common sense with which they made a reality of their idea. They formed an advisory committee, consisting of Messrs. Raymond F. Bacon, H. B. Faber, Charles H. Herty, Arthur D. Little, Wm. Cooper Proctor, E. F. Roeber, George D. Rosengarten, T. B. Wagner and Utley Wedge. Associated with Messrs. Roth and Nagelvoort in the management of the exposition was the International Exposition Company, with Mr. F. W. Payne at the head, whose experience gained in the past in managing fifty large expositions contributed greatly to the success of the present exposition and to the satisfaction of every exhibitor.

The attendance was excellent and high-class in that chemical engineers, managers and superintendents, in general, men with buying power, were present, many of them from out-of-town places and from quite distant states. In honor of the visiting chemists the Chemists' Club held a smoker on Thursday night with vaudeville entertainment; it was a well attended and greatly enjoyed affair.

The general public was also greatly attracted by the exposition; on most of the evenings the show was quite crowded. The average daily attendance was quite a little over 10,000. It may thus be hoped that the exposition has promoted a better understanding by the general public as to what the chemical industries are and stand for. Certainly never before in the history of the world have the New York daily papers shown as much interest in chemistry as during the exposition week.

The adjoining illustrations will give an idea of the attractiveness and comprehensiveness of the exhibition; more details will be found in the concise summary of the different exhibits. We will finally give a review of the numerous meetings and lectures held in connection with the exposition—some of the papers presented are given in the present issue, while more had to be reserved for publication in later issues.

Finally great credit is due to the Bureau of Commercial Economics of Washington, D. C., which had arranged a very interesting moving-picture program on many chemical, metallurgical and industrial subjects, the films varying from day to day.

A concise summary of the exhibits arranged in alphabetical order of the names of the exhibiting companies follows:

Abbe Engineering Co., New York City, exhibited small jar or ball mills in actual operation and also showed a small size of their improved "Max" mill which has a vertical shaft, designed to reduce vibration. Mr. Henry Kleinfeld was in charge.

American Bitumastic Enamels Company, New York City, showed diagrams of the lock gates of the Panama Canal which were treated with their enamel after two years' test with various materials. The enamel has an asphalt base. Messrs. Sealey, Kerns and Ellis were in charge.

American Chemical Society exhibited publications and charts showing the growth in membership during the last few years. Also booth for entertainment of visitors.

American Electrochemical Society:—Pictures of pioneers in electrochemistry and electrometallurgy and also a large portrait of Robert Hare. Historic electric lamp exhibits, an exhibit showing the development of the tungsten lamp; argon-filled lamps, Cooper-Hewitt lamps. Various fine samples of electrochemical products from Niagara Falls. This was undoubtedly the most interesting Society booth at the show. Dr. Doremus, Mr. Bowman and Mr. Muir were responsible for the exhibit.

American Hard Rubber Company, New York:—Acid pumps, buckets, bottles, piping and various other utensils all made of hard rubber. Messrs. F. R. Greuse and E. Johnson were in charge.

American Institute of Chemical Engineers had a booth for entertainment of visitors.

American Paper and Pulp Association, New York City, showed photographs of woods and pulps made from them. This exhibit was loaned by Joseph H. Wallace & Co. of New York.

American Transformer Company, Newark, N. J., had an exhibit in conjunction with that of the Research Corporation, they having supplied the 100,000-volt transformer for the demonstration of the Cottrell electrical precipitation process. Mr. W. F. Hubley was in charge.

Ault & Wiborg, Cincinnati, Ohio, manufacturers of printing ink.

Automatic Weighing Machine Company, Newark, N. J., showed very instructive photographs of their automatic weighing and sealing machines. Messrs. H. D. Bowman and J. B. Mockridge were in charge.

J. T. Baker Chemical Company, Phillipsburg, N. J., had an attractive exhibit of Baker's analyzed chemicals neatly arranged in show cases.

Beach-Russ Company, New York City:—Small sizes of their rotary vacuum pumps and pressure blowers in operation. Their compound dry vacuum pump is guaranteed to produce a vacuum within 1/10 in. of barometer. Messrs. H. C. Russ and J. Buckley were in charge.

Christian Becker, Inc., New York City:—Exhibition of analytical balances. The feature of this exhibit was their new chain balance which weighs without weights, by having a gold chain fastened to the lever arm, the other end of which is raised or lowered to give different weights which are read on a scale, provided with vernier. Readings are accurate to 1/10 of a milligram. Messrs. C. G. Machilas and W. C. Symington were in charge.

W. Beckers Aniline and Chemical Works, Brooklyn, N. Y.:—A very neat exhibit of American made aniline and alizarine colors. The exhibit showed coal as a raw product, then the intermediate products, and finally the finished colors and the dyeing solutions. Messrs. Gustav Drobegg and Cillessen were in charge.

Benzol Products Company, New York City:—An interesting exhibit of coal tar products, including benzol, nitrobenzol, aniline oil, aniline salt, and oxide of iron as a by-product. Mr. J. R. de la Torre Bueno was in charge.

Bethlehem Foundry & Machine Company, Bethlehem Pa.:—A fine tantiron exhibit. A comparative corrosion test was in process with nitric acid dropping on a small piece of "tantiron" and then on ordinary cast iron. A new piece of ordinary cast iron was used each day and the same piece of tantiron was used all the time. The superiority of tantiron with respect to resistivity to corrosion was evident. Messrs. Lehman, Wilbur, A. H. Stevens and Ettle were in charge.

Brown Instrument Co., Philadelphia, Pa., exhibited their electric pyrometers, stationary and portable, also recording electric pyrometers. Messrs. Goheen, Andrews and Printz were in charge.

Buffalo Foundry & Machine Company, Buffalo, N. Y.:—This was one of the most attractive exhibits and occupied the whole back wall of the Exposition Hall. Numerous colored plates, lit up from the inside, showed various castings made by this concern. These were on the rail surrounding the booth. In the booth were many large castings, including a large reducer for aniline work, a caustic pot, crystallizing pan, condenser and cooler bodies for nitric acid, vacuum dryer and vacuum shelf dryer, and dry vacuum pump for pumping within 1/20 in. of barometer. A test was conducted showing the insolubility of "Buflokast" iron in various hot acids, compared with the solubility of common iron. Great surprise was shown by many people at the very large and varied line of work in chemical industries, as illustrated by this exhibit. Messrs. H. D. Miles, E. G. Rippel, E. G. Sleeper and H. B. Underwood were in charge.

Celluloid Zapon Co., New York City:—Lacquer enamels and lacquer, nitro-cellulose and a complete display of different materials treated by "Zapon." Mr. N. E. Dabolt was in charge.

Chemical Catalog Company, New York, N. Y., showed a dummy illustrating the nature of their catalog of chemical apparatus which will appear about the middle of 1916. Mr. R. R. Johnston was in charge.

The Chemists Club, New York City, had on exhibit a series of old photographs and prints of famous chemists, which attracted considerable attention.

Cinnakol Chemical Sales, Bayonne, N. J.:—Samples of their Cinnakol disinfectant, which is non-poisonous and soluble in water.

Detroit Range Boiler Co., Detroit, Mich.:—The Perfect metal bilge barrels on exhibit by this company attracted considerable attention as they have removable heads which can be made liquid tight to conform to I. C. E. specifications. They also exhibited 110-gal. drums which they made for customers who could not get them from Europe. Mr. W. B. Goddard was in charge.

J. P. Devine & Company, Buffalo, N. Y., exhibited one of their vacuum pumps and other apparatus and machinery of their design for the chemical industries. Also a very interesting exhibit showing the quantities of raw material required to produce one pound of phenol crystals from pure benzol in a process installed by them on a large scale. Messrs. F. H. Mason, Charles Devine and R. D. Kehoe were in charge of the exhibit.

Dorr Cyanide Machinery Company, Denver, Col.:—Very instructive working models of the Dorr classifier, agitator and thickener; also a complete working model of their recent continuous causticising apparatus in which demonstrations were given of the manufacture of caustic soda from soda ash and lime, applying the principle of continuous counter-current decantation (see our issue of August, 1915 p. 514). Messrs. J. V. N. Dorr, Noel Cunningham, H. N. Spicer, R. W. Shafor and L. B. Donaldson were in charge.

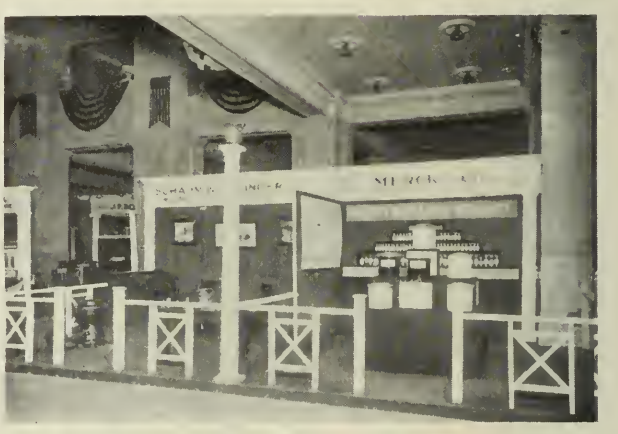
Driver-Harris Wire Company, Harrison, N. J., showed tests on their "nichrome" resistor wire, passing an electric current through of sufficient strength to heat the wire to bright redness in open air, the wire retaining its stability. They also had on exhibit a basket which had been immersed in fused potassium cyanide for eight months (steel hardening process), remaining unaffected. Messrs. Tracy, Bensel, Hart and Henderson were in charge.

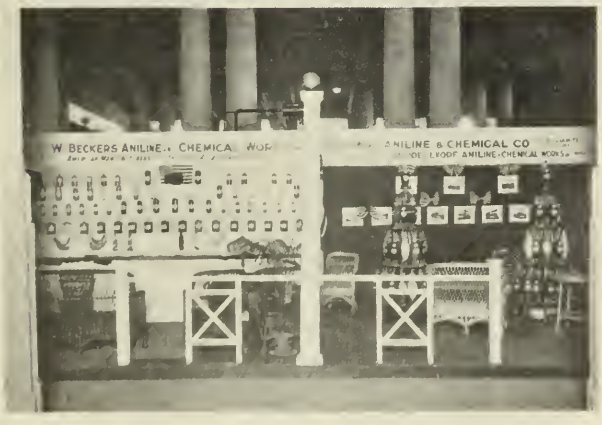
DuPont Chemical Company, New York City (owned by Dupont Powder Co.) showed samples of their various products, among which were benzol, pyroxylin or soluble cotton, commercial amyl acetate. Their various split leather solutions were shown by samples of rough split leather. An exhibit of Fabrikoid was also included. Mr. R. L. Vilas was in charge.

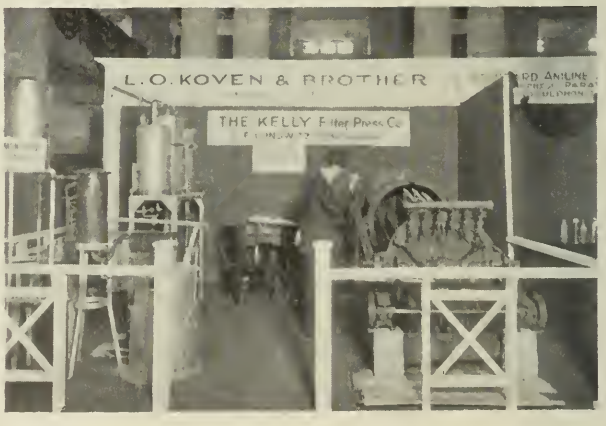
Duriron Castings Company, New York City, exhibited nitric and sulphuric acid condensers; a sulphuric acid concentrator for making 66 deg. Be acid from chamber acid; solid "Duriron" valves and a new 4-in. x 8-in. acid pump used largely for filter press work. Messrs. J. R. Pitman, I. D. Horton and P. D. Schenck were in charge.

Thomas A. Edison, Orange, N. J.:—Benzol, toluol, xylol, and numerous other products. A motor truck size of his new alkaline battery showing the nickel flake, nickel hydroxide, and iron oxide attracted considerable attention. Mr. W. Mallory was in charge.

Eimer & Amend, New York City, exhibited a great many of their laboratory supplies, among which were the Barnstead automatic water still, hydraulic hardness testing machine; "Eanda" American flasks and beakers, and porcelain ware and the Fleming absorption tube. A source of particular interest was found in the new "High-Temp" electric







Exhibits at First National Exposition of Chemical Industries

New York City, September 20 to 25, 1915

furnace manufactured by the Electric Heating Apparatus Co., which was in actual operation. Mr. E. Child was in charge of the booth and Mr. Smalley demonstrated the furnace.

Elyria Enameled Products Co., Elyria, Ohio, exhibited four enameled kettles, illustrative of their line of seamless, one-piece, acid and alkali resistant chemical apparatus. Messrs. William E. Gray, vice-president, J. O. K. White, and E. P. Poste were in charge.

Charles Engelhard, New York City, exhibited the Heraeus Le Chatelier pyrometers for temperature measurements up to 1600 deg. C. This exhibit was in conjunction with the Hanovia Chemical Co. of Newark, N. J. Mr. R. A. Newcomb was in charge.

Fairview Fluorspar & Lead Co., Golconda, Ill., exhibited large blocks of fluorspar, lead ore (galena) and gravel and ground fluorspar.

Foote Mineral Company, Philadelphia, Pa.:—Exhibit of unusual ores, including zirconia ore. Refractory bricks, pure zirconia oxide, silicate, zirkite cement, all made from zirconia ore formed an important part of their display. Mr. H. C. Meyer was in charge.

Geissinger Regulator Company, New York City:—Demonstration of the Geissinger industrial temperature-control system for all classes of temperature-control work, such as conveyor type ovens, large flue dampers in superheaters, dryers, etc. This exhibit was in connection with that of Gerdes & Co.

General Bakelite Company, New York City:—Various products made from this material, showing its wide range of applicability. Included in this exhibit were Weston galvanometers, general molded insulation apparatus, high tension molding for automobile work, some beautiful parasol handles, and cane handles, fountain pens and billiard balls which are more elastic and less resistant to damp weather than ivory. The exhibit was in charge of Mr. H. S. May.

General Chemical Co., New York:—Demonstrations of the baking qualities of their new baking powder "Ryzon," which they have recently placed on the market. Mrs. E. J. Martin was in charge.

Gerdes & Company, New York City, showed their hygienic ventilating apparatus, gears, castings and the Hopes pyramid grate, for improved fuel economy in both natural and forced draft. Mr. Theodore R. N. Gerdes was in charge.

Glens Falls Machine Works, Glens Falls, N. Y., exhibited the Tromblee & Paull rotary sulphur burner, of which they are sole manufacturers. Mr. Hall was in charge of the exhibit.

Emil Greiner Company, New York City, exhibited glassware and miscellaneous laboratory supplies. A feature of their exhibit which attracted attention was a "day-light arc lamp." A filtering glass is placed below a concealed source of light so that the different colors pass through in the correct proportion of daylight spectrum; for color and paint plants, dyeing works and in general for purposes where exact color matching is important.

Hanovia Chemical Co., Newark, N. J.:—Showed Heraeus quartz glass, long distance thermometers, Heraeus pure platinum laboratory furnaces, for temperatures up to 1400 deg. C. and Heraeus transparent quartz glass chemical apparatus. Mr. S. W. Robinson was in charge.

Hardinge Conical Mill Company, New York City:—Complete working model of the Hardinge Mill with glass arranged so that the inside working could be seen. This is a continuous feed and discharge grinding machine. Mr. R. Clark was in charge.

Heller & Merz Company, Newark, N. J.:—Aniline colors, also Bleachette laundry blue and Alderney butter color. Mr. W. J. Robertson was in charge.

Huff Electrostatic Separator Co., Boston, Mass.:—Small working model of the Huff separator which uses 12 to 28,000 volts on ore separation, and a small model of the Plumb pneumatic jig for ore separation. These are both dry processes. Mr. H. P. Johnson was in charge.

F. C. Huyck & Sons, Albany, N. Y.:—Samples of their woven woolen filter cloths. Mr. J. C. Standish was in charge.

International Filtration Corporation, New York City, showed a rotary continuous vacuum filter and their movable leaf or cell type vacuum filter. This consisted of three tanks with an overhead travelling set of filter plates provided with suction. This set of plates could be transferred from one tank to the other for washing after forming the cake in the first tank. Messrs. Dickey, Wheat, Faber and Crosby were in charge.

International Instrument Company, Cambridge, Mass.:—Shaking machine for small bottles, and a complete laboratory centrifugal on exhibit. Mr. Arthur Kendrick was in charge.

Kieselguhr Company of America of Los Angeles and New York City, showed their "sil-o-cel" bricks, and powder made of pulverized celite, and gave a demonstration of the heat withstanding qualities by applying a blast lamp directly to a "sil-o-cel" brick. Messrs. D. S. Collins and P. A. Boeck were in charge.

Lead-Lined Iron Pipe Company, Wakefield, Mass., exhibited valves and pipe fittings, all lead-lined; a feature of their exhibit was a sample piece of 16-in. lead-lined iron pipe furnished by the Chile Copper Company, Antofogasta. Mr. T. H. DuBois was in charge.

Lenz & Naumann, New York City:—General laboratory supplies, including the Riché adiabatic calorimeter, Link's patented water purifier. Tirrell gas making machine for making gas from kerosene, Lenzmann micrometer, Bavarian porcelain ware (imported) of which they still have a supply. Dr. Lenz and Messrs. Naumann, Greenberg and Kartenhaus were in charge.

Emil E. Lungwitz, New York, exhibited the Kelly filter press in conjunction with L. O. Koven & Brother. This was a regular size press of which all the features could be examined. Dr. Lungwitz was in charge.

Macbeth-Evans Glass Company, Pittsburgh, Pa., showed chemical glassware made in U. S. A. to take the place of Jena ware. This included all sizes and shapes of beakers and flasks. Messrs. George D. Macbeth and F. S. Irving were in charge.

Merck & Company, New York City, exhibited a shelf of their well-known "blue label" reagents and large jars of hydro-quinone (manufacture in the United States begun in 1914), synthetic carbolic acid, pure benzol, aniline oil and other products.

Metallurgical and Chemical Engineering placed its booth at the disposal of visitors and exhibitors with respect to telephonic, clerical and stenographic service. Mr. Burns was in charge. Messrs. Muir, Bedell, Munn, Bergen, Cain and Hays were in attendance.

The Mogul Company, New York; exhibit of their liquid for treating miscellaneous materials to render them acid and waterproof; also of materials treated by their products. Messrs. A. Gottlieb and C. H. Klepper were in charge of the booth.

Monsanto Chemical Works, St. Louis, Mo.:—Samples of acetphenetidin, caffeine, chloral hydrate, coumarin, phenolphthalein, saccharin and vanillin. Mr. B. M. Couvalt was in charge.

J. L. Mott Iron Works, New York City, showed cast-iron steam-jacketed porcelain-lined mixer and other acid resisting kettles of different kinds. Mr. R. H. Horne was in charge.

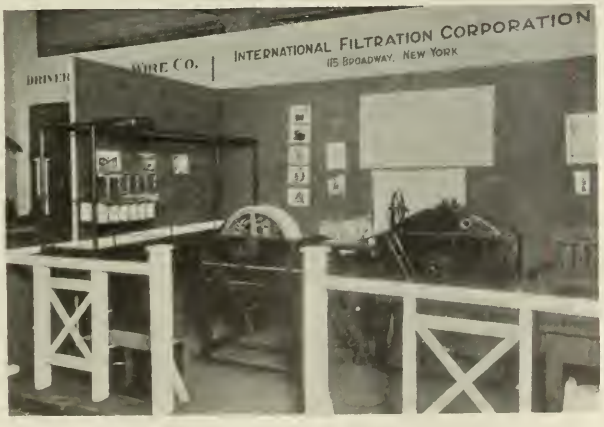
National Aniline & Chemical Company, New York City (selling agents for Schoellkopf Aniline & Chemical Company, Buffalo, N. Y.), had a fine exhibit of aniline colors and intermediate products, of which they have been the oldest American manufacturers. Mr. Henry Metz was in charge. Mr. I. F. Stone, president of the company, presented an admirable paper on Wednesday night on the aniline dye situation, which is printed in full elsewhere in this issue.

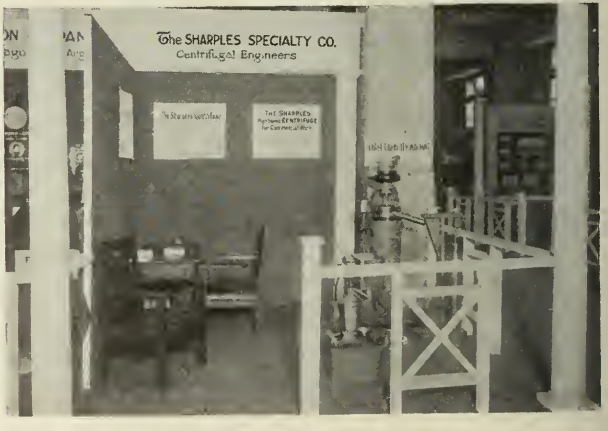
Norton Company, Worcester, Mass.;—Exhibit of alundum crucibles, tubes for carbon determination and various other refractory apparatus of alundum. A demonstration was made of the porosity of alundum by constantly dropping a liquid through a crucible of this material. Grinding materials were also shown. The columns at the corners of the booth were built up of grinding wheels. The booth was in charge of Mr. M. A. Williamson.

Pfaudler Co., Rochester, N. Y.:—Exhibited an upright open tank, and an upright open jacketed tank lined with their acid proof enamel. These were small tanks but the construction was on the same basis as many of their larger tanks. Messrs. F. L. Craddock and N. G. Williams were in charge.

Raritan Copper Works, Perth Amboy, N. J.:—Exhibited ingots and wire bars of refined copper; also nickel sulphate and copper sulphate recovered. Their exhibit of selenium and tellurium, which are by-products, deserves especial mention. Selenium was exhibited in several different forms, namely, viz: red amorphorus as powder, vitreous form as powder, sticks and half-pound cakes. Tellurium was in sticks and cakes. Besides this there were gold, silver, platinum and palladium. Messrs. S. Skowronski and C. H. Aldrich were in charge.

The Research Corporation, New York City, showed a small working model of the Cottrell electrical precipitation process for removing dust from gases. Frequent demonstrations were given and attracted a great deal of attention. The voltage used was about 40,000, whereas in actual practice up to 100.000 volts are used. The transformer was furnished by the American Transformer Co., Newark, N. J.





Exhibits at First National Exposition of Chemical Industries

New York, September 20 to 25, 1915

Mr. Linn Bradley of the Research Corporation and Mr. W. F. Hubley of the American Transformer Co. were in charge.

Schaeffer & Budenberg Company, Brooklyn, N. Y., exhibited recording gages and thermometers of their Columbia and Crescent brands; also steam calorimeters, engine indicators, and stationary and hand tachometers. Their recording apparatus was demonstrated by a complete testing outfit. Messrs. Wimmers and Undertsch were in charge of the booth. Great credit for the attractive arrangement of it is due to Mr. Carlier.

Schaum & Uhlinger, Philadelphia Pa., exhibited the parts of a small centrifugal; also a small undriven basket type centrifugal together with photographs of their various designs. Messrs. C. W. Schaum and Leslie Griscom were in charge.

Schutte & Koerting Company, Philadelphia, Pa., had a complete working installation of the Bihn-Jones automatic air-lift except that the lift was not so high as would be encountered in practice. They also exhibited the Auld reducing valve for steam and air reduction, lead-lined valves and ejectors and various other engineering specialties. Dr. E. Kimberly was in charge.

E. Scott & Co., Fall River, Mass., showed photographs and blue prints of plants and machinery designed and installed by them, especially vacuum and distillation plants. Messrs. H. Austin and A. B. Kennedy were in charge.

Sharples Specialty Co., West Chester, Pa., showed their smallest and largest types of centrifugals. Principal interest in these machines is their high speed, the small one travelling at 20,000 r.p.m. and the large one at 40,000 r.p.m. They are hung from balls and are free at the bottom.

Sowers Manufacturing Co., Buffalo, N. Y., showed two standard type "Dopp" seamless kettles and a small experimental vacuum kettle. Messrs. C. M. DeForest, W. Bowman, and P. Coxe were in charge.

Stamford Manufacturing Co., New York City, showed furs, silks, buttons, wool, cotton and leathers dyed with their vegetable dyes. The logwood produces the blacks and blues, the fustic produces the yellows and browns, the hypernic produces the reds, and these are further mixed to produce other shades. Mr. C. L. Young was in charge.

Sweetland Filter Press Co., New York:—The demonstrations of this filter press attracted very considerable attention as a complete small working filter was in operation with the necessary solutions, etc., for a complete demonstration. The metallic filter cloth used in conjunction with the press was also a source of much interest. Messrs. A. W. Wright and Howard Runyon were in charge.

Swenson Evaporator Company, Chicago, Ill., exhibited two of their standard evaporators, one the standard horizontal tube evaporator of the submerged tube type, the other the patented basket type, vertical tube "Seco" evaporator having 250 sq. ft. of heating surface by passing the liquid up through vertical tubes surrounded by steam in the basket, the vapor emerging at the top of the tubes. Messrs. F. M. De Beers and P. B. Sadtler were in charge.

Tennessee Power Company, Chattanooga, Tenn., exhibited photographs and maps showing their completed and proposed hydro-electric developments on the Ocoee and Tennessee rivers. Messrs. E. A. Hitchcock and C. F. Long were in charge.

Thwing Instrument Co., Philadelphia, Pa.:—Thwing Pyrometers, high-resistance multiple-recording pyrometers, also duriron and carborundum protecting tubes for thermocouples. A feature of their exhibit was a new apparatus for directly reading the moisture content of coal. The exhibit was in charge of Dr. Charles B. Thwing.

Toch Brothers, New York City, exhibited the different pigments used in making R. I. W. paints; also finished surfaces and hollow tile showing their water-proof paints and photos showing the many large buildings on which their paints are used. Among these are many of the largest structures in New York City. Messrs. E. A. Marx and F. A. Milligan were in charge.

Tolhurst Machine Works, Troy, N. Y., had on exhibit a large centrifugal driven from above and also two small laboratory centrifugals. Messrs. Tolhurst and Patton were in charge.

Troegerlith Tile Co., New York City:—Samples of their tile flooring in all different colors, their cork composition flooring, "Pollo Oil" and N. B. water proofing for floors. Messrs. Hyde, Richardson and Cheney were in charge.

Union Sulphur Company:—Refined sulphur and a most interesting sample of synthetic indigo made within the last two weeks by a Michigan manufacturer who wishes to withhold his name. Mr. Wilkinson was in charge.

United Gas Improvement Company, Philadelphia, Pa., exhibited by-products of coal-tar distillation, including intermediates, light refined products, road compounds and pitches.

United Lead Company, New York City:—Lined and covered pipe, in lead, tin, brass and copper. Lead rope for caulking. Ulcoloy, a new alloy of 50 per cent Cu. and 50 per cent Pb. They also had on exhibit a piece of lead pipe 2000 years old from Rome. This was well preserved and attracted considerable attention. Messrs. L. B. Gallison, Thomas Wettstein, E. J. Bredehoft and O. M. Hovemaner were in charge.

U. S. Government Departmental and Bureau Exhibits, Washington, D. C.:—This was the largest exhibit and contained a great volume of interesting apparatus, photographs, materials and publications. The feature which attracted the most attention was the demonstration of the Rittman oil cracking process, for making gasoline, benzol and toluol from petroleum. The Bureau of Foreign and Domestic Commerce showed all their publications, the Bureau of Mines showed the Westphalia and Draeger apparatus for mine rescue work; also Edison's electric mine lamp, first-aid cabinets and oxygen reviving apparatus. The lungmotor adopted by the U. S. army and navy was shown. The Geological Survey showed some of the economic minerals studied by them, and their various publications. Among the minerals were alunite, niter from Oregon and crude K_2SO_4-40-50 per cent obtained from the water of Owen's Lake, Cal. The agricultural and forestry service were represented by publications and photos. The Bureau of Soils and Plant Industry showed different fertilizers, kelps and brine from Searles Lake, Cal. The Bureau of Census was represented by their publications on chemical industries. The Bureau of Standards had a very large exhibit showing all their publications and the apparatus used in their work. This included gas calorimeters and meters, pyrometers, thermometers, hydrometers, standard weights, chemical apparatus and much other material. The following men were in charge: Bureau of Mines, Mr. M. F. Leopold; Rittman Process, Mr. S. H. Hartig; Foreign and Domestic Commerce, Dr. Thomas H. Morton, W. A. Johnston, Jr., Messrs. Brock and Penfield; Bureau of Standards, Dr. William Blum, E. C. McKelvy.

U. S. Smelting, Refining & Mining Co., Boston, Mass.:—Specimens of products from all of their subsidiary companies including different brands of copper, lead, spelter, selenium, gold, silver, platinum, palladium, crushed slag, hydrofluoric acid and miscellaneous ores. Also an exhibit showing the different stages in the process from ore to refined copper. Messrs. Sidney Rolle, A. Butts and W. C. Smith were in charge of this very well arranged and representative exhibit.

Valley Iron Works, Appleton, Wis., had on exhibit a complete Vesuvius sulphur burner, so arranged that all parts could easily be seen. Messrs. E. A. Peterson and R. W. Fannon were in charge.

Wilson-Mauelen Company, New York, who are shortly to move to their new factory at Whales Avenue and 142nd Street, Bronx, New York, had their "tapalog" on exhibition. This is a multiple-recording pyrometer giving on one chart four records and four colors of the temperatures of four different sources of heat. Mr. Wilson was in charge.

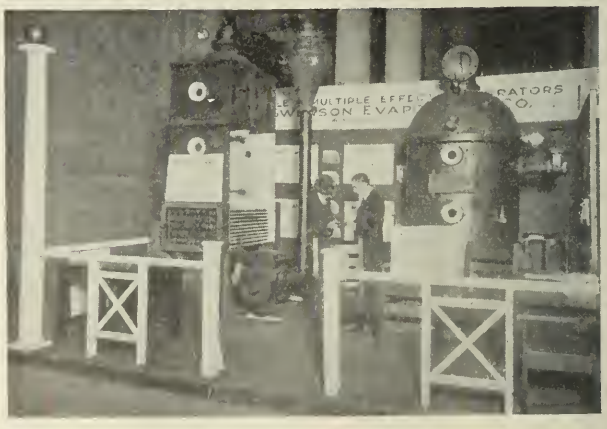
Zaremba Company, Buffalo, N. Y., showed interesting photographs of their evaporating apparatus of different sizes and designs.

Official Opening of the Exposition

The exposition was officially opened in the lecture hall on Monday evening. Dr. C. A. DOREMUS introduced the speaker of the evening, Dr. CHARLES H. HERTY, president of the American Chemical Society.

Dr. Herty, in his own delightful way, said there could be no more pleasing privilege than to open the First National Exposition of Chemical Industries ever held in this country and to extend congratulations to its originators, and he expressed the hope that the exposition might help the American public to find the right attitude toward the American chemist.

The German chemist has been largely responsible for the industrial successes of modern industrial Germany. Now since the war has cut off the importation of many chemical and allied products from Germany to this country, the American newspapers and the American public have found fault with the American chemist. But the American public should remember that as a nation it has never taken the same friendly attitude



Exhibits at First National Exposition of Chemical Industries

New York City, September 20 to 25, 1915

toward the American chemist which the German nation has taken toward the German chemist. This is a fact.

What is needed for the further development and growth of the chemical industry in America? The chemical manufacturer needs a little time to adjust himself to changed conditions. Brains and punch the American chemist has. But American ingenuity and energy cannot do without American capital, and American capital hesitates to make investments if they are to be rendered insecure by a sudden stoppage of the war. What is needed is protection—not forever, but just for a reasonable time until the American chemical industry has adjusted itself to new conditions. Dr. Herty's plea for a protective tariff for a limited time was very strong.

Dr. Herty also emphasized that now when the interest of the nation has been aroused in the chemical industry the public should be seriously warned against stock-jobbing concerns which are playing on the aroused interest in chemistry. It is the legitimate chemical industry which must be protected in its present healthy growth.

American Electrochemical Society Meeting

On Tuesday night a meeting was held at the Lecture Hall of the exposition by the New York section of the American Electrochemical Society.

Dr. COLIN G. FINK, of the Edison Lamp Works of Harrison, N. J., chairman of the section, opened the meeting by defining electrochemistry as the science which treats of the production of electricity by chemical changes, of the production of chemical changes through the agency of electricity, and of the electrical properties of chemical substances.

Electrochemistry became a real science in 1887 when the master mind of Wilhelm Ostwald systematized and interpreted the empirical results and generalizations of Berthelot of France, of Guldberg and Waage of Norway, of Willard Gibbs of America, of van't Hoff of Holland, of Arrhenius of Sweden, of Faraday of England, and of Bunsen of Germany. Electrochemistry has a decidedly cosmopolitan pedigree.

From an economic and commercial standpoint our own country ranks as the most important electrochemical center of the world.

Dr. Fink then introduced as the first speaker Mr. DAN. T. PIERCE of the Barber Asphalt Company, with "his lively troup of trained molecules."

Mr. Pierce spoke on the properties and methods of mining and utilizing of Trinidad asphalt, showing a set of most interesting moving pictures. But the most interesting and highly novel part of his lecture was what he said about colloidal clay in Trinidad asphalt. For the first time the Brownian movements of colloids were shown in a moving picture on this evening.

There is a very important difference between Trinidad asphalt and any other bitumen in commercial use or of which we have any knowledge. This difference lies in the fact that Trinidad asphalt in its natural state contains a considerable proportion of mineral matter in colloidal form. That is to say, mineral particles so finely divided that they cannot be settled out or filtered out, and which are in constant motion.

For a great many years it has been observed that there was a small residue of mineral matter recovered from the most carefully filtered solutions of Trinidad asphalt. This residue was never identified or satisfactorily accounted for until Mr. Clifford Richardson, the engineering chemist of The Barber Asphalt Paving Company, conceived the idea that this matter consisted largely of colloidal clay. This conception on Mr. Richardson's part followed closely upon a lecture on colloids by Professor Ostwald at the laboratory of the College of the City of New York, in March, 1914.

Subsequent investigations with the aid of the ultra-microscope and the laboratory work carried out by Mr. Richardson and his assistant Dr. Schneeberger, have verified the belief that in Trinidad asphalt we have a true bitusol—that is to say, dispersed solid colloids in solution in bitumen. The extreme fineness of this colloidal matter is demonstrated by the fact that it is not deposited from solutions of the bitumen after standing for years, and that under the ultramicroscope it is demonstrated to be in that active state of motion called the Brownian movement which is characteristic of all highly dispersed colloidal material.

The moving pictures [shown by Mr. Pierce] are unique in that they afford the first opportunity to observe the Brownian movement of colloidal matter in form of moving pictures. These pictures were taken by joining the lens of a cinematograph camera to the eye-piece of the ultramicroscope, thus reproducing on the film the movement observed by the eye through the microscope. So far as is known this is the first time such a motion picture has been made and this is the first exhibition of the film.

When it is considered that the colloidal particles are as small or smaller than one ten-thousandth of a millimeter, this example of motion photography becomes all the more remarkable.

A few words will emphasize the importance of Mr. Richardson's discovery with relation to the asphalt paving industry. The theory of an asphalt pavement is that of a mixture of sands in which by grading the voids will be reduced to the lowest possible limit, bonded together with the asphalt. A mixture contains from, say, 12 to 18 per cent of filler dust which will pass a screen of 200 meshes to the inch. The larger the proportion of fine sand in a mixture the more bitumen it will carry and the more durable will the pavement be, for the obvious reason that the more finely the mineral matter is divided, the larger surface area it presents for the adhesion of the asphalt.

The presence of colloidal matter carries us a step further, for not only does colloidal matter add to the paving mixture particles of a fineness never artificially combined with bitumen—it also gives us the advantage of the absorptive power of colloids. That is to say, the power such matter has of holding the asphalt cement about itself in the form of a film.

The filler ordinarily used in an asphalt mixture is estimated to run about 192,000,000,000 particles to the pound, and none of it is of colloidal fineness. The dimensions of such filler would be from 8/100 to 25/10,000 of a millimeter. Imagine a cube having a dimension of 1 centimeter reduced to particles of the coarsest colloidal size—1/10,000 of a millimeter—and we have increased the surface area of the material in the 1 centimeter cube 100,000 times.

The importance of colloidal matter in an asphalt mixture is therefore due to two causes, namely, the vast increase in the surface area presented, and the tenacity and thickness of the film of asphalt which surrounds the colloidal particles.

For many years the industry has been familiar with what it called the "stability" of Trinidad asphalt. Colloidal chemistry has now enabled us to account for this characteristic on rational grounds.

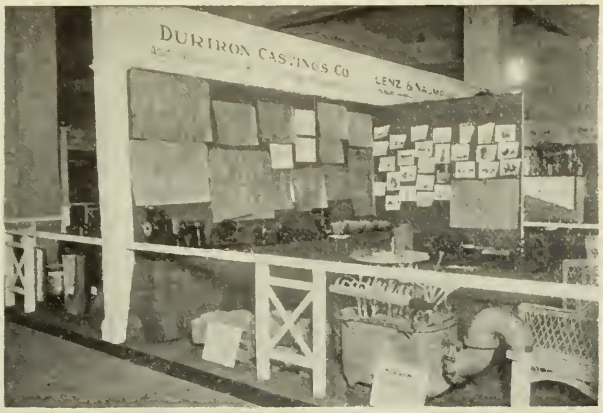
Mr. LINN BRADLEY, of the Research Corporation, followed with an interesting address on "the solution of the smoke, dust and fume nuisance by electrical precipitation" by the Cottrell process. This address gave a very good concise summary of the present status of the process, and is reserved for publication in a future issue.

The last speaker of the evening was Mr. HARRINGTON EMERSON, who spoke on "efficiency in the conservation of our natural resources." His theme was: "Utilizing Efficiently Our Natural Resources."

The natural resources of the universe become *our* natural resources when we can use them for our service. They are only partly our resources when we merely adjust ourselves to them as parasites. They are distinctly ours when we can control and harness them. About sixteen years ago, I visited Snoqualmie Falls, near Seattle. A great river plunged over a ledge and fell to the gorge below, a height 100 ft. greater than that at Niagara. Here was a tremendous natural resource, not yet harnessed, not yet ours.

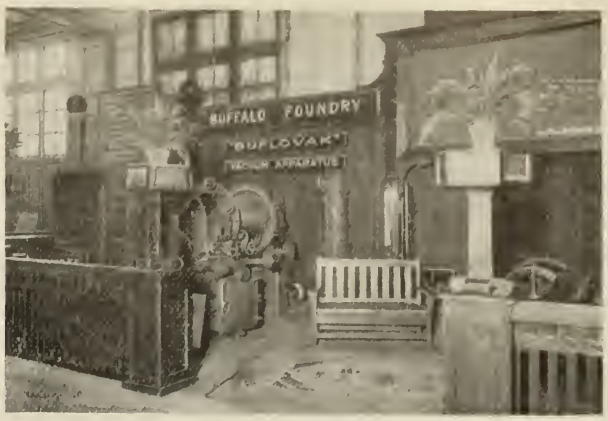
I visited the same falls this summer. Scarcely a brook trickled over the bared ledge, but miles away in Seattle and in Tacoma, trolley cars were running, machinery was driven, lights were blazing, because the falls had been harnessed and controlled. The natural resource was *ours*, and it was being efficiently utilized in forms that were no longer natural, but distinctly a product of man's mind.

To utilize efficiently our natural resources we must know what resources are natural, what is their extent,



Exhibits at First National Exposition of Chemical Industries

New York City, September 20 to 25, 1915



Exhibits at First National Exposition of Chemical Industries

New York City, September 20 to 25, 1915

what control we can attain over them, what part of those controlled has value, what the maximum value is, our efficiency in extracting the values.

Natural resources are physical, mental and emotional. The sun is one of our greatest natural resources.

The evaporation of water is one of the most universal phenomena in nature, but it took millions of years before an animal wise enough to boil water appeared on earth, and it took several hundred thousand years more before man was wise enough to confine steam in a strong container and make it push a piston. . . .

The radiations from the sun are incomparably our greatest natural resource, but as yet the efficiency of utilization is very low. There is probably no field so promising of immediate great returns as more efficient utilization of that small fragment of the sun's radiation which the earth intercepts. At the present time only about one-thousandth part is utilized at all. It is conceivable to me that we may ultimately discover some device by which condensation of the moisture of the air into rain can be concentrated at one point, even as we now divert the water of a stream into a flume, lead it many miles away and there harness it. More immediate and practical is our power to make the sun serve us by planting and covering the available surface of the earth with more suitable vegetation.

Mr. Emerson then discussed our natural mental and emotional resources.

The human seed is so small that it requires a microscope to be seen. Give this seed nourishment, heat, sunlight, and air, and it grows, perhaps into one of the great leaders of humanity. Socrates was the teacher of Plato, Plato was the teacher of Aristotle, Aristotle was the tutor of Alexander, and at 33 Alexander was weeping because there were no more worlds to conquer. What kind of a world would it be if the human plasm developed exclusively into such sequences as I have enumerated?

On the one side we would have the infinite material universe extending from the center of the earth to the uttermost confines of space, and on the other infinite mental and moral capacities of human excellence utilized efficiently to conquer these infinite resources for the benefit of humanity. These are the two biggest problems in the world as I see them and every act, every thought, every emotion can be gaged with reference to their solution. By far the more important of the two is the efficient use of the human elements.

Mr. Emerson then gave instances how some nations do better with their natural resources than others, so that we can at least set up comparative standards. "Henry Ford is able to make American mechanics worth to themselves $5 a day instead of $3. He makes the worth of his company $10 a day instead of $4. If all American workers were doing as well as the Henry Ford workers they would be earning $40,000,000 a day more for themselves and would be producing $80,000,000 more a day than the workers now do."

Meeting of the American Institute of Chemical Engineers

On the evening of Wednesday, Sept. 22, a meeting of the American Institute of Chemical Engineers was held. The president, Dr. GEORGE D. ROSENGARTEN, made a few opening remarks and then introduced Dr. THOMAS H. NORTON, of the Department of Commerce, Washington, D. C., who spoke on "Foreign Markets for American Chemicals." The first part of the lecture was augmented by numerous lantern slides, showing the loading, unloading and transportation of American goods in foreign countries. This part of the talk was very general and included such apparatus as agricultural implements, oil engines, cement, etc. He emphasized

the importance of packing goods for export very securely, and showed pictures of damaged goods which had arrived in foreign port. Every facility of the Department of Foreign and Domestic Commerce is open to manufacturers to assist them in their export problems.

Detailed statistics were then given showing the increase in our exports of chemicals during the last year, the figures for the month of June, 1915, showing a 161 per cent increase over the month of June, 1914. Data are now being obtained on the geographical distribution of the export increases. The chemical market of the world was placed at $598,000,000 in value, the share of the United States being but $48,000,000.

The potash situation was then briefly discussed, and the active part which the Department of Commerce has taken in this work was explained. Many processes have been proposed, but few are commercially available. The efforts to solve the potash problem are sure to avail something before very long, but the commercial process and the capital must be brought together.

The dyestuff situation was next briefly discussed as of equal importance to potash. The Department of Commerce has also taken an active interest in working out this problem and has endeavored to bring the capitalists in touch with the engineer and chemist. Dr. Norton thought it might be a year or two before our production of dyes would equal our demand, but if sufficient protection is assured we are bound to have our independent industry.

Mr. I. F. Stone, president of the National Aniline and Chemical Company, then presented a lecture on the aniline dye situation. This lecture is given in full elsewhere in this issue.

Meetings of the American Paper and Pulp Association

On the morning and afternoon of Thursday, Sept. 23, the newly formed technical section of the American Paper and Pulp Association held two well attended and very interesting sessions. The morning session was opened by the presidential address of Mr. Frank L. Moore. Other papers on the program for the two sessions were:

"Some Experiences in Refining Groundwood Slivers," by D. L. Bellinger.

"A Method of Determining the Current Capacity of a Cell in an Electrolytic Bleach Plant," by F. B. Wheeler.

"The Relation of Ink and Paper in Halftone Printing," by H. P. Carruth.

"The Possibilities of Accurate Determination of Groundwood in Papers," by Max Cline.

"Work of the German Association of Cellulose and Paper Chemists," by Henry F. Obermanns.

"Suggestions for the Adoption of Standard Tests and Processes," by Otto Kress.

"The Elimination of Fuzz in Soda Pulp by Proper Cooking Conditions," by S. D. Wells.

"Prospects of Relieving the Scarcity of Dyestuffs Used in the Paper Industry," by I. F. Stone.

Meeting of the American Chemical Society

The meeting of the New York Section of the American Chemical Society on the evening of Friday, Sept. 24, was opened by the address of the chairman, Dr. T. B. Wagner.

Dr. Leo H. Baekeland followed with an admirable address on "Industrial Chemistry." This is published in full on page 677 of this issue.

Mr. Howard H. Gross, president of the Tariff Commission League, spoke on "The Tariff Question" (See page 676 of this issue).

The concluding address of the evening was made by Dr Sam. P. Sadtler, of Philadelphia, Pa., on "Some American Contributions to Industrial Chemistry." The chief part of this lecture dealt with the development of the American petroleum industry, but the author also dealt with the fertilizer industry, the water gas process, the industries of sulphur, cottonseed oil, starch production, and the electrochemical and electrometallurgical industries. An account of this interesting lecture is reserved for one of our next issues.

Other Lectures Held at the Exposition

The afternoons were devoted partly to the demonstrations of moving pictures and partly to special invited lectures. The program of the latter included the following:

"Accident Prevention in the Chemical Industries," by Fred W. Keough.

"Transportation and Shipping Facilities with Foreign Countries," by Welding Ring.

"The Manufacture of Chocolate," by D. C. Lightner.

"Explosives," by J. L. Taylor.

"Potash," by H. A. Huston.

"Paint," by G. B. Heckel.

"Chemical Effect of Dynamiting the Soil," by Geo. Frank Lord.

"The History of Cement," by E. S. Conwell.

"The X-ray," by W. D. Coolidge.

"Refined Tars for Road Construction and Maintenance," by Philip Sharples.

"Synthetic Phenol and Picric Acid," by A. H. Ney (published in full on page 686).

"Research and Progress in American Manufacturing," by Raymond F. Bacon.

"Manufacture of Vegetable Oils," by Charles V. Bacon.

"Alundum and Crystolon," by M. A. Williamson.

"Heat Insulation with Kieselguhr," by D. S. Collins.

"The Evolution of the Glass Industry," by Robert L. Frink.

"The Possibilities of Niagara for American Electrochemistry," by Thomas H. Norton.

"The Great Pan-American Opportunity," by John Barrett.

"Opportunity for American Chemical Industry," by E. E. Pratt.

The three last-named lectures were presented in the concluding session, held on Saturday night under the auspices of the New York Section of the American Electrochemical Society, with Dr. Colin G. Fink in the chair. We reserve a number of these lectures for publication in future issues.

Recent Chemical and Metallurgical Patents

Oils

Catalyser for Hydrogenation of Fatty Oils.—A catalyser of electrolytic nickel for the hardening of fatty oils is patented by Carleton Ellis of Montclair, N. J. The method of preparing this nickel is to deposit it from the sulphate or ammonium sulphate solution using a nickel anode, and as cathode a mass of powdered charcoal, graphite or a metal support, capable of occluding hydrogen. The nickel may deposit in the form of a spongy mass on the charcoal particles, powdered graphite or metal support. A current of relatively high density is employed for this purpose. Five per cent of a titanium salt may be added or a small amount of zinc sulphate. The titanium aids in hydrogen absorption

and the zinc sulphate favors the production of a spongy nickel.

The prepared catalyser is introduced into fatty oil heated to 180 deg. C. Hydrogen or a hydrogen-containing gas is introduced and the oil hardened to the desired point. The catalyser may be placed in a tower through which the oil is caused to flow, or it may be agitated with the oils in the presence of hydrogen. The catalyser may be regenerated when it becomes spent by oxidizing and again reducing.

The advantage claimed for this catalyser is that it provides a pure material which may be used for a considerable length of time without becoming poisoned. In wet methods, such as precipitating nickel by alkali from the sulphate solution, it is difficult to free the precipitates from sulphates, and sulphides may form when the precipitate is reduced with hydrogen at 350 deg. and catalyser will be poisoned. The reduction by hydrogen also has a tendency to sinter the product, thereby causing a loss in catalytic value. The use of nickel without a carrier of clayey material removes an objection to the catalytic process, viz., the disagreeable earthy taste imparted to the oil by the clayey material which is difficult to remove. (1,151,003, Aug. 24, 1915.)

Iron and Steel

Process of Treating Cast Iron.—For certain purposes it is desirable that all of the oxygen should be removed from cast iron in order that the iron may be free from chilling properties and the carbon in the flaky graphite rather than the combined form. A process for accomplishing this purpose is patented by Joseph E. Johnson, Jr., of New York City. In this process the cast iron is heated in an electric furnace, preferably of the inductive type, to about 3000 deg. Fahr. This causes the occluded oxygen to combine with silicon and iron present, silica rising to the top of the bath, and CO escaping as bubbles. In order not to have an oxidizing atmosphere above the bath, CO gas is injected into the chamber above the charge, even up to 100 per cent if necessary. Hydrogen or any satisfactory gas could also be used, or a vacuum may be maintained above the charge. The process is preferably carried out in an induction furnace, as the high conductivity of the bath would require very large electrodes were an electrode furnace used. (1,150,201, Aug. 17, 1915.)

Alloys

Copper-Titanium Magnesium Alloys.—In the elimination of gases and deleterious substances from copper and copper alloys for casting purposes cupro-titanium has been used. In order to still retain the effects of the titanium and further improve the metal it is proposed, in a patent of Charles Vickers of Niagara Falls (assigned to the Titanium Alloy Manufacturing Company) to add an alloy of copper, titanium and magnesium to the bath of molten metal. It is believed that the titanium combines with the oxygen and other undesirable elements forming titanic acid and the compounds of magnesium combine with them to form slags so fusible that they are entirely eliminated from the bath. The surface of the resulting castings are substantially free from undesired specks and blemishes. Ordinarily the constitution of the alloy to be added would be about 5 per cent titanium, 93 per cent copper, and 2 per cent magnesium. Usually about ten minutes is required for the elimination of impurities. (1,151,744, Aug. 31, 1915.)

Alloys of Iron, Cobalt, and Chromium.—Ternary alloys of iron, cobalt, and chromium are described in a patent issued to Elwood Haynes of Kokomo, Ind. In a previous patent (No. 873,945) he described alloys of cobalt and chromium which had many valuable properties. As a rule the hardness increased with the amount of chromium present. These alloys were somewhat difficult to work, and were costly on account of the high temperature required. Their hardness is also greater than is required for making knives, auger bits, gimlets, etc., and filing and grinding are somewhat difficult. The addition of iron softens these alloys to any desired degree, but they will be of sufficient hardness for saws and similar tools, being as hard or harder than the ordinary tempered steel. A series of these alloys with low carbon content was prepared with a constant percentage of chromium (20 per cent) and percentages of iron from 10 to 75 per cent. They show little variation in physical or chemical properties so long as they contain 5 per cent or more of cobalt and from 20 to 25 per cent of chromium. They are malleable at a bright red heat and retain a beautiful luster. Several bars of these alloys were ground smooth and covered with a strong solution of ammonium chloride. These were then subjected to moist air for several days, but failed to show any stain or tarnish. It is desirable to have a low percentage of carbon (1 per cent or under) in these alloys. Ferrochromium may be used in making the alloys, but on account of its usual high carbon content, it is necessary to first remove the carbon. At least 10 per cent of chromium should be in these alloys to insure the desired properties, the preferable amount being 20 to 30 per cent. (1,150,113, Aug. 17, 1915.)

Notes

Overhead Trolley and I-Beam Carrying Equipment is described in the recent catalog of the Richards-Wilcox Manufacturing Co. of Aurora, Ill. Their apparatus are made for carrying capacities up to 4 tons, and are useful where floor space is limited.

Teniente Topics, a monthly booklet devoted to the interests of the Braden Copper Co. has been launched forth on its first issue in June. It is published at Sewell, Chile, by the Teniente Publishing Co., the company consisting of men connected with the Braden Copper Co. The object of the publication is to give descriptions of the daily activities at Braden for outsiders and to give also those at Braden descriptions of activities in other fields.

Reducing Sulphur Content at Robesonia Furnace.—After an exhaustive study, accompanied by numerous practical tests, of the possibility of reducing the sulphur content of its ore burden, the Robesonia Iron Co., at Robesonia, Pa., which specializes in low-sulphur, low-phosphorus pig iron, has adopted the recommendations embodied in a report by Mr. John W. Gocher, consulting engineer, of Johnstown, Pa., and is now constructing a plant, under his supervision, to carry out the plan proposed. At the present time the ore, which is from the well-known Cornwall mines, is roasted in Gjers kilns, the lumps as they come from the mine being roughly broken by hand before charging. It is proposed to crush and screen the ore, all that passes through a ⅜-in. screen to be sintered in Greenawalt sintering pans, while for the present all of the coarse ore, ranging in size from ⅜ in. to 2½ in., will be roasted in the Gjers kilns, as heretofore. It is expected that the sulphur content of the fine ore will be reduced from about 2.4 per cent as it comes from the mines to not over 0.2 per cent in the sinter. The coarse ore roasted in the kilns will average about 0.6 per cent sulphur. After a suitable trial period, with various proportions of sinter and roasted ore, if the results are as expected the amount of sinter will be gradually increased, with the idea of ultimately sintering all of the ore.

Rennerfelt Electric Furnace

The first Rennerfelt furnace was constructed in 1912 at Hallstahammars Iron Works in Sweden. In several important details the new furnace was quite different from previous types. Mr. Rennerfelt, under whose supervision the work was carried on, obtained such satisfactory results that within one year a steel foundry containing four Rennerfelt furnaces was established.

Since then the increased use of the furnace has been very rapid. By 1914, fifteen furnaces, ranging in size from 600 lb. to 3 tons, had been placed in operation or ordered, and by July 1 of this year this number had increased to thirty, of which four are found in England, five in Russia, two in Switzerland and the rest in Sweden and Norway. It is very well adapted for the manufacture of tool steel and steel alloys, for steel castings, for the melting of copper, brass, and for any other purpose for which a high heat and a quiet metal are required.

DESCRIPTION OF THE FURNACE

The Rennerfelt furnace has generally been built with a horizontal, cylindrical steel shell, supported on rollers or trunnions, and with one close-fitting charging and casting door on the side or in the end of the furnace. The shell is lined with asbestos board, next to which firebricks are built in rings. Inside this is the actual acid or basic lining.

Centrally in the roof and horizontally through the gables of the sides enter water-cooled bronze electrode-holders, through which slide three Acheson graphite electrodes turned to exact size. The diameter of these electrodes varies from 1½ in. for the small sizes up to 4 or 5 in. for the larger sizes. As stated, any available current can be used. In case of a direct current, the horizontal electrodes are coupled in parallel, while the vertical electrode is connected with the other pole.

If three-phase alternating current is used, it is converted in stationary transformers by the Scott arrangement into two-phase current at 70 to 110 volts. One phase of the current is connected to each side electrode. The central vertical electrode is connected to the common point between the two phases of the transformer. The currents entering through the horizontal electrodes neutralize one another, but the action of the returning current into the central electrode generates a magnetic field which deflects the arcs downward to the bath, forming an inverted arrow-head.

This form of arc is one of the special features of the Rennerfelt furnace. The heat generated in the arcs is concentrated in the bath, though the electrodes do not actually touch or even approach the slag or metal. The arcs are sweeping all over the central place underneath the points of the electrodes, insuring a uniform heating of the charge and rendering the slag very fluid and chemically active.

When the furnace is to be preheated the current is simply turned on, there being no necessity for solid fuel or metal in the furnace. This can be charged with cold or liquid metal. During the charging the electrodes may be drawn back and raised so as to prevent their being injured. Once the furnace is charged, the electrodes are adjusted into proper position, the door is carefully closed, and the current turned on.

For smaller furnaces the electrodes are manually adjusted. For larger furnaces automatic regulation is used. Only the horizontal electrodes need adjusting during the operation.

The consumption of electrodes is very low. In a 1200-lb. furnace running continually on charges of cold scrap and pig, the average consumption of electrodes has been found to be 5 to 6 lb. per ton of steel. Even when melting pig iron and afterward decarburizing it by means of ore, the consumption of electrodes has not exceeded 6.6 lb. per ton in spite of the highly oxidized slag carried in the charge.

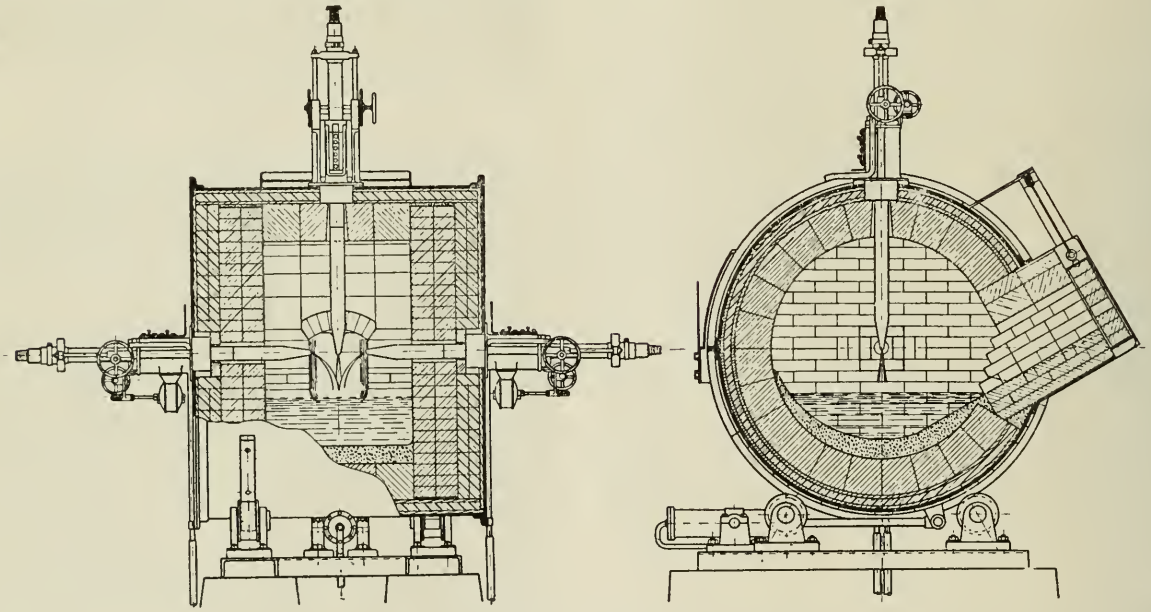


FIG. 1—RENNERFELT ELECTRIC FURNACE

Some curves are reproduced in Fig. 2 which illustrate the performance of the Rennerfelt furnace when melting cold scrap. The curves are obtained from a 600-kg. furnace running on tool steel in a Swedish mill at Trollhättan. The furnace is rated normally at 125 kw., but as indicated by the curves only about 100 kw. are utilized. It is running day and night on cold charges, drawing its power from the adjacent large government power plant.

Certain portions of the curves are also affected by the operation of some rolling mills, which caused very strong fluctuations in the power curve in spite of heavy flywheels provided to reduce fluctuation. The curve is rather peaky when the rolling mills are on, but comes down almost to a straight line at night and noon, when the furnace alone is working. The peaks of the furnace are comparatively low and rarely exceed 50 per cent of the normal load.

The 1¼-ton furnace is rated at 200 kw., and is being

operated without any automatic regulators or similar protective apparatus, receiving the surplus energy from a hydroelectric power plant of about 800-hp. capacity. Only an ordinary oil switch with time relays is needed to insure sufficient protection from the generators, the circuit breaker being adjusted so as to operate at 400 kw., or double normal furnace load. The furnace works as a large inclosed arc lamp, practically without any disturbing influence from the charge beneath the arcs.

Simultaneous readings of kilowatts, volts and amperes indicate a very satisfactory power factor. In one instance a value of 0.97 has been obtained at a furnace operated with a current of 50 cycles.

A very interesting paper on the use of liquid ferromanganese in the steel processes was presented by Axel Sahlin at the fall meeting, 1914, of the (British) Iron and Steel Institute. He speaks about the use of the Rennerfelt furnace in this connection and gives details of a number of tests made to ascertain the efficiency of the furnace. At one test, for instance, 1 ton of ferromanganese was melted in 2 hr. 45 min. The current consumption per ton amounted to 441 kw.-hr. at a temperature of 1500 deg. in the furnace when the metal

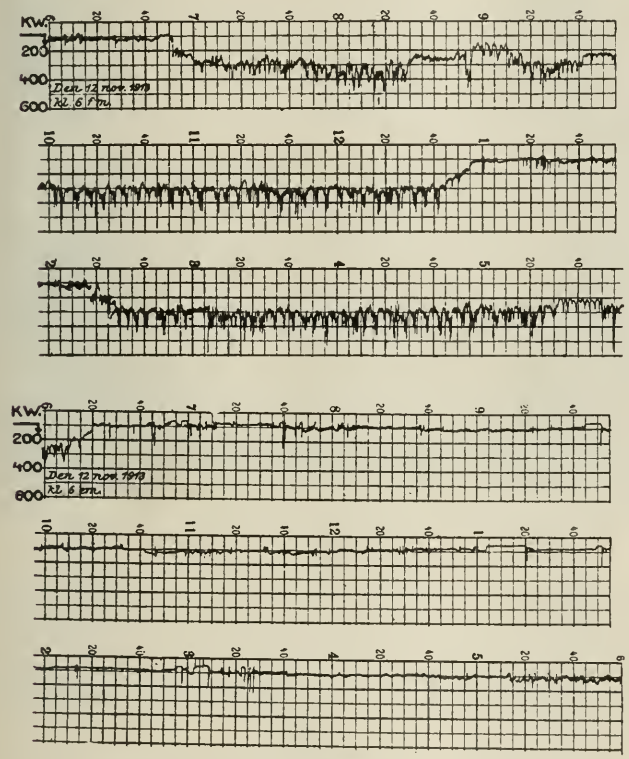

FIG. 2—FURNACE-PERFORMANCE CURVES

was charged. The corresponding efficiency of the furnace is 78 to 79 per cent. Loss of manganese was about 1 per cent.

	C. %	Mn. %	Fe. %
Analysis before melting.....	6.07	78.90	11.70
Analysis after melting.....	5.69	79.50	12.30

The steel produced by the Rennerfelt furnace is of excellent grade. From pig iron and ore, tool steel has been produced of equal quality with the best crucible steel.

A recent test of a piece of high-carbon steel produced in this electric furnace showed an elastic limit of 68,270 lb. per square inch and a tensile strength of 103,800 lb. per square inch with an elongation of 12.3 per cent. The steel analyzed C., 1.44 per cent; Si., 0.30 per cent; Mn., 0.36 per cent; S., 0.021 per cent, and P., 0.017 per cent.

Another piece with 0.96 per cent showed an elastic limit of 127,000 lb. per square inch and a tensile strength of 177,800 lb.

Soft steel with carbon around 0.20 is made daily in several of the Swedish plants. It is converted into steel castings of most intricate and thin-walled forms. Such steel has at testing shown a tensile strength of 60,000

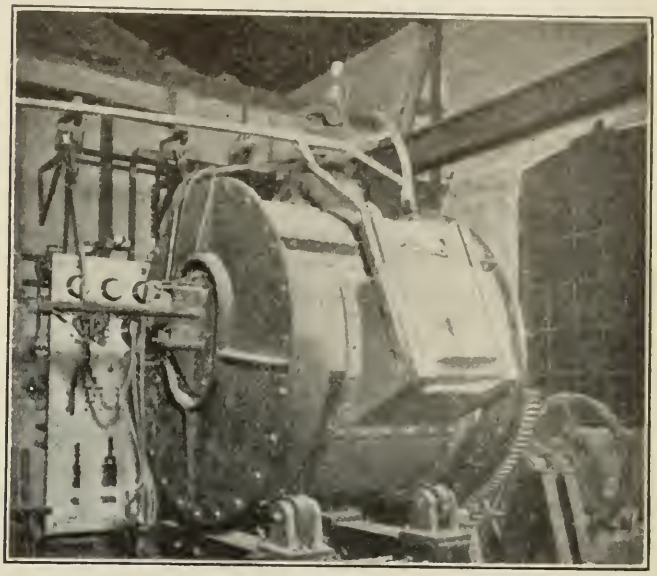

FIG. 3—1¼-TON FURNACE, HALLSTAHAMMAR WORKS

to 75,000 lb. per square inch, with an elongation of 20 per cent and more.

The Rennerfelt furnace is being introduced in this country by Messrs. Hamilton & Hansell, 17 Battery Place, New York City.

Protecting Polyphase Motors Against Phase Failure and Reversal

Accidental rotation of a motor in a direction opposite to that which the operator expects is often liable to result disastrously. An elevator may be dashed to the pit or through the overhead—costly machines, cranes, hoists, etc., may be seriously damaged if the direction of rotation is unexpectedly reversed when the starting device is closed. With alternating-current polyphase motors this may happen due to reversing of the phases and engineers have turned their attention to the problem of eliminating this source of accident. Failure of one phase may also cause burning out of the motor.

PHASE-FAILURE AND PHASE-REVERSAL PROTECTIVE DEVICE

A new compact type of phase failure relay, shown in the accompanying illustration, has been developed in the engineering department of The Cutler-Hammer Manufacturing Company, Milwaukee. This device is suitable for use on any system similar to a vertical motor having a two or three-phase stator winding and a squirrel cage rotor winding. The rotor shaft extends at the top, and to this extension a casting is secured carrying contacts designed to close a pilot cir-

cuit which controls the motor starter. This phase failure relay provides against abnormal drop in voltage, against failure of one of the phases and against reversal of the phases.

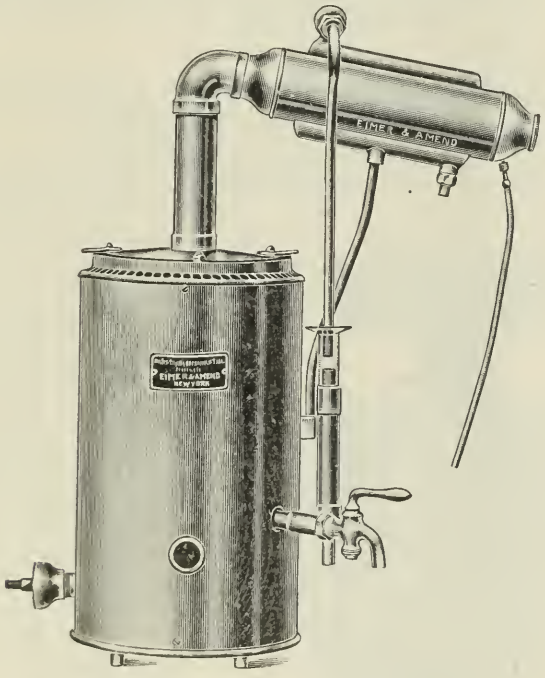
If the supply voltage falls below about 70 per cent of normal the relay opens the control circuit of the motor controller and keeps it open until the line voltage returns to at least 85 per cent of normal. These limits tions.
can be adjusted before shipment to suit special condi-

In case of phase failure, caused by the opening of one of the supply lines at any point, the relay opens the control circuit if the motor is under appreciable load and keeps it open until the fault is corrected. If the load on the motor is very light, so that no harm would result from its running single phase on account of the phase failure, the device may not operate until the load is increased or the motor shut down. If the motor is at rest at the time of phase failure the relay will act immediately. Thus the motor is allowed to run as long as no damage can result.

In case of phase reversal the relay opens the control circuit immediately and keeps it open until the phases are reconnected in the proper order. Accidents due to the motor running in the wrong direction when started up are avoided.

Water Distilling Apparatus

The necessity for distilled water of a high degree of purity in laboratories and manufacturing operations has led to the development of more efficient apparatus. The latest Barnstead-type water-stills furnished by Messrs. Eimer and Amend of New York City are for



BARNSTEAD WATER STILL, TYPE L

heating by steam, gas or electricity and the general type is shown in the accompanying illustration.

The operation of these stills is automatic and continuous. The water produced is free from ammonia, and all gaseous and organic impurities. The construction is such that the heat generated is used to preheat the incoming raw water.

The gas and electric types are portable and can be placed on the laboratory bench, or supported on a bracket attached to the wall.

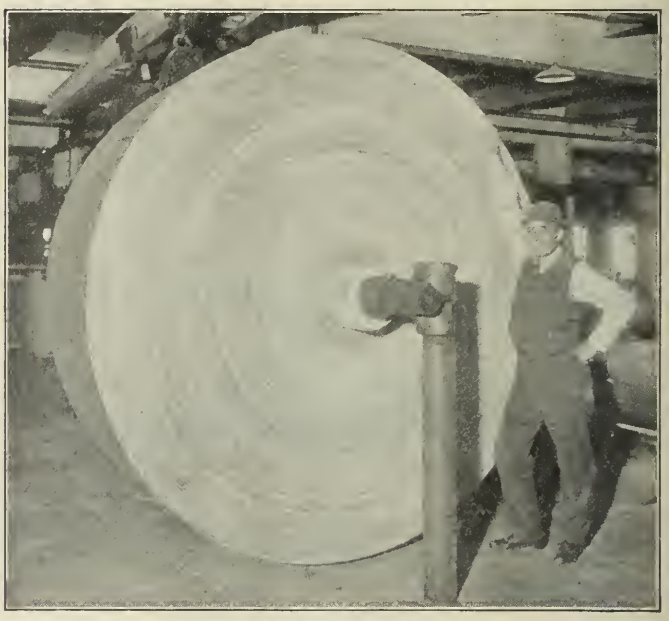
The boiler of the still is easily accessible for thorough cleaning by simply turning the thumb clamps which rigidly hold the condenser and hood to the boiler.

The electrically heated still is furnished with replaceable heating units which can be attended to by the operator.

Gigantic Conveyor Belts

Conveyor belts of great size have been tried and found successful by the California-Hawaii Sugar Refining Company. In February, 1906, they installed a 36-in. 7-ply Goodrich belt for the purpose of catching 125-lb. bags from a fall of 4 ft. and conveying them. This belt received and carried 2,000,000,000 lb. of sugar before showing any radical signs of wear.

Recently the same company ordered another belt from the B. F. Goodrich Company to be 1443 ft. long and 36 in. wide. This belt weighed 11,983 lb., and is shown in the accompanying illustration.



GIANT CONVEYOR BELT

Figuring eight hours' run without any delays a bag of sugar would drop onto the belt every nine seconds, and if the speed of the belt was such that it made twenty-six or twenty-seven revolutions every eight hours the bags would rest 12 ft. apart and a continuous load of 7500 lb. would be carried.

Chilean nitrate exports to the United States are reported to be again normal. Direct exports to certain European countries have increased somewhat, while to others they are entirely suspended.

An electric furnace for operating above 2000 deg. C. will be described in a paper to be delivered before the October meeting of the American Chemical Society in Pittsburgh by Mr. Frederick T. Snyder, president of the Snyder Electric Furnace Co. of Chicago. The furnace is adapted to be operated on powdered material.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in March, 1915, was sixty-three. The total quantity of ore milled during that period was 2,421,218 tons. There were 9840 stamps in operation, with an average duty of 9.35 tons per 24 hours. Tube-mills in commission numbered 314. The yield for the month was 753,935 fine ounces gold. The report indicates a larger tonnage milled and more equipment in operation than a year ago. The yield also shows an increase.

"Fair Protection" for the American Chemical Manufacturer

The two papers by Mr. I. F. Stone and Mr. Maximilian Toch presented before the New York Section of the American Chemical Society last week and reported on page 710 of this issue, are more than mere papers. They are human documents of a most lively and important episode in the history of the American chemical industries. The quiet unassuming way of the authors typifies the quiet, unassuming way in which, since the beginning of the European war, the American chemist has gone ahead and has done things. Mr. Stone's paper is a record of a long string of big achievements. Mr. Toch's paper is the story of the creation of the new American barium industry.

As was said at this place last month, part of the present enormous activity in the chemical industries will stop when the war stops, since it has to do with war materials, but by far the most of the present activity will be lasting for the benefit of the whole country, if the American nation is willing that it be so. What is it that the chemical industry has a right to expect from the American nation? Nothing more nor less than a fair attitude of mind of the American nation toward the American chemical industry: a fair appreciation of its accomplishments and its aim, a fair recognition of the fact that chemical brains need capital for realization of their ideas and that capital needs fair protection. It seems right to discuss now more in detail what such "fair protection" would consist of.

In the first place, protection must be procured against unfair practices on the part of foreign competitors. But how shall such "unfair practices" be defined? The principal point is that when the war is over there will be great danger that the newly created chemical industries in this country be quickly destroyed by dumping on the markets of this country foreign products at a price below the selling price of the products in the producers' home markets. The American chemical industry has a right to expect from the nation's law makers that such methods of destroying dangerous competitors as are considered unfair and are now forbidden by law to Americans in the United States, should also be considered unfair and forbidden by law to importers from other countries. That is, the American chemical industry has a right to expect the enactment of an anti-dumping clause.

But whoever reads carefully Mr. Stone's and Mr. Toch's papers in this issue, or Mr. Stone's elaborate paper on the aniline dye situation in our issue of Oct. 1 (page 663) or Dr. Herty's opening address at the Exposition of Chemical Industries in the same issue

(page 695), or who endeavors to get exact knowledge concerning the situation from anybody who has a first-hand knowledge of the facts, will recognize that the enactment of an anti-dumping clause is not all that is needed. Tariff reform must be fairly and squarely considered. There are two main points which fairness requires in such consideration.

In the first place it must be strictly kept in mind that the American chemical industries face "a condition, not a theory." The abstract question of the desirability or undesirability of protective tariffs has been and will continue to be a fit subject of extended discussions by political economists, but it has nothing to do with the special concrete situation with which the chemical industries of this country and all who depend in some way on the products of the chemical industries are now confronted. The situation is such that academic discussions are almost out of place. But it may be said in parenthesis that if in these days any American chemist has an idle moment, he can find a great deal to satisfy his sense of humor in reading over the volumes of political economy which have been written on the theory of protective tariffs and contrasting the theory with the facts of the present moment. Just one example will explain what we mean. Chapters and chapters have been written on the question: Should industrial entities correspond to political entities? As a general academic question it is highly debatable. But it will be hard to find any sensible person of whatever party affiliations who has not learned from the experience of the past year the lesson that it is all important for the future of the American nation to be industrially self-contained. As Dr. Herty expressed it in his admirable presidential address before the American Chemical Society in Seattle, "in these days of rapidly shifting international relations the only sound and rational policy is national self-containedness." Likewise the old argument that a protective tariff, being a restraint, cannot have any positive virtue and cannot create industries, has absolutely no application to the present situation. The chemical industries which this country needed have been created during the past year by the pluck of the American chemist backed by American capital. Shall they be permitted to grow until they are firmly and permanently established? And what is necessary to accomplish this end?

This is the only real question. But to find the right answer, it is all important—and this is the second point to be kept in mind—that the whole consideration of the matter be taken out of party politics. The most promising and a decidedly practical way of accomplishing this was outlined by Mr. Howard H. Gross, president of the Tariff Commission League, in two addresses before the National Exposition of Chemical Industries in New York last month. As reported in our last issue (page 676), Mr. Gross argued that the net result of thirty years of "tariff tinkering" has been that nobody is satisfied, that business has been periodically upset, that hundreds of millions of money have been lost and millions of workers distressed. What is needed now is a really strong permanent non-partisan tariff commission of the highest personnel with long tenure of office, to make impartial investigations and recommend to Congress needed tariff adjustments on scientific principles. Whatever may be done in general, the conditions of the chemical industries require that something be done for their protection and that something be done very soon.

Shall the present vigorous growth of the American chemical industry remain but an episode in its history or shall it be the beginning of a new era? The American chemist has done his part faithfully and vigorously. It is for the American nation, as represented by Congress, to do the rest.

Non-Ferrous Metals During the War

Wide fluctuations in the price of a metal are usually ascribed to speculation, but the course of metal prices since the opening of the European war, although showing wide fluctuations, is not to be attributed to speculative influences. There is rather a dislocation of the ordinary movement of material whereby it becomes difficult to forecast the relation between supply and demand, while it is probably also the case that there have been important changes in the employment of metals for various war purposes, which have effected quick changes in the relation between supply and demand.

The non-ferrous metal markets certainly have pursued no orderly course in the fourteen months that have elapsed since the war opened. The first movement attributed to the war was a violent advance in tin, resulting in a doubling in the price before the war was a fortnight old. There was a veritable scare, due to the possibility that it would be found impossible to move tin from the Far East. A similar advance occurred in antimony, which advanced to three prices. Spelter, on the other hand, advanced because it was reported that large tonnages would be exported to England. The advances were practically all lost by the middle of September. Later there began a more orderly but still quite irregular advance in nearly all the metals. Lead, traditionally associated with war, was conspicuous by its failure to advance, though eventually it did advance in moderate fashion.

That there have been changes in the technique of war material manufacture is suggested by some of the market fluctuations. Spelter, which early rose and fell, and then toward the close of the old year began a definite and important rise, reached a very high point early in June, at more than five times its price of before the war, and since then it has been declining until lately it has sold at less than three prices. Aluminium, on the other hand, did not begin any sharp advance until last May, and the advance did not become sensational until September, about three months after spelter had started its sharp decline. Early this month it crossed the 50-cent line, truly a remarkable performance. The divergent movement between spelter and aluminium can hardly be ascribed entirely to manipulation or to a misjudging of market prospects by either buyers or sellers.

Regular consumers of the non-ferrous metals, entirely unaccustomed to such violent fluctuations as have char-

acterized the markets during the war, have not only been greatly inconvenienced but in many cases have suffered very severe losses. In many cases, probably, trade has been permanently lost. Unable to secure supplies of given materials at former prices, consumers of many products have been driven to the use of substitutes, and the substitute may in many cases find permanent employment.

The sheet-galvanizing industry has not yet been able to determine whether it has permanently or only temporarily lost a large proportion of its trade. It is estimated that since early in the year, when the advance in spelter forced the mills to ask much higher prices for galvanized sheets, the demand has ranged from 20 to 35 per cent of normal, the normal demand being nearly a million net tons a year. To an extent the consumptive requirements have been met by stocks in the hands of jobbers and manufacturing consumers, but there has doubtless been substitution in many instances, and whether the galvanized-sheet trade will ever regain its former proportions remains a matter of doubt. Prices lately asked by the mills for galvanized sheets are not considered sufficiently high to curtail consumption to any great extent, provided they were steadily maintained, but buyers are chary of purchasing, fearing sharp declines at any moment.

Iron Industry Making New Records

In the last two months of 1914 the iron and steel industry was in a state of unparalleled depression. The production of steel, in proportion to available capacity, was the smallest on record. Pig iron prices were lower than at any time in ten years, and steel prices lower than at any time in fifteen years. For November and December the United States Steel Corporation reported the lowest monthly earnings in its history, earnings at the rate of only $32,000,000 a year.

Never has the iron industry experienced so complete a change as that which has occurred since then, in approximately ten months. The production of both pig iron and steel ingots is now at a new high record rate, and there has been a continued and very important advance in steel prices, while in the past four months there has been a moderate improvement in pig iron prices. In all the past there can be found no precise parallel to this general movement. In 1908 production reached a relatively low rate, but prices did not decline correspondingly. In 1905, in 1909, and in 1912 there were sharp upward movements in prices, corresponding in general to the rate of the past ten months, but there was not a corresponding increase in tonnage outputs, as the percentage of idleness at the beginning of these various movements was not as great as was that at the beginning of this movement. Passing back to 1899 one finds more rapid price advances, spectacular as compared with those of recent months, but these occurred through demand having developed, in a period of low prices, to such an extent as to engage almost the full capacity of the industry. The price boom of 1899 followed two years each of which in its turn had broken all previous records in the production of pig iron and steel ingots, whereas the pig iron output in the second half of 1914 was less than two-thirds the record output for a half year.

In August certainly, and possibly in July, the steel works attained a new record rate in the production of ingots, and in September the country reached a new record rate in the production of pig iron, the new record pace in pig iron developing later than the new record in steel because the iron foundry trade is not busy and the production of steel-making pig iron had to proceed far enough to absorb the slack thereby produced.

Lake Superior iron ore shipments in August were heavier than in any previous August, and September in turn made a new record for that month, prospects being that the season's shipments will fall very close to the previous record, despite the slow movement early in the present season.

The current production of pig iron is at the rate of fully 36,000,000 tons a year, the best rate previously attained having been 34,000,000 tons a year, in February, 1913, while the greatest production in a calendar year was 30,966,152 tons, in 1913, while the highest production in two successive half years was 32,143,265 tons, in the twelvemonth ended June 30, 1913.

The current production of steel ingots, while it cannot be estimated closely, is known to be at a much greater rate, in proportion to pig-iron production, than has ever obtained before. While pig-iron production is easily at record rate, the consumption of pig iron in iron foundries is distinctly below rates that have obtained in several periods in the past, while in addition to this the output of steel ingots is particularly large in proportion to the pig iron charged. This condition arises in turn from two influences. There is a larger proportion of open-hearth capacity, in proportion to Bessemer, than ever before, and some of the open-hearth works are charging unusually large proportions of scrap as they are working largely upon war orders requiring altogether exceptionally great discards from the ingot. The pressure for steel is such that it is remarked the minutes, even the seconds, are counted against the open-hearth heat, and any practice that conduces to shortening the time is followed.

In striking contrast with the pressure for steel, as steel, is the relatively light operation of many of the finishing mills. There is always, of course, an excess of steel finishing over steel making capacity, and there is the further item that at the present time an altogether abnormal tonnage of forging steel is being produced. In ordinary years about half a million tons of forging billets are produced, but the rate of production at the present time is several times that amount.

The remarkable demand for steel is caused largely, of course, by the war, though the regular domestic demand is fairly good. The war is distinctly responsible for the fact that the change in conditions in ten months is so altogether unprecedented, for it was the war that caused the acute stagnation that characterized the closing months of last year, so that it has emphasized the contrast in each direction.

The Naval Consulting Board's First Meeting and First Recommendation

The Naval Consulting Board was created by Secretary Daniels, but eleven national engineering societies share with him the responsibility for its personnel. Its members, men of highest standing in the professions, serve without remuneration. At the first meeting held in Washington, D. C., on October 6 and 7, the Board organized and decided that the name should be the Naval Consulting Board, not Advisory Board. This is significant. The first recommendation of the Board is that of a large Research Laboratory for the Navy. This plan is in line with the present world-wide recognition of the value of scientific research not merely for the upbuilding of industries, but for the very independence of a nation. The Board is to meet every two months.

THE first meeting of the Naval Consulting Board was held in Washington, D. C., on Oct. 6 and 7, and was concerned largely with matters of organization, though one very important recommendation was made—that of the creation of a large research laboratory for the U. S. Navy.

The board was created by Secretary Daniels of the Navy, who appointed Mr. Thomas A. Edison chairman of the board, but left the selection of the 22 other members of the board to eleven national engineering societies. These eleven societies and their 22 representatives on the board are as follows:

American Institute of Electrical Engineers—
Frank Julian Sprague and Benjamin G. Lamme.
American Institute of Mining Engineers—
William L. Saunders and Benjamin B. Thayer.
American Society of Mechanical Engineers—
William LeRoy Emmet and Spencer Miller.
American Society of Civil Engineers—
Andrew M. Hunt and Alfred Craven.
American Chemical Society—
W. R. Whitney and L. H. Baekeland.
American Electrochemical Society—
Joseph W. Richards and Lawrence Addicks.
Inventors' Guild—
Peter Cooper Hewitt and Thomas Robins.
American Society of Aeronautic Engineers—
Henry A. W. Wood and Elmer A. Sperry.
American Society of Automobile Engineers—
Howard F. Coffin and Andrew L. Riker.
American Aeronautical Society—
Mathew B. Sellers and Hudson Maxim.
American Mathematical Society—
Robert S. Woodward and Arthur G. Webster.

The Board elected the following officers on Oct. 7:
Chairman, Thomas A. Edison.
First Vice-Chairman, Peter Cooper Hewitt.
Second (Acting) Vice-Chairman, W. L. Saunders.
Secretary, Thomas Robins.

Mr. Saunders was the acting chairman at the sessions of the Board which were attended by members of the Board only, with the exception of Mr. M. R. Hutchinson, who was present as Mr. Edison's "ear" and private assistant. Secretary Daniels conferred with the members repeatedly.

It was decided that the name, originally suggested as Naval Advisory Board, should be changed to Naval Consulting Board..

President Wilson received the Board on Oct. 6 at the White House and made the following address:

"There is very little that I can say to you, except to give you a very cordial welcome and to express my very great pleasure in this association of laymen with the Government. But I do want to say this:

"I think the whole nation is convinced that we ought to be prepared, not for war, but for defense, and very adequately prepared, and that the preparation for defense is not merely a technical matter, that it is not a matter that the Army and Navy alone can take care of, but a matter in which we must have the co-operation of the best brains and knowledge of the country, outside the official service of the Government, as well as inside.

"For my part, I feel that it is only in the spirit of a true democracy that we get together to lend such voluntary aid, the sort of aid that comes from interest, from a knowledge of the varied circumstances that are involved in handling a nation.

"I want you to feel, those of you who are coming to

LAWRENCE ADDICKS

THOMAS A. EDISON

LEO H. BAEKELAND

J. W. RICHARDS

WM. L. SAUNDERS

WILLIS R. WHITNEY

the assistance of the professional officers of the Government, that we have a very serious purpose, that we have not asked you to associate yourself with us except for a very definite and practical purpose—to get you to give us your best independent thoughts as to how we ought to make ready for any duty that may fall upon the nation.

"I do not have to expound it to you; you know as well as I do the spirit of America. The spirit of America is one of peace, but one of independence. It is a spirit that is profoundly concerned with peace, because it can express itself best only in peace. It is the spirit of peace and good-will and of human freedom; but it is also the spirit of a nation that is self-conscious, that knows and loves its mission in the world and that knows that it must command the respect of the world.

"So it seems to me that we are not working as those who would change anything of America, but only as those who would safeguard everything in America. I know that you will enter into conference with the officers of the Navy in that spirit and with that feeling, and it makes me proud, gentlemen, that the busy men of America—the men who stand at the front of their professions—should be willing in this way to associate themselves voluntarily with the Government in the task in which it needs all sorts of expert and serious advice.

"Nothing ought to be done in this by any single group of persons; everything ought to be done by all of us, united together, and I welcome this association in the most serious and grateful spirit."

It is interesting to reflect that in creating a Naval Consulting Board of scientists and engineers, Secretary Daniels had a predecessor in Napoleon (see Dr. Boekeland's paper in our last issue, page 677). But there is this big difference that as expressed in President Wilson's address the object of the Naval Consulting Board is to help in preparedness for defence, not for aggression. There is another difference in the democratic make-up of the Board in that eleven national engineering societies share with Secretary Daniels the responsibility for the personnel of the Board. The Board is made up of men who stand so high in their professions that they would accept no remuneration for serving their country.

By changing the name from Naval Advisory Board to Naval Consulting Board, the members have made it clear that they do not intend to force their advice unasked upon the Naval Board proper, but that they stand ready to place all their knowledge at the disposal of the Navy in consultation. This move has resulted in very cordial personal relations between civilians and navy men.

The first official recommendation of the Board has been the creation of a Naval Research Laboratory on such a scale that the first investment would be $5,000,000 and the annual operating expenses between $2,500,000 and $3,000,000. We are sure to interpret this recommendation correctly by saying that it is directly in line with the present world-wide recognition of the fact that scientific research on the largest scale is not merely the basis of the creation and evolution of industries, but is indispensable for national self-containedness and the very independence of nations. Germany has understood this truth for many years; Great Britain recognizes it now. The recommendation of the Board means that the United States should have a Naval Research Laboratory commensurate to the national importance of the U. S. Navy.

News from the Chemical Field

The Status of the American Chemical Industry and the New American Barium Industry

The first regular meeting of the session 1915-16 of the New York Section of the American Chemical Society (Dr. T. B. Wagner, chairman) was held on the evening of Oct. 8 in Rumford Hall, Chemists' Building. Two papers were presented which were exceedingly interesting by the manner in which they illustrated the enormous present activity in the chemical field.

Mr. I. F. Stone reviewed **"The Status of the Chemical Industries in the United States at the End of 1915."**

The production of *benzol* has become well established and benzol has become a serious competitor of gasoline as automobile fuel. About 100,000,000 gal. of gasoline are consumed by automobiles per year. Benzol has been carefully tested for automobile service and has been found to have 25 per cent more motive power than gasoline. The price has come down almost to that of gasoline, whereas before the war it was selling for two and three times that of gasoline.

Aniline dyes are produced to-day in the United States in three to four times the quantity produced before the war. By 1916 enough dyes will be manufactured in the United States to take care of the entire demand.

Carbolic acid is another important product now manufactured in this country in large quantities.

As regards *napthaline,* 2,500,000 lb. per year were produced before the war. This year 8,000,000 lb. will be turned out—almost covering the United States consumption of 9,000,000 lb.

Barytes: The imports in 1913 amounted to 40,000 tons. Since the war started Tennessee (Toch Brothers), Missouri and other States practically supply the demand. The present duty of 15 per cent must be increased if this industry is to continue in this country after the war is over.

Carbon Tetrachloride: Before the war only one-half of the CCl_4 consumed in the United States was made here. By 1916 all of it will be made here.

Acids: The general situation in the acid manufacture and consumption is very serious. We cannot make anywhere enough to supply the demand.

Alkalies and *bleach* industries show a great prosperity. We can take care of the entire American demand. Much of the Prussian blue is now made from soda instead of potash.

Oxalic Acid: Most of the acid consumed in this country is now made here.

In conclusion Mr. Stone said that the status of the American chemical industry as a whole is very satisfactory, and the industry in this country is very prosperous.

Mr. Maximilian Toch, partner of Toch Brothers, followed with an equally interesting and very encouraging paper on

"The Barium Industry in the United States Since the European War."—A little over a year ago there was no barium industry in this country. Germany and Austria have large mines of practically pure witherite, also cheap hydrochloric acid. It was impossible for American manufacturers to compete. This country does not possess similar rich mines and costs of labor, transportation, etc., are here much higher. Furthermore, the Governments abroad have subsidized the industry, enabling German and Austrian shipments to be unloaded here at $1.85 per ton (against crude United States barytes at $3 per ton).

However, barium salts have become an actual necessity in this country.

An important application of barium sulphate is in the gray paint of our battle ships; it resists the action of sea water and contains 45 per cent $BaSO_4$. Mr. Toch received the Government contract. To fill it, soon after the outbreak of the war, Mr. Toch went to Sweetwater, Tenn., and bought up the Gilman plant, now called the Durex Chemical Works.

Here at Sweetwater the mineral (barytes) occurs as a residual deposit, but not in such large masses as in Germany but in scattered small lumps. A large number of interesting slides of the deposits, mines, washers, furnaces, etc., were shown by Mr. Toch. Within a few weeks Mr. Toch expects to have the production increased to 32 tons of barium salts per day.

The barytes are mixed with coal and heated to bring about the following reaction:

$$BaSO_4 + 2C = BaS + 2CO_2$$

Fluorides, lead salts and other impurities prevent complete transformation into BaS or "black ash." This is subsequently fused with soda.

$$BaS + Na_2CO_3 = BaCO_3 + Na_2S.$$

The sodium sulphide by-product is sold to the dye manufacturers for making "sulphur black"; it competes easily with the Na_2S made by the reduction of Na_2SO_4 by coal. Barium salts are an important constituent of lithophone.

At present the salts are made in New York (on Long Island), but it would be cheaper to make them near the mines at Sweetwater, since zinc mines are close at hand there and labor and coal are abundant. It is interesting to note that Mr. Toch uses iron leaching tanks; FeS is formed on the surface of the iron which protects the metal underneath.

Mr. Toch emphasized that if the barium industry is put on a good solid business foundation with ample Government protection it will survive after the close of the European war. Industrial chemistry after all is 49 per cent chemistry and 51 per cent business.

In the discussion of the paper Dr. Doremus emphasized the importance of electric furnace methods for the reduction of barytes, and referred to the Jacobs process formerly carried out at Niagara Falls.

American Institute of Chemical Engineers

The winter meeting of the American Institute of Chemical Engineers will be held in Baltimore, Md., from Wednesday to Saturday, Jan. 12 to 15. The date selected is somewhat later than usual because the summer meeting was held late in August instead of June as is customary.

Excursions are being arranged to a number of chemical plants, Baltimore being a center of considerable industrial chemical activity. The experimental laboratories of Johns Hopkins University and the Naval Academy at Annapolis will also be visited.

Dr. John C. Olsen, Cooper Union, New York City, is the secretary of the institute.

Armco Iron Rust-Resisting Products and **Defeating Rust** are the titles of two interesting recent publications of the American Rolling Mill Co., Middletown, O.

Aluminium is the most abundant of all the metals. In the form of its oxide, alumina, it constitutes about 15 per cent of the earth's crust, according to the U. S. Geological Survey. Bauxite, however, from which aluminium is extracted by present commercial processes, is by no means plentiful, but known deposits are sufficient to make aluminium the important metal it is. The great future of this metal may lie in the perfection of a process whereby it can be commercially extracted from the unlimited deposits of alumina-rich clays and rocks in all parts of the world.

The Iron and Steel Market

The market pace in the steel trade has been rapid in the past fortnight. The scarcity of steel has been greatly accentuated, both by mills finding they were more oversold than they thought, and by demand broadening in several quarters, particularly in the line of railroad material.

The railroads are now definitely in the market for their steel requirements for 1916. They have already contracted for about 400,000 tons of rails, and with a further inquiry in the market the most vital needs of all the important roads will probably have been covered within another month. The railroads are not buying large individual tonnages of rails, their purchases being approximately equal to the average of the past two or three years, and their appearance in the market at this time is due simply to the fact that with so much rail mill capacity engaged in the rolling of large rounds for shells it is necessary to contract early to insure desired deliveries. Car buying is steady, although moderate. There is fairly heavy contracting for track supplies, at a time much earlier than usual.

There is a marked increase in the demand for steel from neutral countries, and exports of such material are likely to increase steadily from month to month, while the demand for steel from countries at war shows no abatement, covering not only munitions and material for munitions, but railroad and other material required really for war purposes, but somewhat less directly. Some South American countries are now taking more steel from the United States than they ever did in the past, marking a very decided improvement in this trade, as on account of industrial depression in South America the demand had decreased markedly during the twelvemonth before the war started.

Rates of Production

We estimate that at the middle of October pig iron is being produced in the United States at a rate of more than 36,000,000 tons per annum, contrasting with a previous maximum of 34,000,000 tons, reached in February, 1913. The steel interests have increased their pig-iron production by more than this amount, as the merchant furnaces are producing at a rate about 1,500,000 tons less than at their previous high record rate. We estimate the rate of production of steel ingots at between 38,000,000 and 39,000,000 tons per annum, against actual production of slightly more than 30,000,000 tons in each of the two best years on record, 1912 and 1913. The production of ingots is somewhat larger, relative to the production of pig iron, than normal, owing to the heavy cropping of ingots involved in the production of special steel required for war purposes. By reason of this heavy cropping of ingots, and by reason further of the heavy production of forging billets, also for the production of war material, the production of finished rolled merchant steel is an unprecedentedly small percentage of the total ingot tonnage.

Pig Iron

The pig-iron market has been practically stationary in the past fortnight. During the first six months of the year pig-iron prices were almost stationary, advances occurring in July, August and September averaging from $2 to $2.50 per ton in the different districts. The market the past fortnight has been distinctly less active than it was, on an average, during the first half of the year. The advances in recent months were due partly to sentiment, as steel prices were advancing, and as the slightly expanding demand required the blowing in of furnaces having higher costs than those already in operation. Now the pig-iron market awaits a fresh stimulus. There is ample production of merchant iron to meet all current requirements and as quite a number of merchant stacks could be blown in on short notice there is no uneasiness on the part of buyers. To cause another important advance in pig iron will require either a large increase in activity at gray and malleable iron foundries, or large buying of merchant iron by steel works, such as might, perhaps, be caused by their having been drawing upon stocks lately, or by some of their own furnaces being forced out of blast for relining. The steel works can hardly consume more pig iron than they have been consuming in the past two months. We quote: No. 2 foundry delivered Philadelphia, $16.25 to $16.75; f.o.b. furnace, Buffalo, $15.50 to $16; delivered Cleveland, $15.25; f.o.b. furnace, Chicago, $14.25 to $14.75; f.o.b. Birmingham, $11.50 to $12.50, the higher figure being for first half 1916; at valley furnaces, 95 cents higher delivered Pittsburgh; Bessemer, $16; basic, $15; malleable, $14.50 to $15, depending on manganese specification; No. 2 foundry, $14.50 to $15, depending on delivery; gray forge, $14.25 to $14.75, depending on delivery.

Steel

The market for ordinary soft steel open-hearth billets has disappeared, and Bessemer billets, the market quotation for which has been made chiefly by reference to the market for open-hearth, has not developed a clear cut market, but the commodity can be quoted roundly at $25 to $26, f.o.b. maker's mill, Youngstown. Neither Bessemer nor open-hearth sheet bars are really a market commodity now, as sheet and tin mills are covered largely by old contracts and have such selling prices, apparenty dictated by the cost of their steel, that they could not afford to pay prices that would be asked for sheet bars, which normally command an advance over open-hearth.

The disappearance of the market for ordinary soft steel open-hearth billets is due to the large demand there has been for forging billets, for making large shells, and for analysis billets for rolling large rounds for smaller shells, generally about 3-in. The most common specification for steel for rolling such rounds is not over 0.04 per cent sulphur, 0.04 to 0.08 per cent phosphorus and silicon, say 0.20 to 0.30 per cent or 0.30 to 0.40 per cent, with carbon 0.32 to 0.42 per cent in the case of French and 0.47 to 0.57 per cent in the case of English. The carbon is, of course, very ordinary for a carbon specification, the sulphur is not really difficult and the phosphorus is particularly easy. The silicon merely requires the proper blast furnace Bessemer ferrosilicon addition. The cropping varies, from a total of 20 or 25 per cent to a maximum of 40 per cent, 35 per cent top and 5 per cent bottom. The cropping usually must be done from the ingot, requiring sawing, and the ingots must be chipped to avoid seams that would be dangerous—at the wrong time—in the thin shell which is ultimately produced. These specifications involve no problem, yet as high as $45 is being paid for the billets. Naturally the mills able and willing to produce such steel have no occasion to quote on ordinary soft steel billets, as buyers could not think of paying such prices as they would be disposed to ask.

While the demand for steel billets of this character is heavy, there is another condition making steel particularly scarce as a market commodity and that is that a number of steel mills made a curious over-

sight in selling against specifications involving heavy cropping, in that they neglected to observe that their output ratings were referable to their ingot-producing capacity, the rating therefore including the material that is cropped as well as the material that is sold, and if a mill can produce 10,000 tons of ingots in a given time it cannot crop 25 or 30 per cent of the ingots and still have 10,000 tons of material to apply on the sales contract. A number of mills find themselves oversold through neglecting to observe this arithmetical fact.

Finished Steel

Finished steel prices are steadily advancing, in one commodity or another. The basis for present advances in finished steel is not the specifically heavy demand for this finished product or that, but the general scarcity of steel. In the large mills making a variety of products very few departments are allotted steel to their rolling capacity. Thus the bar mills may be breaking their records, rolling 110 or 120 per cent of their rated capacities, and being given steel to do so because the orders for bars are in hand for a run of six weeks or perhaps several months, while the structural mills may be allotted only enough steel to operate at 60 or 70 per cent, the structural mills perhaps having specifications for operating four or six weeks at this rate. Upon the wire mills there is special pressure. They are operating at an overload, filled with specifications in the barb wire departments for perhaps three months, with heavy specifications for plain wire and specifications for perhaps four weeks of output in nails.

Bars, plates and shapes for early specification and delivery at mill convenience, have advanced from 1.35c. to 1.40c. in the past fortnight, and while a few weeks ago 1.40c. was freely quoted on first quarter contracts this figure is now quoted with reserve, and some mills are practically refusing to quote for first quarter.

Current quotations, f.o.b. Pittsburgh, unless otherwise noted:

Rails, standard section, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.40c.

Shapes, 1.40c.

Steel bars and bands, 1.40c., base; steel hoops, 1.50c., base.

Iron bars, 1.559c. to 1.609c., Philadelphia; 1.35c., Chicago; refined iron bars, 1.45c. to 1.50c., Pittsburgh.

Plain wire, 1.60c.; galvanized wire, 2.30c.; painted barb wire, 1.90c.; galvanized barb wire, 2.60c.; wire nails, $1.75 base.

Sheets, blue annealed, 10-gage, 1.60c. to 1.70c.; black, 28-gage, 2.00c. to 2.10c.; galvanized, 28-gage, 3.50c.; painted corrugated, 28-gage, 2.30c.; galvanized corrugated, 28-gage, 3.55c.

Tin plate, $3.10 to $3.20 for 100-lb. cokes.

Steel pipe, ¾ to 3-in., black, 79 per cent off list; galvanized, 63½ per cent off list.

Boiler tubes (less than carloads): Steel, 71 per cent off list; iron, 60 per cent off list.

Structural rivets, 1.60c.; boiler rivets, 1.70c.

The unfilled obligations of the United States Steel Corporation at the close of September are reported at 5,317,608 tons, representing an increase during September of 409,153 tons, against a loss in August of 20,085 tons. September shipments may be estimated at 95 per cent of rated capacity (at about 47,000 tons daily), the increase in obligations representing 35 per cent of capacity, so that the bookings appear to have been 130 per cent of capacity.

American Institute of Metals

The annual meeting of the American Institute of Metals was held at Atlantic City, N. J., Sept. 28 to 30 inclusive, in conjunction with the convention of the American Foundrymen's Association. The attendance was very good, the natural advantages of Atlantic City at this time of the year probably inducing a great number to enjoy the convention.

The tenth annual Foundry and Machine Exhibition which was held on Young's Pier as a part of the convention was opened on Sept. 25 and continued to Oct. 1. The exhibition was representative of the great progress of the metal working industries during the past few years. On Tuesday morning, Sept. 28, a joint session of the American Institute of Metals and the American Foundrymen's Association was held in the Greek Temple on Young's Million Dollar Pier.

The American Institute of Metals held its first independent session Tuesday afternoon at the Hotel Traymore. The paper by Gilbert Rigg and Henry C. Morse on "The Influence of the Impurities of Spelter on the Cracking of Slush Castings" brought out some discussion in which it was concluded that cadmium produces a hot short condition in zinc which renders it unfit for castings. Lead produces a bad effect also, in making heavy castings. Arsenic has little or no effect in the small amounts usually found. A paper on "Standard Test Specimens of Zinc-Bronze" was presented by Dr. H. S. Rawdon of the Bureau of Standards. Dr. G. K. Burgess read a paper on "An Investigation of Fusible Tin Boiler Plugs" which was abstracted in this journal Sept. 1, page 568.

On Wednesday morning the session was opened by a paper on "The Effect of the Present European War on the Metal Industries," by Thomas F. Wettstein. The discussion brought out the fact that a great number who had been using Lake copper were forced to experiment with electrolytic with the result that very few would go back to the use of Lake copper as long as there was such a wide difference in the prices. The subject of "sherardizing" was illustrated by a number of diagrams sent by the General Electric Company.

On Wednesday afternoon the session was given over to the discussion of aluminium and its alloys. A paper by Charles Pack on "Aluminium Die Casting a Commercial Achievement" discussed this important use of aluminium. A paper on "Melting Aluminium Chips" by Dr. H. W. Gillett discussed the difficulty, on account of a thin film of oxide on the chips formed when they were cut. Two commercial methods were given in detail. A paper by W. M. Corse on "Auminium-Bronze Alloys" took up the remarkable changes in hardness which can be brought about above 7 per cent of aluminium and discussed the commercial possibilities of these alloys. Other papers presented were "The Autogenous Welding of Aluminium" by E. V. Pannell and "The Manufacture and Use of Alumino-Vanadium" by W. W. Clark.

Papers presented at other meetings of the Institute included a paper on "An Acid-Resisting Alloy" by S. W. Parr. An alloy was found and described which would withstand the continued action of nitric acid without loss. Two papers on brass were read, viz: "Some Experiences with Brass in Civil Engineering Works" by A. D. Flinn, "The Failure of Structural Brass" by Dr. P. D. Merica. We reserve fuller accounts of a number of the papers presented for future issues.

At the business meeting of the Institute Mr. Jesse L. Jones of the Westinghouse Electric & Manufacturing Company was elected president succeeding Mr. G. H. Clamer. Mr. W. M. Corse of the Titanium Alloy Manufacturing Company was re-elected secretary.

The Range of Applicability of the Liquid Sulphur Dioxide Method for Determining Aromatic Constituents in Hydrocarbon Mixtures[1]

BY W. F. RITTMAN AND R. J. MOORE

One of the most convenient and widely used methods of separating the constituents of liquid mixtures is that based on differences of solubility in some reagent. To make this method effective it is necessary that these differences shall be considerable and that the solvent shall be easily removable from each of the two fractions after the extraction has been accomplished.

When used at sufficiently low temperatures liquid sulphur dioxide has the property of dissolving readily aromatic and unsaturated hydrocarbons and leaving unaffected the saturated paraffins and naphthenes. In addition, it is easily removable from hydrocarbons, either by evaporation or by washing with an aqueous alkaline solution.

On the basis of these properties Edleanu[2] has developed a commercial process for the refining of petroleum and also has worked out the details of a laboratory method of analysis. His problems were in the line of estimating aromatic constituents as impurities in ordinary petroleum mixtures and he records the obtaining of excellent results.

In connection with work on the production of aromatic hydrocarbons by the cracking of petroleum methods of analysis and separation were sought which should be reliable, accurate and convenient. Results of the major portion of these researches are recorded in another communication.*

The present note describes some experiments in which the liquid sulphur dioxide method was tried out with known mixtures. The results obtained were sufficient to indicate clearly the range of applicability as regards concentration of aromatics.

Experimental

Mixtures were made up which contained known proportions of aromatic and non-aromatic constituents. For the former was used a mixture of 16 per cent cymene, 42 per cent xylene and 42 per cent toluene. This mixture had a specific gravity at 15 deg. C. of 0.874 and a refractive index of 1.494. The paraffins were represented by a gasoline of specific gravity 0.720 and refractive index 1.400, which gave no coloration when treated with a mixture of nitric and sulphuric acids. The known mixtures were made up on a basis of percentage by volume.

The experiments here described were performed by a modification of the Edleanu method which seemed to be sufficiently accurate for present purposes. Apparatus consisted of a fifty cubic centimeter graduated tube equipped with well ground glass stop-cocks at either end, a jar to contain cooling mixture and a small tank of liquid sulphur dioxide. The apparatus is shown in Fig. 1.

The mixture to be tested was introduced into the graduated tube and the latter immersed in a cooling mixture of ice and salt. Connection was made with the sulphur dioxide tank by means of a length of heavy walled rubber tubing, the valve was opened and the gas allowed to distill over into the oil. After the latter became saturated, a second (lower) layer appeared which consisted of liquified sulphur dioxide, holding in solution the aromatics. The two layers were separated by running out through the lower stop-cock and the sulphur dioxide slowly boiled off until a temperature of 50 deg. C. was reached. This method of procedure undoubtedly was responsible for a certain amount of loss which could have been avoided in case it were necessary by the washing with aqueous alkaline solution recommended by Edleanu. Specific gravities and refractive indices were determined for the residues from both layers. Their quantities were of course measured.

The results of experiments with mixtures of varying composition are shown in Table I. It appears that with a concentration of aromatics not exceeding 25 per cent, separation may be obtained by the use of sulphur dioxide at temperatures in the neighborhood of — 20 deg. C. The separation was not, however, satisfactory at concentrations exceeding 15 per cent, as above this point there are no good figures for percentages and physical constants of the fractions separated. The matter of temperature once more was shown to be of great importance. As the two layer system, obtained in the graduated tube, is permitted to warm up the line of demarcation becomes blurred and finally disappears when temperatures in the neighborhood of 10 deg. to 15 deg. are reached.

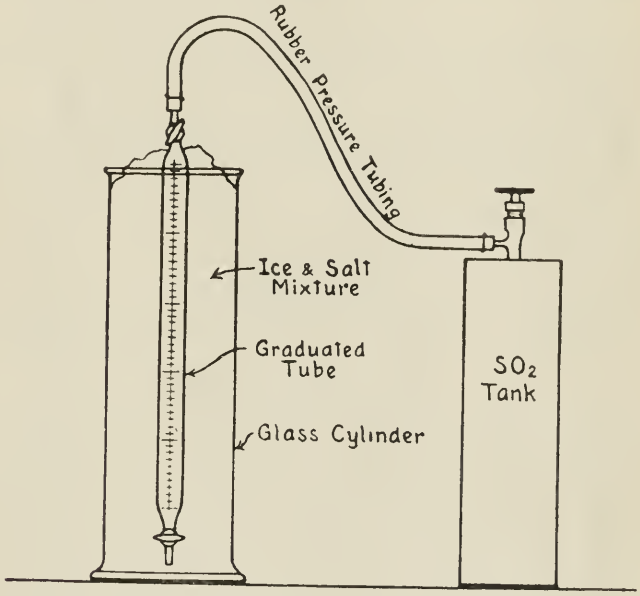

FIG. 1—APPARATUS FOR SULPHUR DIOXIDE SEPARATION

TABLE I.

SULPHUR DIOXIDE SEPARATION OF KNOWN MIXTURES

Constituents used:

Paraffin—A gasoline giving no coloration with nitric-sulphuric acid mixture. Specific gravity 0.720. Refractive index 1.400.

Aromatic—A mixture of 16 per cent cymene, 42 per cent xylene and 42 per cent toluene. Specific gravity 0.874. Refractive index 1.494.

*Rittman, Twomey & Egloff, Metallurgical and Chemical Engineering, October, 1915.

Edleanu records obtaining at —10 deg. separation with a mixture containing 40 per cent of aromatics. With the hydrocarbons used in the present experiments the limit seems to be much lower. Multiple extraction, as recommended by Edleanu, would undoubtedly improve results between the limits of 15 per cent and 25 per cent, but it is difficult to see how this device could help when a first extraction failed to obtain separation into layers.

Summary

1. It has appeared that although the liquid sulphur dioxide method works well for the estimation of small quantities of aromatics in hydrocarbon mixtures it is not applicable if the content exceeds a limit in the neighborhood of 25 per cent.

If it is desired to determine aromatics by this method when the concentration is greater, use must be made of the device of diluting with a pure paraffin mixture such as water white Pennsylvania kerosene. Diluting with an equal volume will bring mixtures containing from 25 per cent to 50 per cent below the limit of separation. Dilution with three volumes of the paraffin will take care of oils whose aromatic content ranges between 50 per cent and 100 per cent.

2. Temperature at which extractions are performed must be low, preferably in the neighborhood of —20 deg. C.

The experiments here described were performed in the laboratory of the Department of Inorganic Chemistry of Columbia University, New York.

Liquid Jets

A Study of a Phenomenon of Importance in Flotation and Cyanidation

BY C. TERRY DU RELL

The whole subject of flotation depends upon gas absorption. The mineral to be saved as a concentrate must have occluded sufficient gas to prevent its being wetted by the flotation liquid. Once wetted with the flotation liquid, its tendency is to sink as there can then be no surface tension effect tending to float it. The flotation liquid may be assumed in all cases to be water as it has been proven that no liquid except mercury has such great surface tension. Water will enter the pores of a solid from which all gas has been driven out and adhere to the surface so that the solid becomes as a part of the liquid so far as surface tension effects are concerned. That is, if there is a force of adhesion existing between the molecules of the water and the molecules of the solid, flotation cannot take place. If the particles be on the surface of the water, this truth is readily seen when an attempt is made to float them with say a Henry Wood type of machine, but it is not so readily seen when an attempt is made to float them by means of bubbles or froth if the particles be below the surface of the water.

Hereinafter then, only flotation of submerged particles will be considered. If a particle is to be floated by means of minute bubbles, these bubbles must be attached to the particle; or, if it is to be floated by means of froth, the particle must be attached to a bubble. The surface tension of a liquid film surrounding a gas bubble, being much greater than the adhesive force between a gas and a solid, holds the gas firmly inside the film so that attachment in this case between the gas and solid cannot take place. It is easily proven that gas, to be attached to a solid in a liquid, must be in a nascent state in the liquid. On being driven out, it will collect in the form of bubbles. It is therefore quite evident that, if the solid contain some of this gas, it will be a nucleus for the collection of these bubbles due to cohesive force existing between molecules of gas at the surface of the solid and molecules of gas in the liquid immediately surrounding the solid. Since air is readily soluble in water (especially the oxygen) and also since it is occluded by most solids, due especially to the chemical affinity of the oxygen, it is by far the most preferable gas for flotation as well as the cheapest, and will be hereafter the only one considered.

Due to the fact that air is soluble in oil and that oil is practically insoluble in water, it is readily seen that gas can be much easier attached to oiled mineral particles. Molecular attractions only being considered, the thinnest possible film of oil is all that is necessary. "Oil prevents the wetting of mineral particles" is evidently an erroneous statement since it is common practice to oil-coat the mineral particles while they are in the water. The particle contains gas and therefore can be oiled. Due to the cohesive force of the oil, a film may be formed which adds strength to the water film and prevents the bubbles from bursting so easily.

By the addition of an acid or an alkali to the water to form an electrolyte, an ionized condition is produced which creates a selective action of flotation due to occlusive power of at least some of the minerals being affected.

Role of Air in Flotation

After examination of all the different materials used in connection with flotation, it is seen to depend entirely on, first, dissolving air in preferably an electrolyte as well as in the ore and, second, the expulsion of this air. This all depends on Henry's law.[1] From this law it is readily seen that air may easily be expelled from either the electrolyte or ore particles[2] by heat or reduction of pressure.

It is evident that it makes no difference whether the gas be absorbed at high pressure and liberated by reduction to atmospheric pressure or absorbed at atmospheric pressure and liberated by vacuum. Naturally then the fundamental requisite for flotation is the production of a state whereby both water and mineral will absorb air. This eliminates any process in which air, dissolved at atmospheric pressure and temperature, is liberated by a vacuum, as such a process, necessarily limited to low altitudes, is crude and full of too many mechanical difficulties which make it unnecessarily expensive to operate. This has been the experience of plants operating by such a method.

According to the law of Henry, it would be possible, by varying temperature and pressure, to make water absorb its own volume of air since, for instance, at 10 deg. C. it is known to dissolve 2 1/3 per cent of its own volume at sea level. As an example, it would be quite easy to subject the water to say 90 lb. pressure per square inch or six atmospheres when, at the ordinary mill water temperatures of 10 deg. C., it would dissolve 15 per cent of its volume of air. As this requires some power, it is well to investigate the quantity necessary to be dissolved to effect flotation. That is, what degree of saturation is necessary?

As noted above, it is only the air that is driven out of solution or nascent air that can be used for bubble making or flotation. These bubbles, on coming to the surface, tend to burst, due to expansion, etc. Then the greater the pressure of the gas in the bubble the greater will be this bursting tendency. Therefore it would seem desirable to form these bubbles at com-

[1] At constant temperature, gas dissolved in a given volume of liquid varies directly as the pressure. Each gas is dissolved independently of all other gases.

[2] Cook's Chemical Physics. Solution of gases.

parative shallow depths in the water and with as little pressure as possible. In other words, mere supersaturation of the water with air near the water surface.

Supersaturating Liquids with Gases

A simple way to supersaturate water with air at atmospheric pressure is to beat it in with paddles or stirrers. The Minerals Separation Co. has patents describing this means. "Beating air into solution" does not well explain just what action takes place. To study this, take the simplest case of a single paddle, say a piece of wood partly submerged in water. Move it rapidly through the water. The instant the water is divided, a film of air forms on these division walls. As the water closes in again behind the paddle, this air film is taken into the interior of the water. Being a mere film, it is absorbed. The water, being already saturated with air, cannot hold any more so the excess must come out in the form of bubbles.

If there be paddles or blades on a shaft revolving rapidly below the surface of the water, a vortex is created and the water, on going down to take the place of that thrown out from the ends of the blades, carries air in with it as a film on the surface. It is readily seen that surface tension is the cause of this air being carried in and absorbed by the water. If the bubbles form fast enough, froth is produced, especially if there be sufficient material present to coat and toughen the bubbles.

This is a common method for getting air into solution and of every day occurrence. Eggs are beaten to a froth and the bubbles toughened with sugar. A small boy drags a stick rapidly through the water to see the bubbles in its wake. The water astern from a ship is white with the reflection of light from the air bubbles of supersaturation caused by the propeller. The surface tension at the crest of a wave, on "breaking," causes the air to be absorbed and given out as bubbles.

Another way of supersaturating a liquid with a gas has hitherto not been taken advantage of in flotation. Common occurrences of this are to be noted as well. On drawing water from a tap into a wash basin for instance, bubbles are seen to form and rise to the surface. Where does this air come from? If water from a hose be turned by means of a nozzle into a bucket some little distance away, a froth is formed. Fish in an aquarium rise to the surface for want of air. The attendant opens a jet of water fixed a short distance above the surface. This water shoots down into the aquarium, a stream of bubbles rise to the surface and the fish goes back to the bottom satisfied.

A stream of pulp is turned into a thickening tank from some little distance above, either directly or through a pipe straight down and below the surface and the millman is driven distracted by the froth that forms and causes a muddy overflow. It is then necessary to fit an interior ring as a barrier against the bubbles in order to obtain a clear overflow.

These phenomena are therefore worthy of investigation as air can apparently be taken into solution this way as well as with paddles or stirrers. This may be classified and defined as streams of liquid projected through a gas and into a liquid. The term liquid jet is applicable as it is a phenomenon of a jet of liquid as shown by the cited examples.

Phenomena of Liquid Jets

In investigating this. it would be well to first investigate the injection of a liquid into a gas. The liquid may be injected (1) vertically upward, (2) vertically downward or (3) at an angle. With a jet turned straight down, gravity is bound to accelerate the fall of the liquid. At some distance from the nozzle, the liquid will be traveling faster than that portion leaving the nozzle, due to this acceleration. This, it is seen, will tend to break the stream up into short cylinders and stretch the intervening liquid into long thin cylinders. Further acceleration will break these larger portions off. Surface tension, having rounded the edges previous to their breaking off, will immediately form them into drops and at the same time form smaller drops from the long thin cylinders in between. Thus there will be a falling succession of drops alternating large and small. The surface tension of the air film is so great that these small spheres are formed. Pictures have been taken showing this action in detail.

With the jet turned straight up, gravity retards the stream so the velocity becomes less as the distance from the nozzle increases. The whole stream is surrounded as before with an air film, the surface tension of which carries it along. When the gravity plus the weight becomes equal to the initial pressure, portions must be forced out sideways and spherical drops formed as described above. The surface tension of the surrounding air films prevent their re-uniting so that they will actually rebound from one another.

With a jet turned out at an angle (horizontal or inclined), gravity retards and pulls the stream down until portions are broken off to form spherical drops. The viscosity of a liquid tends to counteract this so that glass, for instance, can be spun or drawn out into threads.

The intensity of this surface tension effect may be shown by directing a jet of water onto an oiler or dusted surface when the globules of water will be held intact and roll the same as if they were enclosed in a solid substance when, in reality, they are only enclosed in a "skin of air."

The jet of liquid before breaking up was thus seen to be enclosed in a cylinder of gas, the surface tension of which caused it to move with the liquid and at the same velocity. The rush of air into a large nozzle to form this enclosing air cylinder may be readily felt by the hand. In other words, a jet of liquid turned into a gas does not merely slide through that gas or a cylinder of that gas but carries the "gas cylinder" along with it.

If the jet of liquid, passing through a gas, be turned into the surface of a liquid, the enclosing gas cylinder is evidently carried into the liquid and, if the liquids mix or are soluble in each other, the gas must be liberated. That is, the cohesion or adhesion, as the case may be, of the liquid jet for the liquid it has penetrated is sufficient to overcome the surface tension of the gas cylinder. The gas, being in such a thin film, is so finely divided it enters in between the molecules of the liquid in the intersticial spaces, and, if the liquid is not already saturated, remains there. A jet of gas entering a liquid, would, due to this surface tension effect, act the same as a jet of liquid entering a gas.

A simple way to prove that this gas cylinder goes into solution is to turn a jet of water into a vessel of water that has been boiled and cooled. On reheating, air will be expelled from the water in this vessel while none will be expelled from a similar quantity of water into which no jet has been turned.

When a liquid is entirely saturated with a gas brought in with a jet, supersaturation has the effect of producing nascent gas which collects in the form of bubbles. This fact is taken advantage of for flotation and will eventually be put to many other uses.

At the present time, this principle is used to a large extent for the hydraulic compression of air, where the surface tension causes the air film to be entrained and carried down a pipe of shaft to be liberated at the bot-

tom in a chamber under pressure. Frizell, although not recognizing this principle of air introduction with his air compressor design, does recognize the fact that it is not necessary to have a large number of small air inlet pipes at the intake. The simplest form is used for ventilating mines and, since oxygen is more soluble in water than nitrogen, the liberated air contains nearly 35 per cent oxygen against less than 21 per cent oxygen in the air introduced by a blower, for instance.

Importance in Cyanidation

It seems strange that this liquid-jet phenomenon has not been recognized before by many cyanide metallurgists since it has been the direct cause of many cyanide plant failures. Visit any old or modern cyanide plant and see the numerous jets of solution passing through the air and into a tank of solution. Pumps deliver streams here and there and through the air into tanks of solution or of pulp. Everything is supersaturated with air.

With sand leaching, this does not prevent operations being carried on, although, with some ores, an extra cyanide and lime consumption results. The millman simply remarks that the ore has a latent acidity, dumps in more cyanide and lime and lets it go at that. He does not bother with a reason for certain contained minerals being rapidly oxidized.

However, it is with the slime that big troubles occur. When the slime is very fine, and settlement and filtration difficulties are experienced, the millman, knowing it is not a crystalloidal slime, assumes that it must be a colloidal slime and that settles the question though not the slime. Simple logic this. It must be one of two things. Therefore, since it is not the one, it must be the other. The last few years, many cyanide metallurgists seem to think only of "the gel state" or "the sol state" and seem to have forgotten that a state of suspension can exist so that a pulp may only resemble a colloidal state.

This excess air coming out of solution is attached to even the smallest particles of slime as well as the larger particles. The larger ones can perhaps settle in spite of this buoyant tendency while the smaller ones may not show the slightest tendency to settle. It is a well known fact that settlement of the particles or of a precipitate takes place rapidly after the solution has been boiled and cooled. The only effect of the boiling is to drive out the air.

In many cases, when a solution of water stands until it appears perfectly clear, boiling and cooling will show an appreciable sediment on the bottom of the container.

It is certainly extremely difficult to thoroughly mix a pulp ready for filtration when some of it is floating, due to air bubbles, and the balance settles out readily. Much trouble is thus caused with the cake on a vacuum machine as well as in a press.

Plenty of trouble is caused in a cyanide plant when the bubbles are practically microscopic but great difficulty has been experienced at some plants where the bubbles were quite large and at a few where froth formed.

It seems doubtful if there is a single case of difficult slime settlement due entirely to a true colloidal condition as most pulp solutions are so supersaturated with air that they are more nearly ready for a flotation plant than they are for a cyanide plant.

Comparative Tests of Piston-Drill Bits is the title of the August, 1915, Bulletin of the University of Missouri School of Mines and Metallurgy. The authors are Prof. C. R. Forbes and L. M. Cummings.

Notes on Concentration at Nevada Consolidated Copper Co.

(Editorial Correspondence)

In common with other large Western producers of copper, the Nevada Consolidated Copper Company has been pushing work to the limit of plant capacity. The concentrator, which ordinarily has handled an average of 1000 tons per day in each of the eight sections, is now treating a total of over 10,000 tons per day. From 3 tons to 4 tons of water is required per ton of ore treated, fluctuating with changes in the character of the ore, so that the problem of securing an adequate water supply has made it necessary to resort to various means of recovering water that might otherwise go to waste. With some changes and improvements now contemplated, to be mentioned later, it is expected that the water requirement will be reduced and that the present supply will be ample.

At the present time the water piped from Duck Creek is supplemented by spring water pumped up from the valley, and some water is recovered from tailing ponds. Dorr thickeners, however, are playing the important part in the latest plan for water conservation, because they simultaneously recover a large volume of water and thicken a dilute slime for the flotation machines. The recovered water is used as a wash for concentrating tables. Some very slimy water, containing from 10 per cent to 15 per cent solids, is used at the smelter for granulating reverberatory slag. Eight 50-ft. Dorr thickeners have been in use at the mill for some time, and four more, 70 ft. in diameter, have been recently added.

Thickeners Operating in Earth Excavations

These are erected in the open on a bench of ground behind the mill; with only a small housing for the individual 3-hp. motors, and embody a number of interesting features conceived and executed by Mr. George C. Riser, mill superintendent. Wishing to reduce the cost of construction as much as possible, he dispensed with the usual wooden tanks and excavated a suitable opening in the earth in which to operate the thickener mechanism. The sides of the earth "tank" slope 45 deg. from the circumference toward the center, as shown in Fig. 1. Around the circumference a narrow bench is excavated to support a concrete collar that forms the overflow launder and supports the weir. The detail of this construction is shown in vertical section in Fig. 2. Bolts are embedded along the inner edge of the collar to secure pieces of wood for attachment of the weir. In the same manner pieces of pipe embedded along the uppermost surface form a support for an iron-pipe railing that surrounds the finished thickener. The trusses are supported on 12-in. I-beams resting on concrete

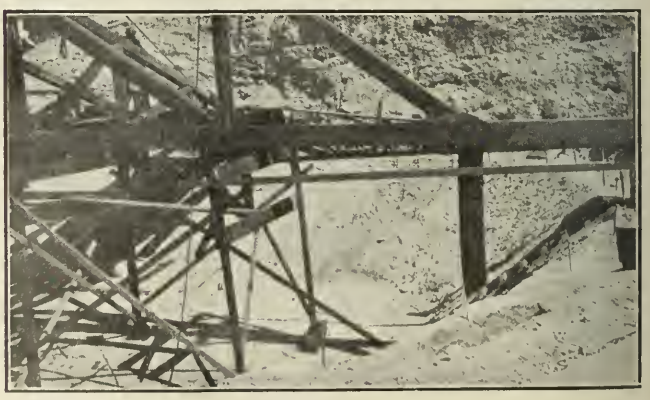

FIG. 1—EARTH EXCAVATION OF 70-FT. DORR THICKENER

piers. Fig. 3 shows a completed thickener operating in an earth excavation. This thickener gradually forms its own impervious walls and bottom of fine slime and no trouble is experienced from seepage. The 8-in. pipe for discharge of thickened slime is embedded in the bottom of the excavation and extends through the earth wall, issuing on the slope of the bench of ground in which the excavation is made. A similar pipe carries off the overflowing clear water.

The feed to these thickeners is carrying about 5 per

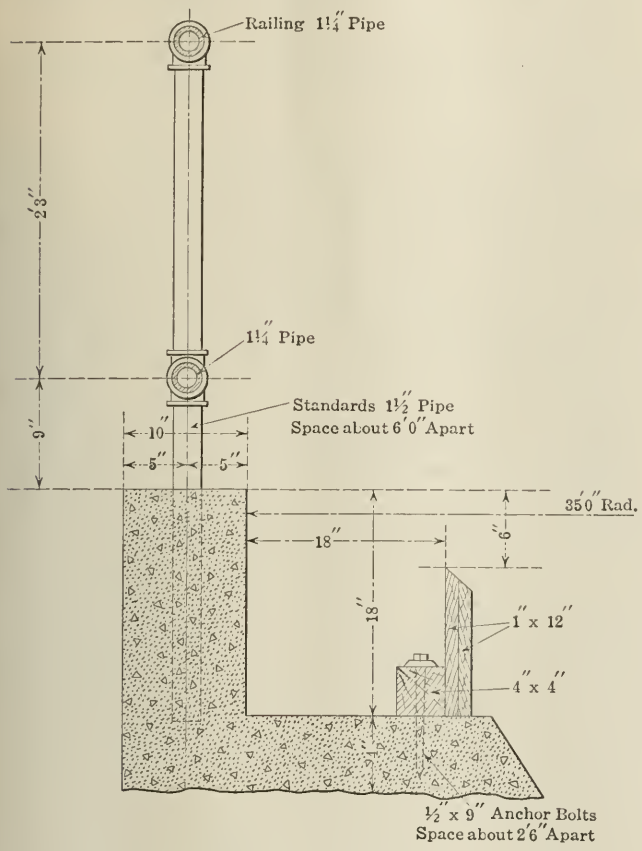

FIG. 2—DETAILS OF OVERFLOW LAUNDER

cent solids, and the discharge about 30 per cent. The only measurement of water recovery, made shortly after one of the thickeners was put in operation, indicates a recovery of 3 sec.-ft. for each 70-ft. thickener.

Changes in Grinding Practice

A number of changes are to be made in the present methods of grinding and concentrating which will greatly simplify the practice, increase capacity and recovery, and reduce the quantity of water required. For the present no change will be made in primary crushing, but rolls are to be abandoned for secondary crushing and fine grinding replaced with Hardinge ball mills. One section of the concentrator is to be remodeled for this experiment.

FIG. 3—COMPLETED THICKENER OPERATING IN EARTH EXCAVATION

In the present system the gyratory product is crushed in rolls, elevated and screened in trommels making two sizes for regrinding, 5/16 in. for return to coarse rolls and 3/16 in. to fine rolls. The product of the latter is elevated to 2-mm. trommels, the oversize of which is returned. The undersize flows to a four-compartment classifier. First and second classifications are treated on Wilfley tables, the tailings being reground. Third and fourth grades are similarly concentrated, the tailings being wasted. The classified overflow is thickened and treated by flotation in Janney machines. The reground Wilfley tailings are again classified into four products and treated on further Wilfley tables, all making final tailings except those handling the fourth classification, the tailings from which are treated on vanners.

In the section to be remodeled the rolls will be supplanted by Hardinge ball mills and the ground product elevated directly to classifiers. All grades plus 40-mesh will be treated on Wilfley tables as before, while the minus 40-mesh material will be treated by flotation. The tailings from the Wilfleys will be reground and also floated, vanners being eliminated in this section. The new plan offers obvious advantages over the old, both in the preparation of the ore and its treatment. The simplifying influence of flotation is seen in the elimination of some Wilfley tables and all vanners, and is the most important aspect of the proposed change. The changes in grinding will result in less handling of pulp and the use of less water.

Coal-handling machinery is in the August issue of the *Labor Savor*, a pamphlet by the Stephens-Adamson Mfg. Co., Aurora, Ill.

Sirocco Service, a pamphlet published by the American Blower Co., Detroit, gives many facts regarding the different uses of Sirocco Blowers.

Talc and Soapstone.—The United States produces more talc and soapstone than all the rest of the world combined, the 1914 production being 172,296 short tons, valued at $1,865,087.

Lump fluorspar for the manufacture of hydrofluoric acid showed an increase of 55.8 per cent in quantity and 91.3 per cent in value of sales in 1914 over 1913, according to U. S. Geological Survey.

Cyanides.—In the twelve months ending March, 1914, Canada imported 1,165,490 pounds of potassium and sodium cyanides and 166,901 pounds of yellow and red prussiate of potash.

Tin.—According to Mineral Resources of the U. S. there were no domestic tin ores smelted in the U. S. in 1914, though some tin concentrates were shipped from Nome, Alaska, to Singapore for treatment, and there was considerable agitation for the domestic smelting of both Alaskan and Bolivian tin ores. An increased output from Alaska may result in the establishment of a tin smelter on the Pacific Coast.

Primary Mercurial Resistance Standards.—The Bureau of Standards has just issued Scientific Paper 256, dealing with the construction of four standard ohms in the form of mercury columns in glass tubes, and the work involved highly accurate measurements. Comparisons of the four standards showed the average deviation of their individual values from their mean value to be less than one-one hundred thousandth of an ohm. England, Germany, France, Russia, Japan and the United States now have mercury standards of resistance which all agree to a high accuracy.

Thermal Principles of the Blast Furnace

BY J. E. JOHNSON, JR.

The doctrine of the conservation of energy and the interconvertibility of its forms was well established about the middle of the last century, but the latter was well in its third quarter before any systematic effort was made to apply that doctrine to the blast furnace.

This was first done by Sir Lothian Bell, who had made in his works-laboratory countless experiments conducted with a degree of scientific skill and breadth of vision rare in that day. With the results of these and the data on thermal capacities, heats of reaction, etc., so carefully and laboriously determined by the physicists of various countries, particularly France, he prepared a heat balance of the furnace showing the quantity of heat developing and the amounts utilized and lost in various ways, which was the beginning of any comprehensive knowledge of the subject, for without a knowledge of the theoretical amount of heat necessary to bring about the desired reactions in the furnace it is impossible to say whether we are getting a reasonable efficiency from the fuel or not.

Since that time heat balances without number have been prepared and used to prove any contention that it might please the fancy of their makers to uphold, but frequently without carrying much conviction. The reason for this was that while taking careful account of the quantity of heat they ignored the quality factor, that is, temperature-head or intensity. It was as if a hydraulic engineer tried to figure the water-power obtainable at a given site by accurate and painstaking determinations of the quantity of water passing without any regard to the head, or an electrician were to try to figure the power of a given circuit from the amperes of current without respect to its voltage, or more accurately still as if a steam engineer tried to figure the power he could obtain from a definite quantity of steam without knowing the temperature, on which its pressure depends.

This condition is all the more curious because in the case of the other great application of heat, the steam engine, the importance of the intensity factor was worked out and stated in mathematical language many years before the doctrines of the conservation and convertibility of energy were discovered, and both of these were known and the theory of the steam engine was complete, virtually in its present form, about the time Sir Lothian Bell's work on the heat balance of the blast furnace was begun.

This theory of the steam engine was completely enunciated by two laws known as the First and Second Laws of Thermodynamics. These may be expressed for our purpose as follows:

1. The quantity of work produced by transformation of heat bears a definite and unchanging ratio to the quantity of heat transformed.

2. The proportion of any given quantity of heat which can be utilized for conversion into work depends upon the temperatures at which the heat is applied and discharged.

The first of these laws is simply a special form of the law of conservation of energy, and by substituting "chemical change" for "work" it would express the law of the blast furnace which Sir Lothian Bell and his followers understood. But that the blast furnace depended also upon a similar "second law" was totally beyond their knowledge, although it is just as important in this case as in that of the steam engine. This accounts for the failure of the elaborate calculations based on the first law alone, to explain many of the well-recognized phenomena of blast-furnace practice.

For instance, the introduction of the hot blast reduced the fuel consumption of soft-coal furnaces more than a half, although the heat of the blast introduced was only about 18 per cent of the total produced—a preposterous state of affairs viewed only in the light shed by the heat balance—and Sir Lothian Bell spent not pages, but chapters, in trying to prove that the benefit of the hot blast was strictly limited, and was, in fact, smaller than it was generally known in practice to be, because he could not make the facts square with his incomplete theory.

This is a subject with which I have had some connection in its later development, and it may not be amiss to treat this portion of it from a somewhat personal point of view.

The explanation of the hot blast given in Sir Lothian Bell's works did not seem to me to explain, and I had, moreover, been puzzled by the action of moisture in the blast, a subject treated by him in a similar way, because I had for a number of years been studying that subject carefully and keeping records of humidity in the engine room, which showed that the moisture present in summer above that present in winter was sufficient to account on that basis for only 4 or 5 per cent difference in fuel consumption, whereas the furnace records over a number of years showed 20 per cent difference. In 1899 it began to appear to me that there might be a critical temperature in the blast furnace above which some of the heat had to be supplied, and that as the range between this temperature and the theoretical combustion temperature was only a fraction of the latter, a change in the latter would have an effect on this range (which obviously measures the amount of such heat available), several times as great as the effect on the theoretical combustion temperature. I did not then know what the critical temperature was nor what controlled it, but calculations on this basis with assumed critical temperatures based on the best information obtainable as to the temperature inside of the furnace, seemed to show a better agreement with the facts than did Bell's figures, and this idea grew in strength.

In 1901 a "Lunette" optical pyrometer was procured and observations of temperature made through the tuyeres, and in every other way thinkable, to determine what the critical temperature really was, because as long as it was only assumed it could be arbitrarily chosen so as to bring results which would agree with practice, but which would mean nothing.

The results of these observations revealed the fact that there was a critical temperature, that it was controlled exclusively by the free-running temperature of the slag, and that this temperature for the furnaces under observation was about 2750 deg. Fahr. A totally different investigation revealed the fact that the result of the removal of the moisture from the blast was identical in principle with that of the hot blast, and that its effects could be figured in exactly the same way.

Calculations of heat available above this critical temperature of 2750 deg. under different conditions of blast temperature and humidity agreed with the relative coke consumption under those conditions so well as almost to arouse suspicion of the possibility of self-deception, but the same principle seemed to work quantitatively under the most diverse conditions and to explain many facts not adequately explained before, and I became convinced it was correct.

The idea is so simple that it seemed almost sure that it must have occurred to some one else long ago, and I made the best search I could through the blast-furnace literature of four countries to see if this were true without finding a trace of it anywhere.

I wished to obtain certain patents founded on this principle so kept it secret for three years, until the summer of 1904.

At that time the patents desired were allowed and the preparation begun of a paper to set forth this new theory of blast-furnace action.

In that autumn Mr. James Gayley published his paper describing the actual results he had obtained at the Isabella Furnaces by the application of his system of drying the blast.

This was most fortunate for me, as it supplied authentic data strongly confirmatory of the new theory which were totally inexplicable by the old, and would, as I supposed, hasten the acceptance of the former, for it never occurred to me that the publication of Mr. Gayley's results would arouse any doubts of their correctness or any other sentiment except admiration for the solution of a problem of which all furnacemen must be aware and for which they must desire a solution. As a matter of fact, the announcement of Gayley's results set the whole metallurgical world into a furore, many furnacemen and near-scientists refused to accept the results, and even went so far as to question the correctness, not to say truthfulness, of the furnace records.

My paper entitled "Notes on the Physical Action of the Blast Furnace" was submitted to the American Institute of Mining Engineers in the autumn of 1904, soon after Mr. Gayley's paper was read, but was held up in the secretary's office for almost a year. It was, however, presented orally at the Washington meeting of the Institute in May, 1905.

It was with great trepidation that I attacked the old theory as so incomplete as to be utterly misleading, expecting to be savagely criticized for my temerity and to see efforts made to riddle the new theory, and it was correspondingly surprising to see it accepted without a single protest by American furnacemen and metallurgists, because it explained Mr. Gayley's results. Thus instead of his facts being used to sustain the new theory, as would surely have been expected, the new theory was quite generally accepted because it sustained Mr. Gayley's facts.

It is proper to say that while the acceptance of the new theory seems as far as one can judge to be quite general in America, there are many indications that it has made little or no impression in Europe, and it seems, as far as I can gather, to have been definitely rejected in Germany.

After the lapse of ten years, during which this theory has been used as a tool for the investigation of many of the problems of the blast furnace, the original presentation seems to me to be as good as anything I can offer now, though it is no more than proper to state that it has been presented in slightly different form by various other furnacemen and metallurgists, some of whom seem to regard it as entirely their own.

The original presentation from the paper above mentioned (Trans. A. I. M. E.) follows.

THE RESULTS OF HEATING AND DRYING THE BLAST

The explanations offered by writers on the blast furnace to account for the economic effect of heating the blast are non-quantitative and therefore inadequate. The following paragraphs, translated from Ledebur[1], give perhaps the best example:

"When, later, systematic investigations of the influence of the hot blast began to be made, the surprising fact was frequently observed that by heating the blast more fuel could be saved than was necessary for the production of the heat brought in by the hot blast. Moreover, it was very generally observed that the top of the furnace became cooler the more the blast was heated.

"The two phenomena bear a close relationship to each other. The furnace requires, for each kilogram of iron produced, a certain quantity of heat, and the production of this heat, as has been mentioned earlier, is the primary purpose of the combustion of the fuel by the blast. Each kilogram so burnt furnishes a definite quantity of gas which ascends into the furnace.

"But now, if a part of the required heat, instead of being produced by the combustion of carbon, be brought in by the heated blast, the resulting quantity of gas must be as much smaller as corresponds to the saving in fuel; the smaller quantity of gas gives up its heat more quickly and completely to the counter-current of descending solid material than does the larger quantity of gas resulting with the cold blast.

"The heat is accordingly more advantageously utilized in operating with hot blast, and, by this means, a secondary saving in fuel is made. The consequence of this is that the gas leaves the furnace in a cooler condition, and the top temperature falls."

Bell's explanation is not very different and no more satisfactory.

A simple explanation, which affords a basis for quantitative estimates in close accord with the actual facts, is afforded by considering the temperature at which a part of the total heat must be applied.

In the application of heat to the generation of power, it was realized more than a century ago that the temperature of application was of equal importance with the quantity of heat; and it seems remarkable that, in metallurgy, attention is rarely paid to the temperature at which the heat must be applied for the accomplishment of a given purpose, and that quantitative data bearing on this subject are practically unknown.

Calculations of the total quantity of heat imparted to the furnace by the combustion of 1 lb. of carbon, have often been made; and in a few cases calculations have also been made as to the maximum temperatures obtainable under various conditions, but if there have ever been any calculations as to the quantities of heat available at different temperatures, I have never heard of them.

The point of view from which this subject should be considered differs so slightly, but so radically, from the common one, that the distinction is not easy to make clear, but may perhaps be best approached by the conception of a "critical" temperature. It may be said without reservation that for every set of furnace conditions there is a certain critical temperature above which only, certain necessary operations of the process can be carried out. It is not necessary to know what the operations are, and no attempt will be made to enumerate them here, further than to say that they probably comprise the removal of the final traces of oxygen from the ore, the formation and subsequent superheating of the cinder, and the melting, carbonization and superheating of the iron—"superheating" being used in the sense of heating above the point of fusion.

Given the existence of such a critical temperature, it is easy to see that where the heating is done by direct contact with the combustion and its products, as in the bosh of a blast furnace, the only heat available for performing the operations which must take place above the critical temperature is the portion left after deducting the amount necessary to raise the products of combustion to that temperature. Or, to state the proposition in another way, if all the heat developed by combustion passed into the products of combustion, there would be available for the work of the hearth only that portion, the removal of which would suffice to reduce the products of combustion themselves to this critical temperature.

It is obvious that the nearer the critical temperature is to the theoretical temperature of combustion, the smaller will be the quantity of such available heat. If

FIG. 1—HEARTH HEAT AVAILABLE PER POUND OF COKE, COUNTING 0.85 LB. OF FIXED CARBON ACTUALLY BURNED IN HEARTH, WITH DIFFERENT CRITICAL TEMPERATURES ALSO DIFFERENT BLAST TEMPERATURES AND DIFFERENT MOISTURE CONTENTS IN THE BLAST

the critical temperature is, say, four-fifths of the theoretical combustion-temperature, then the available heat is only one-fifth of the total; and while the other four-fifths are useful for other purposes, they are lost for those under consideration.

The critical temperature varies in the same furnace with varying conditions, but for certain conditions it was determined to be about 2750 deg. Fahr., as a probable average, and results obtained from calculations made on this basis were in such close agreement with the results, that the series was extended to cover other conditions, namely, two other critical temperatures, and varying quantities of moisture in the blast.

Such calculations are extremely simple and involve no uncertain assumptions, the method being as follows:

The combustion receives heat from three sources: the heat of combustion of carbon to CO; the heat brought in by the blast, and the heat brought in by the fuel. The latter may reasonably be assumed to be brought up to the critical temperature by the gas leaving the bosh, as the heat exchange is a true counter-current one, and the contact is intimate.

The heat brought in by the coke is therefore $2750 \times 0.21 = 577.5$ B.t.u., the heat of combustion of 0.9 lb. of carbon is $4450 \times 0.9 = 4005$ B.t.u., and the heat brought in by the air at 70 deg. Fahr. (cold blast) is $5.22 \times 0.2375 \times 70 = 86.8$ B.t.u., a total of 4669.3 B.t.u.

The products of combustion are 4.02 lb. of nitrogen and 2.1 lb. of CO; to heat these to 2750 deg. requires respectively $4.02 \times 0.2438 \times 2750 = 2695.2$, and $2.1 \times 0.2479 \times 2750 = 1431.6$ B.t.u., a total of 4126.8 B.t.u., which deducted from 4669.3 leaves 542.5 as the available heat above 2750 deg.

Now assume the blast to be heated to 1000 deg.; the heat brought in by the blast becomes 1241.8 B.t.u., or 1155 B.t.u. more than before; the other items of heat brought in remain the same, as do those of heat removed by the products of combustion; consequently, the available heat is increased by this amount, which is a little more than twice the original amount, making the available heat in this case 1697.5 B.t.u., or more than three times that in the previous case.

A series of calculations were made on this basis for different blast-temperatures, and also for different critical temperatures; these are given in graphic form in Fig. 1.

It is perfectly obvious that the higher the critical temperature the less the available heat will be for a given blast-temperature, and vice versa.

The modification introduced by variable moisture content in the blast is not quite so simple, but not in the least complicated.

By way of preliminary it may be explained that the unit of moisture in the blast here adopted is 1 lb. per 1000 cu. ft. of air, since the latter is the unit of blast measurement. There being 7000 grains in a pound the commonly-used unit of grains per cubic foot may be reduced to that here used by simply dividing by 7.

(*To be continued in issue of Nov. 1*)

Cryolite.—No cryolite is produced in the United States, the entire supply used in this country being imported from Ivigtut, an Eskimo hamlet on the southern coast of Greenland, free of duty.

Metallurgy at the International Engineering Congress—II

San Francisco, September 20 to 25, 1915

In our last issue accounts were given of the papers and discussions on iron and steel and on copper. In the following we will first report two papers on copper omitted in our last issue on account of limitations of space and then give an account of the symposia on gold and silver, zinc, lead, and fuels.

Copper

(*Concluded from page* 662)

The Metallography of Copper was the subject of a paper by Prof. WILLIAM CAMPBELL of Columbia University. The author discusses the effect of copper oxide on copper and the effect of cold work and hot work on the structure of copper.

To show the effect of copper oxide on copper the author reviews the work of Heyn and Slade and Farrow. The freezing point of copper, 1084 deg. C., is depressed by the addition of Cu_2O, progressing until we reach a minimum of 1065 deg. C. and 3.5 per cent Cu_2O. A further increase in Cu_2O raises the freezing point of the mixture.

The effect of cold work on the structure of copper is to draw out the grains of metal, and the greater the reduction the more the grains are drawn out. The reason for the increase in strength and decrease in ductility is matter of dispute. The "amorphous theory" has gained support. It holds that (a) polishing produces a film of amorphous metal as the surface; (b) when a metal is strained, the slip-lines and slip-bands are covered with a film of amorphous metal, which is less dense and much harder than the crystalline variety; and (c) where the crystals of a metal meet, thin films of residual liquid metal will remain under circumstances which render them incapable of crystallizing, so that they form films of amorphous metal as an intercrystalline cement.

In studying the effect of hot work, the first thing noted was that the Cu_2O of the eutectic was drawn out into long strings of rounded globules. The structure, after different degrees of reduction, resembled that of annealed metal. While the grains became progressively smaller they showed no elongation because the heat was sufficient to cause a rearrangement of the grain.

According to Faust, the crystallites in electrolytic copper arrange themselves parallel to the lines of the current. Electrolytic copper, like worked copper, develops twinning planes when annealed, indicating the presence of internal stress.

Boronized Cast Copper was the subject of a paper by Dr. E. WEINTRAUB of the General Electric Co., Lynn, Mass. The author discusses the theory and practice of the use of "boroflux" for producing cast copper of good mechanical properties and high electrical conductivity. Numerous references to the same subject may be found in the files of this journal.

Boroflux is defined as a material containing boron in a state of oxidation below that of boric anhydride. Such a material takes up oxygen and reduces oxygen-containing compounds. In this reaction the boroflux is transformed into boric anhydride which, being fluid at the temperature of the reaction, comes to the top of the metal, carrying in solution metallic oxides, particularly cuprous oxide. Boron suboxide and boron carbide are generally used, the suboxide being preferable. Three-quarters of one per cent is usually added. An average conductivity of over 90 per cent is regularly obtained. The efficiency of boroflux in deoxidizing copper that has been remelted a number of times is shown in the following table. A.B. indicates the average number of bends; R. indicates the resistance offered by test bar to the bend, given in percentage, assuming virgin copper to be 100 per cent.

	A. B.	R.
Virgin metal	1515	100%
First heat	850	97
Fourth heat	334	96
Boron suboxide	2007	103

The Coolidge tube has been used for making x-ray photographs of metal that has been treated with boroflux, in comparison with untreated metal. The photographs show the porosity of ordinary cast copper and the solidity of copper cast with boroflux.

Gold and Silver

The symposium on gold and silver, which had been prepared and edited by C. W. MERRILL, was the subject of discussion in the session of the morning of Friday, Sept. 24, CHARLES BUTTERS presiding.

A Coarse Crushing Plant of 1000 tons capacity was the subject of a paper by G. O. BRADLEY. The author stated that the equipment and arrangement of crushing plants is now receiving the same attention which was formerly devoted only to other parts of the reduction works. Manufacturers are now producing complete lines of machines suitable for special type of ores. The author outlined the design of a plant for dry crushing a thousand tons of ore of average hardness to ¼ in. in size, using electric power, concrete-steel construction, gyratories, rolls and automatic balanced skips, instead of bucket elevators, giving an estimate of costs and detailed drawings.

Mr. Bradley's paper developed some discussion on the relative merits and the proper use of jaw and gyratory crushers. Prof. Robert H. Richards stated that in his opinion gyratory crushers were specially adapted for large central plants and jaw crushers for secondary work. But the recent construction of the Traylor jaw cushers, 5 x 7 ft., may necessitate a change of this opinion. Crushing practice is now in a period of change.

Crushing and Grinding.—The trend of recent practice in crushing and grinding for cyanidation is outlined in this paper by L. D. MILLS and M. H. KURYLA. Large-scale operations, such as described in the foregoing paper by G. O. Bradley, are in a class by themselves and not adapted to the ordinary cyanide plant. Primary crushing is usually done in two stages: first a jaw crusher breaking from run-of-mine to 6 in., and then cone crushers to reduce this material to 2 in. The Symons disc crusher is a recent machine which is giving good results in crushing from 4 or 6 in. down to 1 or 2 in. This machine is good on hard, brittle ores, but not adapted to wet, sticky ores. Undersize must be eliminated from the feed. Typical costs of coarse crushing and conveying are given below:

Goldfield Consolidated, Nev., crushing and conveying	$0.046
Belmont Milling Company, Nev., crushing and conveying	0.068
Commonwealth Mine, Arizona, crushing and conveying	0.079
Hollinger Gold Mines, Porcupine, crushing and conveying	0.113

Fine crushing or coarse grinding covers reduction from 1½ or 2 in. to 0.25-in. aperture. The term to be used depends on whether the energy is applied by impact or attrition or both.

The gravity stamp crushing by impact is probably used in 95 per cent of the cyanide plants of the world. In spite of its unquestioned disadvantages, it continues in favor. There is a tendency in American and Canadian practice to adopt the ball mill, and it is the authors' belief that few, if any, new stamp mills will be built on the American continent.

The economic limit of battery-screen aperture in modern plants is considered to lie between 0.15 to 0.4 in. This statement applies either to American and Mexican all-sliming practice, 70 per cent or more through 200-mesh, or to Rand practice, 95 per cent through 65-mesh.

Stamp mill practice has reached its highest development in South Africa. The Nissen single stamp has been received with some favor there, showing one-third greater capacity, per pound of falling weight, and an equal gain in efficiency over the ordinary gravity stamp. Of the six new mills built on the Rand since competitive trials were made, however, only one proposes to adopt the Nissen stamp. In modern Rand plants the

Stamp Milling Data

Plant	Tons Milled 24 Hr.	Number of Stamps	Running Weight	Discharge Aperture	Hp.-Hr. P. T. Milled	Stamping Cost, Cts. P. T. Milled	Sizing	
							% −100 (0.0055 In.)	% −200 (0.0029 In.)

Hollinger	585	60	1400	0.263	8.6	16.0	....	15.0
Porcupine Crown	150	20	1000	0.250	6.0	14.0	....	15.0
Liberty Bell	485	80	750	0.041	7.8	19.1	54.0	46.0

cost of stamping does not exceed 20 cents per ton; the average for the district in 1913 was 29.3 cents for thirty of the large plants.

Tube-mills have now been universally adopted for final grinding to a finished product. Classification for the elimination of finished material from the tube-mill discharge is a matter vital to the efficiency of the mill and has received close attention. Cone classifiers with diaphragms a few inches above the apex are preferred on the Rand where coarse grinding is employed. In America the Dorr, Akins, Ovoca and Esperanza classifiers are used, the tube-mills being in closed circuit.

Tube-Milling Data

Plant	Tons Milled 24 Hr.	No. Tubes	Dimensions of Tubes	Hp.-Hr. P. T. Milled	Cost P. T. Milled	Sizing Final Product	
						% −100 (0.0055 In.)	% −200 (0.0029 In.)
		6	5 ft. x 16 ft.				
Mexico Silver Mill	1000	6	5 ft. x 20 ft.	10.8	22.0	98.0	75.0
Nipissing	245	4	6 ft. x 20 ft.	44.6	50.0	100.0	100.0
Belmont	500	7	5 ft. x 18 ft.	16.8	40.9	99.0	72.3
Silver Peak	500	1	5 ft. x 18 ft.	2.4	2.6	64.0	50.0
		2	5 ft. x 14 ft.				
Homestake	4500	2	5 ft. x 18 ft.	0.5	1.2	87.0	66.0
Hollinger	585	6	5 ft. x 20 ft.	16.0	18.8	100.0	90.0
		1	5 ft. x 16 ft.

Liberty Bell	485	3	5 ft. x 22 ft.	4.3	7.7	87.0	73.4

The authors note that the efficiency of the closed circuit has been questioned, but add that the contentions against it are not borne out in practice. As to moisture in tube-mill feed, 38 to 40 per cent has been generally accepted, and is probably correct for mills discharging within 6 in. of the central axis; but for mills with peripheral discharge, higher moistures will be found advisable. The proportion of tube-mill capacity to stamp capacity has been increased, and costs have been lowered as more work has been thrown on the tube-mill. It is possible that ball and tube-mills in series may supplant the stamp. Various substitutes for pebbles are being investigated, such as hollow cast iron or steel balls, and special polyhedron shapes. The Marathon or rod mill also has been tested with favorable results. Tube-milling costs in the newer plants on the Rand are about equal to stamp-milling costs; 18 to 20 cents per ton milled.

The use of stamps, Chilean mills and tube mills for stage crushing and grinding at the Goldfield Consolidated is unusual, but productive of low cost of operation. Stamps weigh 1050 lb., crushing through 4-mesh screen; 6-ft. Chilean mills have 30-mesh screens; tube-mills are 5 ft. by 22 ft. Following are costs per ton milled:

	Stamps		Chilean Mills		Tube Mills	
Labor	$0.039		$0.018		$0.014	
Supplies	0.041		0.041		0.065	
Power (232 hp.)	0.054	(210 hp.)	0.047	(357 hp.)	0.087	
	$0.134		$0.106		$0.166	

Power consumed by stamps, Chilean mills and tube mills.....22.5 hp.-hr. per ton milled
Total combined cost for stamps, Chilean mills and tube mills..$0.406 per ton milled

Chilean mills are used at the Portland mill, Cripple Creek, for final grinding where a fine product is not required. Six-ft. Akron Chilean mills run at 36 to 41 r.p.m., using 2.5 to 3 tons of solution per ton of ore. Steel consumption per ton of ore ground is 0.797 lb. gross and 0.692 lb. net. Power consumption per ton of ore in coarse-crushing department is 1.86 hp.-hr. and in Chilean mills, 13.26 hp.-hr., or a total of 15.12 hp.-hr. Following are cost data.

	Coarse Crushing, per Ton	Chilean Mills, per Ton	Total, per Ton
Power (at 0.842c. hp.-hr.)	$0.0199	$0.1118	$0.1317
Labor (operation)	0.0318	0.0179	0.0497
Labor (repairs)	0.0103	0.0039	0.0142
Supplies	0.0284	0.0482	0.0766
Total	$0.0904	$0.1818	$0.2722

Dry crushing in ball mills is still retained at Kalgoorlie, the data for No. 5 and No. 8 mills, respectively, being as follows: Size, 7 ft. 6 in. in diameter by 3 ft. 10 in. long, and 8 ft. 10 in. by 4 ft. 6 in.; screen areas, 70 and 100 sq. ft.; speeds, 25 and 23 r.p.m.; power consumption, 25 and 60 hp.; capacities, 40 and 95 tons per day, the feed being about 2½ in. and the discharge through 28-mesh screen containing from 40 to 50 per cent minus 200-mesh; steel consumption per ton milled varies from 0.4 to 0.7 lb.; average cost of ball-milling, $0.50 per ton milled.

Wet crushing ball mills are coming into favor with excellent results. They run smoothly and are free from the noise produced by stamps. Recent tests on an 8-ft. Marcy mill showed that when operated in closed circuit on 4-in. maximum feed, the finished product may be kept under 48-mesh if desired. Steel consumption was 0.75 lb. per ton crushed, and power consumption about 12 hp.-hr. per ton.

Griffin mills and grinding pans, once widely used, are now rarely installed in new plants.

In the discussion of the paper Mr. Charles Butters predicted that steel balls would displace pebbles for tube milling, as they would permit the use of shorter tubes with smaller diameter, running at a higher speed, with a consequent reduction in first cost and in operating cost. One pound of steel balls is equivalent to three to five pounds of pebbles.

Solution of Gold and Silver.—In this paper by M. H. KURYLA, on the solubility of gold and silver in cyanide solutions and the methods of treating ores to effect the dissolution of those metals, the author covers an extensive subject in small compass. The paper is already so condensed that abstracting is difficult. An effort is made to give typical examples and costs of treatment from different parts of the world. On the chemical side it is pointed out that the classical equation of Elsner,

$$2Au + 4KCN + O + H_2O = 2KAu(CN)_2 + 2KOH,$$

so generally accepted as representing the final reaction, is inadequate as a guide to the consumption of cyanide in the treatment of complex ores. The equation calls for 1.51 units of gold or 0.83 units of silver per unit of KCN. This relation is closely approximated in the treatment of many silver ores, but with gold ores a consumption of 20 of KCN to 1 of gold is considered satisfactory and 40 to 1 is more common.

The strength of cyanide solution for silver ores will probably average 4 lb. KCN per ton, and for gold ores, 1.5 lb. Average chemical and mechanical loss of cyanide will average 2 lb. for silver and ¾ lb. for gold ores. Sand leaching plants have contacts of from four to seven days, while the time of contact for slime in gold ores is about 8 hr. and in silver ores 48 hr. Heating solutions has been of benefit in silver ores, increasing dissolution by an ounce or two at a cost of from 10 to 25 cents per ton.

Amalgamation is an important accessory process to cyanidation, particularly in recovery of such coarse gold as may retard or escape dissolution in cyanide. As practised at the average plant it costs between 5 and 10 cents per ton, and the plate area is about 2 sq. ft. per ton milled. On the Rand the plate area ranges from 0.25 to 2 sq. ft. per ton milled, and the mercury consumption about 0.1 oz. At the Homestake, with inside and outside amalgamation, the plate area is about 11 sq. ft. per ton milled, with a mercury loss of 0.13 oz.

Concentration is another accessory process, practised for (a) shipment of high-grade concentrates to smelters; (b) recovery of lower grade concentrates for local cyanidation; and (c) removal of concentrates for finer grinding and subsequent return to the mill pulp.

Wet desulphurizing is accomplished at the Nipissing mill by grinding a complex arsenic-antimony-silver ore in 0.25 per cent NaOH solution and tube-milling with aluminium ingots and agitated in tanks containing aluminium sheets. The cost amounts to 48 cents per ton.

The standard systems of cyanidation, in order of prevalence, are slime agitation, sand leaching and filter slime treatment.

For slime agitation the ore is first thickened to a dilution of 1.5. Thickening is done in various forms

The cost ranges from 5 to 15 cents per ton, averaging perhaps 10 cents. The following table gives condensed data on cyanidation of concentrates. The details of the processes have been given in the technical press.

Roasting is practised prior to cyanidation when the ore contains tellurium, arsenic or antimony, with which the gold may be intimately associated, either physically or chemically, the object being to liberate the gold for contact with cyanide. This is practised most extensively at Kalgoorlie, and to some extent on Cripple Creek telluride ores and on the graphitic ores of the Ashanti Goldfields. It is also practised on the concentrates at Goldfield, Nev. At Kalgoorlie the cost is about 65 cents per ton when using Merton or Edwards furnaces. Hearth area per ton of ore roasted in 24 hr. varies from 17 to 29 sq. ft. The cost of roasting Cripple Creek ore at the Portland mill in Holthoff and Pearce furnaces is 62.85 cents per ton. Chloridizing-roasting in the Holt-Dern furnace costs 51.5 cents per ton, including 35 cents for salt and 4.6 cents for coal dust.

of tanks, but the Dorr continuous thickener is favored. An average of 6 sq. ft. of settling area is allowed per ton of granular slime, and 10 to 15 ft. for flocculent material. Capacity may be greatly increased by the use of submerged trays in the same tank. Power requirement of a 30 ft. by 12 ft. Dorr thickener running at 1/5 r.p.m. is ¼ hp., and the operating cost about 1 cent per ton.

In agitation the trend is toward continuous operation. Four types of agitators are in use, one of which, the pump transfer system, is used mainly on the quick settling slime of the Rand. The other three systems are the mechanical, pneumatic and a combination of the two. The mechanical type has paddle-arm stirrers; the pneumatic uses compressed air in a central air-lift, as in the Brown or Pachuca; the combination uses both mechanical and pneumatic agitation, as in the Dorr.

The following figures on the cost of dissolution by slime agitation are merely numerical averages of compilations from representative plants in various parts of the world. The cost of dissolution includes thickening, agitating, proportionate pumping, supervision, cyanide, lime and lead salts.

	Cost of Dissolution	Cost of Filtration or Decantation Precip. and Refining	Total
Average gold ore	$0.29	$0.25	$0.54
Average silver ore	0.83	0.42	1.25

Sand leaching is practised most extensively on the Rand. Cost figures from 10 Rand plants in 1912, show the following averages:

Total cost of sand treatment per ton of sand (including classification, collecting, treating, precipitating, refining and residue disposal), ranging from 37 to 45 cents, average	39.8 cents
Average extraction on $3.17 sand heads	79.8%
Average extraction in recent sand plants	89.5%

At the Homestake the cost for sand leaching is 17.8 cents per ton; at the Pittsburgh Silver Peak, 23.5 cents. Itemized costs for the Rand and Homestake are:

Cost of Sand Treatment per Ton of Sand

Rand		Homestake	
Labor	6.54 cents	Superintendence	1.06 cents
Assaying, sampling	0.32	Assaying	0.48
Lime	0.56	Neutralization	1.54

Miscellaneous	0.59		
Total	40.94 cents	Total	17.78 cents

Direct treatment of slime in filters is practised at the Homestake and at the Pittsburgh Silver Peak. The cost at the former is 18.38 cents per ton and at the latter 26.3 cents.

In the discussion which followed, J. C. Clennel mentioned the bad effect of an oxidizing roast on silver extraction. C. W. Merrill cited a case in which after the roast a 15 per cent lower extraction was obtained than on raw ore. G. H. Clevenger mentioned the same effect was produced by natural surface oxidations of silver ores, also containing manganese dioxide. Charles Butters spoke of the importance of the dilution of pulp on silver extraction. He is now working on new problems of cyaniding flotation concentrates.

Filtration of Slime.—In this paper by L. D. Mills, all processes for separating and recovering valuable metal-bearing solution from slime are considered. This is one of the most vital points in cyanidation. The various methods considered are: Thickening, vacuum filtration, pressure filtration, continuous decantation and intermittent decantation.

The use of the Dorr continuous thickener has become almost universal. Discharges as low as 33 per cent and up to 60 per cent moisture can be obtained, varying with the nature of the slime. On the Rand, with colored labor at $0.75 or less per day and power at $5.50 per hp.-month, it is still found economical to retain intermittent settlers. The cost of thickening will vary from $0.005 to $0.02 per ton of ore milled, depending on local conditions and scale of operations.

Among vacuum filters, the author considers the Butters by far the most widely used. Others are the Moore, Oliver, Portland and Ridgeway. Average cost of operating Butters filters on the Rand is given as $0.065 per ton filtered. The caking effluent is worth $2 per ton, and the dissolved loss amounts to $0.05 or less. At the Goldfield Consolidated, the cost of operating a Butters filters is $0.05 per ton. Dissolved loss is $0.06. Other Butters operating costs are:

McNamara, Tonopah	150 tons silver,	$0.237 per ton filtered
Montana-Tonopah, Tonopah	146 tons silver,	0.230 per ton filtered
Loretto, Pachuca	700 tons silver,	0.07 per ton filtered
Flores, Guanajuato	160 tons silver,	0.06 per ton filtered
Dos Estrellos, El Oro	750 tons gold,	0.075 per ton filtered

A 1000-ton filter at the Victoria mill, Australia, has an operating cost of $0.0996 per ton filtered. The caking effluent averages $4.60 gold and 1.72 oz. silver, with dissolved loss at $0.048 gold and 0.02 oz. silver. Other Moore filter costs are:

Hollinger, Porcupine	600 tons gold,	$0.103 per ton filtered
Liberty Bell, Colorado	430 tons gold and silver,	0.099 per tonfiltered
La Blanca, Pachuca	300 tons silver,	0.105 per ton filtered
San Rafael, Pachuca	400 tons silver,	0.110 per ton filtered

Note.—These costs do not include royalty.

The Oliver and Portland are revolving-drum continuous filters. Operating cost of an Oliver filter at the Mexican mill on the Comstock is given as $0.072; dissolved loss, $0.09, largely in silver. At the Portland mill, the operating cost of Portland filters is $0.08 per ton filtered; dissolved loss, $0.07, mainly in gold.

Among pressure filters the author discusses the Dehne, Merrill, Kelly and Burt.

Dehne presses were used in the early days of cyaniding, particularly in Africa and Australia. They are adapted to treatment of granular or roasted slime; with amorphous slime the cakes must be thin and the washing is erratic. The average cost of operation in Australia may be taken as $0.25 per ton filtered, with $0.10 per ton additional for residue disposal.

The Merrill automatic sluicing filter press combines the washing efficiency of the plate-and-frame press with convenient wet discharge of cake. When the ore is comparatively granular the press is filled solid full; when amorphous material is present, it is advisable to fill the chambers not quite full. The capital cost of the filter is high, but it has an unusually high washing efficiency and low operating cost. At the Homestake the cost is $0.028 per ton, including labor, power and supplies.

The Kelly enclosed-leaf pressure filter shows an operating cost of $0.25 per ton at the 250-ton plant of the Tigre Mining Co., in Sonora.

The Burt revolving filter is restricted in use to granular slime. At El Oro operating cost was $0.049 per ton. The washing efficiency is stated to be 98 per cent.

Continuous counter-current decantation with Dorr thickeners is becoming a popular process, especially for small plants. The mechanical loss of cyanide is one of the factors that limits its use without filters. Actual operating cost is very low; at the Porcupine-Crown the cost of dissolution and counter-current washing approximates $0.30 per ton.

The author concludes that the handling of slime has reached a development where no further radical changes are to be expected. The mechanics of the various operations will be modified to suit special conditions, and there is always a possibility of reducing capital cost.

In the discussion which followed, Mr. Butters disagreed with the author's conclusion that no more radical changes in slime treatment may be expected. Mr. Butters anticipates that other forces than gravity may be

advantageously employed in the future for settling slime, such as electrical and centrifugal forces.

Precipitation of Cyanide Solutions.—The author of this paper, G. H. CLEVENGER, has gone thoroughly into the history and present status of the processes of precipitating precious metals from cyanide solutions.

CLASSIFICATION OF VARIOUS METHODS OF PRECIPITATION, USED AND PROPOSED

ELECTROLYTIC	(a) Iron anode; lead cathode; low current density; adherent deposit.			
	(b) Peroxidized lead anode; tin plate cathode; high current density; non-adherent deposit.			
	(c) Peroxidized lead anode; lead plate cathode; high current density; adherent deposit.			
	(d) Indirect electrolytic processes have only been investigated experimentally.			
CHEMICAL	Gaseous	Only example; possibly occluded gases in charcoal.		
	Liquid	Sodium sulphide (proposal for precipitating silver cuprous salts in acid solution).		
	Solid	Non-metallic	Charcoal	
		Metallic	Sodium	In form of amalgam, generally produced by electrolysis
			Aluminum	Shavings; Dust
			Zinc	Discs; Shavings; Dust

Electrolytic precipitation by the Siemens-Halske process was developed in South Africa to cope with low-grade solutions resulting from slime treatment. These solutions were not successfully precipitated on zinc. Later the introduction of the lead couple and a drip of strong solution made zinc precipitation satisfactory, and electrolytic precipitation declined and finally was abandoned. The latter process was used also by Charles Butters in San Salvador, Mexico and Nevada, but finally abandoned as zinc precipitation became better understood and improved. The following table gives the essential features of the electrolytic precipitation as practised in the past at various plants:

Process	Location	Number of Plants	Anode	Cathode	Current Density per Sq. Ft. Anode Amperes	Voltage	Metals in Solution	Remarks
Siemens-Halske	Rand, South Africa	20	Iron	Lead foil	0.03 to 0.06	4 to 8	Gold	Used alone
Butters-Andreoli	Minas Prietas, Mexico	1	Peroxidized lead	Tin plate	0.30 to 0.55		Silver, copper, gold	Used alone
Butters-Andreoli	San Sebastian, Salvador	1	Peroxidized lead	Lead plate	1.00 to 1.20	3 to 3.5	Copper, gold, zinc	Followed by zinc shavings
Butters-Andreoli	Virginia City, Nevada	1	Peroxidized lead	Aluminium plate	0.25	2.87	Silver, copper, gold, zinc	Followed by zinc shavings
Butters-Andreoli	El Rayo, Mexico	1	Peroxidized lead	Copper foil	1.20		Silver, copper, gold, zinc	Preceded by zinc dust

Charcoal precipitation is briefly discussed and the principles of aluminium precipitation are given. This latter process has been described in this journal, August, 1914, page 511.

COST OF ZINC SHAVING PRECIPITATION

Name of Plant	Type of Ore	Size of Compartments, In.	Cu. Ft. of Zinc per Ton of Solution Precipitated per 24 Hr.
San Rafael, Pachuca, Mexico	Silver-gold	33x33x30	
Loreto, Pachuca, Mexico	Silver-gold	36x48x30	0.75
Dos Estrellas, El Oro, Mexico	Silver-gold	30x30x24	0.65
El Oro Mining & Railway, El Oro, Mexico	Gold-silver	36x48x24	
Guanajuato Consolidated, Guanajuato, Mexico	Silver-gold	36x48x18	0.40
Guanajuato Reduction & Mines Co., Guanajuato, Mexico	Silver-gold	48x48x30	1.06
Divisadero, San Salvador, Central America	Silver-gold	24x36x18	0.54-0.81
Golden Cycle, Colorado Springs, U. S. A.	Gold	48x24x24	0.56
Tonopah Extension, Tonopah, Nev., U. S. A.	Silver-gold	30x34x26 36x34x30	0.93

Zinc precipitation is discussed under the heads of zinc shavings, wafers and dust. Numerous illustrations are given to show the manner of applying these methods, and considerable space is devoted to the preparation of zinc shavings. The Merrill zinc-dust process is described in detail.

Data on zinc-dust precipitation at the Homestake covering a period of one month are given as follows:

Plant	Heads	Tails	Pounds Zinc Dust per Ton of Solution	Cost of Precipitation per Ton of Ore Treated
No. 1 sand	$2.94	$0.018	0.173	$0.0123
No. 2 sand	2.77	0.034	0.174	0.0109
Slime	1.19	0.028	0.160	0.0165
Average on whole ore	1.87	0.026	0.165	

In refining, preliminary acid treatment of the precipitate has been found unnecessary in most cases where silver predominates, but is still adhered to in the majority of cases for gold precipitate.

The oil-fired tilting-crucible melting furnace has now largely replaced the earlier types of stationary-crucible furnaces, thus making the melting operation much less laborious, as well as considerably reducing its cost.

The Tavener method of refining, involving the melting of the precipitate in a small reverberatory furnace with various fluxes and lead, followed by cupellation, is still in general use in South Africa, but has not gained ground in this country.

The Homestake method of refining, involving acid treatment and briquetting with lead flux, followed by melting and cupellation in the ordinary English cupel furnace, as well as the treating of all the by-products in a small blast furnace, is used by a few American plants.

The melting of the precipitate, briquetted with the proper fluxes, in a small blast furnace, followed by cupellation of the lead, has been found of advantage when dealing with a large volume of low-grade gold precipitate. Losses from dusting, which might appear to be the chief objection to this method of melting, are claimed to be insignificant when a proper flux system is provided. This method of melting is more economical than either the Tavener or Homestake practice.

The most simple and satisfactory method of converting the high-grade precipitate which is obtained, by proper manipulation, from ores in which silver predominates is to melt the precipitate directly, with the minimum proportion of flux, in the tilting type of furnace.

In the discussion of this paper E. H. Simonds referred to the precipitation of low-strength cyanide solutions. He said there was no difficulty if both solution and zinc are perfectly clean. Mr. Butters said that aluminium dust is useful for silver solutions, but offers no advantage for gold.

Zinc

In the Friday afternoon session, in which E. B. BRADEN presided, the symposium on the metallurgy of zinc, arranged and edited by WALTER R. INGALLS, was first taken up.

Some main points in the economics of the metallurgy of zinc was the subject of a paper by WALTER R. INGALLS. The effect of the European war will be to produce even more radical changes in the zinc industry than were in progress when the war began.

The introduction of the Wilfley table in 1896 was an historic event in the zinc industry, for it made possible a better separation of the mixed ores requiring fine grinding. Another important step in the metallurgy of mixed ores was the introduction of the Wetherill system of magnetic concentration, followed by Blake's system of electrostatic concentration. The climax has been reached in the successful use of flotation at Broken Hill.

The development at Broken Hill had many important consequences: it standardized smelting practice in Belgium and Germany; compelled those smelters to go on a zinc-lead basis; showed that mixed ores could be profitable, and resulted in similar development elsewhere in the world.

During the last 50 years there have been three types of zinc smelting (the earlier English and Carinthian processes having disappeared), which are known as the Silesian, Belgo-Silesian, and Belgian. In recent years, the Belgo-Silesian method has become known as the Rhenish, and this has shown a strong tendency to displace the Belgian process in Belgium and an even stronger tendency to displace the Silesian process in Silesia. The reasons for this are discussed in the metallurgical treatises, of which zinc smelting has recently acquired a rich literature. They may be summarized as a superior economy, as compared with the Belgian furnace; and, in Silesia, a change in the character of the ore which causes this method to be better adapted than the Silesian furnace. In the United States, the method of smelting is essentially the Belgian, which has been modified to conform to peculiar conditions.

Another basic factor in the zinc industry which is causing radical change is the manufacture of sulphuric acid from the roasting of blende. This has long been practised in Europe, and is now coming into vogue in America. Every smelter of blende east of the Mississippi River is now making acid.

The author sketches briefly a comparison of European and American practice, and gives the economic reasons for the differences. The following figures are offered as broad generalizations to show the differences in the art as practised here and abroad. They mean that the Europeans, with the aid of better furnaces and superior technical direction, are able to smelt more refractory ores and yet extract a higher proportion of the valuable metals. Such economies as America has effected have been chiefly in the handling of material, which, in zinc smelting, is a relatively small part of the process.

"Per ton of raw sulphide ore, the American smelter uses about 2 to 2½ tons of coal and two or three man-days of labor; and extracts about 84 to 88 per cent of the zinc that is in his ore; if he treats lead-bearing ore, he may recover 50 to 60 per cent of the lead.

"The European smelter uses about 1¼ to 1¾ tons of coal and 3 to 3½ man-days of labor; and extracts 88 to 90 per cent of the zinc that is in his ore, and about 50 to 70 per cent of the lead."

The author concludes with a reference to certain misconceptions respecting the status of zinc smelting, as follows:

"The art of zinc smelting is far from being at a standstill. When we find 1000 kg. of ore requiring 1000 calories of heat being distilled with 1100 kg. of coal equivalent to 8000 calories, as is done in the best practice, we are observing a thermal efficiency of 12½ per cent, which compares favorably with good steam practice. When we find a ton of ore being smelted with 2½ man-days of labor, and consider that we are dealing with a concentrated product, and reflect that the total weight of material handled is relatively small and that the work on it from step to step is often more cheaply done by a man than by a machine, we do not feel unduly mortified by our results. Nor does the extraction of only 85 or 90 per cent of the zinc content of the ore shame us very much when we reflect upon the peculiar and troublesome metallurgical properties of zinc.

"Electric zinc smelting, which has engaged a good deal of attention during the last fifteen years, is metallurgically of the same nature as ordinary smelting; the main difference is that, in one case, the zinc is distilled by the heat of the elecric arc or the heat of electric resistance; while, in the other case, it is done by the combustion of coal. So far, electric smelting has become an art only in Sweden and Norway, where several thousands of tons of spelter are annually produced by this method. The smelters in Sweden and Norway enjoy very cheap power, whereby they have been able to overcome, or at least meet, the main obstacle that has heretofore prevented electric smelting from becoming a commercial art elsewhere."

Development of Zinc Smelting in the United States.—In this paper GEORGE C. STONE directs attention to the tremendous increase in spelter production during the last thirty years, and the fact that more than half of it has been the output of the United States. The first spelter produced in this country was made by the government in 1838 from ore from Franklin Furnace, N. J., and was used for making brass for standard weights and measures. The first serious attempt to make spelter in America was by Joseph Wharton, in Bethlehem, using oxidized ores from Friedensville. In 1856 or 1857 he employed Matthiessen and Hegeler to build a furnace. This was tried and abandoned. In 1859 Colonel Wetherill, of zinc oxide fame, built a spelter furnace that was not successful. Finally, in 1859, according to some reports, and in 1862, according to others, Wharton brought to this country Louis de Gée, an engineer from Liege, who built and operated a plant that, with some interruptions, continued to make spelter until 1911. In the meantime Matthiessen and Hegeler had built a works at La Salle, Ill., in 1858, and were operating successfully when the Civil War broke out. The plant was closed for a time, but opened again when the demand for spelter arose in 1862-3. The credit, therefore, for having first produced spelter on a commercial scale in this country belongs to Matthiessen and Hegeler.

The author traces the development of zinc smelting in different parts of the country, briefly describing the plants and their products. Matthiessen and Hegeler patented their spelter furnace in 1879, and it has been widely used since that time. In 1884 Hegeler patented his roasting furnace which is now used with modifications by every smelter in the country that makes acid. In addition to these important inventions, these metallurgists made many minor improvements in zinc smelting which have since been generally adopted.

The first zinc rolling mill was built by Matthiessen and Hegeler at La Salle in 1868, and has remained in operation ever since.

An entirely new process for making zinc oxide from ore was patented in the early '50s, and three patents were taken out in 1855 by Jones, Burrows and Wetherill, on almost identical lines. Burrows was employed at the Passaic Chemical Works. He states that "one night the flue from one of the furnaces that he was attending leaked, and he covered the hole with a piece of grate bar, throwing a shovelful of refuse on it. The refuse proved to be a mixture of coal and zinc ore, and the heat of the flue being sufficient to light it, Burrows soon noticed a cloud of zinc oxide coming off. He built a small furnace and repeated the experiment, and when he found that it worked again, showed it to the officers

of the New Jersey Zinc Company, among whom were Wetherill and Jones. The grate bars used were what are now usually called 'Wetherill grates,' but were in common use for boiler firing at that time in the vicinity of Newark, where they were made by Renton, who had a machine shop and foundry. Colonel Wetherill frequently stated that he had nothing to do with the invention of these grates, but his name has been persistently attached to them.

Colonel Wetherill proposed to Burrows that they work up an invention together, as Burrows had not the money to do so alone, but the proposition was declined, and each went ahead on his own account. The result was that three people applied for and obtained patents for substantially the same thing in the same year. Wetherill also took out patents for improvements in 1855-6-7-9 and two in 1868. The New Jersey Zinc Company acquired the patents of Jones and Burrows, but could not agree on terms with Wetherill. The latter shortly afterward sold a license to use his process to the Passaic Zinc Company. Both the New Jersey and the Passaic companies put the process in operation, as it proved to be a great improvement on those previously used. Everything went quietly until the Wetherill patent had nearly expired, when he brought suit against the New Jersey Zinc Company for infringement and accumulated profits. The suit that followed was long and hotly fought on both sides. The final decision of the court was that the furnace was Burrows' invention and the process Wetherill's and that half the profits were due to each. As the Zinc Company owned the Burrows' patent, it was obliged to pay half the increased profit due to the use of the invention, to Wetherill. The decision seems a very fair one, as while the original idea appears to have been Burrows', he had not sufficient knowledge or skill to develop it and make a working process of it."

The method of collecting oxide in bags was invented by S. T. Jones of New York in 1852 and is now universally used, not only for zinc oxide but other smelter products.

On the development of magnetic separation, the author says:

"About 1890, Messrs. J. P. Wetherill and G. G. Convers of the Lehigh Zinc & Iron Company, again attempted the separation, and this time with complete success. Their first method was to heat the ore to a very moderate temperature and separate on Wenstrom machines. This was patented by Mr. Convers, Dec. 20, 1892. They were not entirely satisfied with this method and continued their experiments, which resulted in the discovery, by Mr. Wetherill, of a new principle in magnetic separation—that of producing a highly concentrated field by using pointed pole pieces. Mr. Wetherill took out three patents on March 3, 1896, for the general principle, for the application of it to ores containing franklinite, and for the machine. A mill was built, and the willemite separated was used for the manufacture of spelter, and the franklinite for oxide, with a considerable increase in profits. Experiments were continued, and Sept. 28, 1897, Mr. L. G. Rowand patented an improvement in the machines, and March 7, 1905, another, which greatly increased the efficiency and has entirely displaced the earlier types in this country. In the earlier machines, both poles of the magnet were on the same side of the feed belt, with the result that less than half of the field was operative and the strongest part of it did no work. In Mr. Rowand's improvement, one pole is placed above the belt and one below; the former is pointed, the latter blunt. The entire field is thus available and the maximum possible lifting effect is utilized."

In 1901 the Blake-Morscher electrostatic process was patented. This and later patents were acquired by the American Zinc, Lead & Smelting Co., who also bought certain patents of P. H. Wynne and Millard Woodsome, both of which had been assigned to Charles H. Huff. These are the basis of the Huff process which is now used on suitable ores.

The successful application of flotation at Butte & Superior is the latest development in concentration of zinc ores.

Among new processes for treating zinc ores, the author notes hydrometallurgical methods using acids, chlorine and ammonia. None of these has come into commercial use, but a vast amount of experimenting has been done. Some work also has been done on electrolytic precipitation but without success, and the author is of the opinion that it is doubtful whether the method will ever be a commercial success. Electrothermic smelting also has received attention, notably by Woolsey McA. Johnson, who has made greater progress than any one else. The drawbacks to success are high power costs and difficulties in condensation. For ores containing metals other than zinc, the electric furnace may prove advantageous, but is not likely to become a competitor of coal or gas smelting purely for the production of spelter. The paper is concluded with tables and diagrams showing the production of spelter in the United States and the world.

In the discussion which followed, G. H. Clevenger thought that the author underestimated the importance of hydrometallurgy and electrolytic zinc refining. This is bound to become important at some places and interesting experiments are under way at Bully Hill, Palo Alto, Anaconda, Murray, Utah, and Trail, B. C. E. B. Braden said electrolytic zinc received at Selby was 99.7 per cent pure. L. H. Duschak emphasized that the power cost was not the controlling factor in electrolytic zinc production. S. E. Bretherton gave the cost as 1 cent per lb. with power at $36 per horsepower-year and as one-half cent at $17 per horsepower-year.

Lead

The Smelting and Refining of Lead.—A review of the present status of lead smelting in the United States, by Dr. H. O. Hofman of Massachusetts Institute of Technology, begins with the introduction of blast-roasting, which has revolutionized the details of practice. The use of this process has greatly increased blast-furnace capacity, and has modified the design of blast furnaces. Blast pressure has been reduced, and slags of higher silica content are produced. Coke consumption has been diminished. The following table gives a comparison of the work of the Huntington-Heberlein and the Dwight-Lloyd methods of blast-roasting at two different plants.

Item	At Murray	At East Helena
	Advantage Lies in Favor of	
Cost of installation	D. & L.	D. & L.
Cost of roasting	H. & H.	Even
Adaptability to charge	D. & L.	D. & L.
Metal loss	Even	Even
Physical condition of product	H. & H.	D. & L.

Lead bullion is desilverized by the Parkes process, excepting at Grasselli, Ind., and Trail, B. C., where the Betts electrolytic process is used.

"An important innovation with the Parkes process is supplementary treatment at Omaha, Neb., and East Chicago, Ind., of the refined lead by the Pattinson process in order to obtain from bismuth-bearing lead

bullion, as market product, corroding lead with less than 0.05 per cent bismuth. At Omaha metallic bismuth is produced; the bismuth content of lead bullion treated at East Chicago is not sufficiently high to warrant going so far.

"The treatment of blast-furnace matte has undergone some radical changes. Formerly this intermediary product was thoroughly roasted in different kinds of reverberatory furnaces, and added to the blast-furnace charges until its copper content had been enriched to about 14 per cent. The smelting of this pulverulent roasted product caused much trouble, as it separated from the siliceous part of the charge and disturbed the work of the furnace. All this has been obviated by rough-roasting the matte and then blast-roasting it either with siliceous ores or with the other ores that are to be used for making up the blast-furnace charge. The further treatment of 14 per cent copper matte is now carried on in basic converters. The older method, worked out at Maurer, N. J., is to treat lead-copper-iron matte in the same manner as copper-iron matte; i. e., with the additions of siliceous ores. A charge of matte and ore is blown until the ore has been scorified, the slag is poured off, and a second charge of matte followed by ore is given and blown; the operations are continued until the copper in the matte has been brought forward to furnish white metal, which is now blown to blister copper. A departure from the standard method of treatment has been made at the smeltery of the International Smelting Co., Tooele, Utah. Here the lead-copper-iron matte is blown without the addition of siliceous ore until practically all the lead and zinc have been volatilized to be collected in a baghouse. During the blow the iron is oxidized and a large part of the copper; the mixture is transferred to a basic copper-iron matte-converter working in the usual way with siliceous ore, the oxidized iron is scorified and the oxidized copper sulphurized. The result is that the lead blast-furnace has to treat only the lead fume of the baghouse instead of a large amount of lead-iron slag. The results of the modification have been most satisfactory.

"Very little speiss is produced in blast furnaces treating ores; some refineries, especially if they are unfortunate enough, at least from a metallurgical point of view, to have to treat arsenical silver ore from Cobalt, Ont., can not help but make speiss. There is no well established method of treating the unwelcome intermediary product. Blast-roasting has been successful in an experimental way; converting alone in a basic vessel has been a failure; converting with copper iron matte a success.

"The amount of flue dust formed in blast-furnace work has been greatly reduced. In spite of this, competition and the complaints of agricultural and other interests surrounding smelteries have forced these to make every endeavor to prevent fume and dust from passing off into the open. Thus most lead plants of any size are provided with baghouses, even when the pecuniary return they furnish is smaller than the outgo for cost, maintenance and operation. Much attention has been given to the filtration of fumes and dust. It has called attention to the important relation existing between the assay values of filtered fume and dust and the lead-silver content of matte and slag. In earlier times low values in matte and slag formed the criterion of good work; the baghouse has shown that very low assays of matte and slag are usually accompanied by high values of fume and dust; over-reduction caused volatilization. At present a balance is kept between the two.

"The Cottrell system of electric precipitation of fume has been installed at Garfield, Utah, for the collection of lead-bearing fume of copper-iron matte converters after it had been carefully tested on a working scale with a single unit. Experiments with blast roaster and blast-furnace gases have given results which show a satisfactory clearance of the gases from finely divided materials. At Trail, B. C., electric condensation is in operation."

In the discussion of this paper, E. B. Braden mentioned the tendency toward furnace shafts 19 ft. high and referred to a reduction by 50 per cent of the quantity of flue dust, due to sintering, at Selby.

Ore Dressing

Prof. Robert H. Richards' paper on ore dressing was an interesting historical sketch of the advancement of the art from primitive methods to modern times, reviewing the development of tables and jigs, pneumatic, electromagnetic, and electrostatic separation, and finally flotation.

Fuels in Metallurgy

The symposium on the utilization of fuels in metallurgy had been arranged and edited by Prof. C. H. Fulton.

Burning pulverized coal in reverberatory furnaces was discussed in two papers. In the first, by D. H. Browne, the author gives certain data regarding the work at the Canadian Copper Co. The first furnace equipped for coal-dust firing was 112 ft. long by 19 ft. wide, with an extreme inside height of 6 ft. The bottom was an inverted arch of magnesite brick.

The coal was ground to 200-mesh and blown into the furnaces through five nozzles, into which it was conveyed by screws. Early operations showed that furnaces designed along the lines of grate-fired reverberatories were not adapted to the new practice. The roof required frequent repairs on account of the excessive heat. The magnesite bottom was replaced with silica, and the roof was raised to give a combustion space 6 ft. 3 in. high above the skimming line. The manner of charging was changed, the ore being introduced along the sides of the furnace. These changes resulted in increased ratio of charge to fuel. Thus during the first three months of 1914 the monthly average of tons of charge smelted per ton of fuel was 5.0, 5.65 and 6.77.

In the paper by E. P. Mathewson, Anaconda practice is briefly described. Two points are essential for the success of coal-dust firing: the coal must be dry, containing less than 1 per cent moisture before pulverization, and the grinding must be carried to a very fine point. Preferably, 95 per cent should pass a 100-mesh screen, and 75 per cent through 200-mesh. The flame is as easy to handle as gas. About 50 per cent of the ash is absorbed by the charge and the balance caugh in the flue connection to the waste-heat boiler. With the use of coal-dust firing and side-wall charging, it is no longer necessary to stop the furnace for fettling, and in the larger furnaces the flow of slag can be continuous as in copper blast furnaces.

Gas producer development is discussed in a paper by Z. C. Kline. The author finds the gas producer growing in popularity as natural gas becomes scarcer and oil more expensive. Development has been toward mechanically operated producers and toward designs for gasifying bituminous coal and fixing the tarry constituents. Mechanically operated producers are more expensive to install, but labor cost is reduced, capacity increased and more uniform gas produced. The gas-producer industry suffered somewhat from installa-

tions that did not come up to expectations, but the earlier difficulties have been simplified, and many plants are now working satisfactorily.

The trend of gas producer operation will probably be toward the perfection of mechanical types and more experiments toward simplifying and cheapening the methods of obtaining clean producer gas, and, no doubt, a great deal more attention will be paid to the operation of the producers already installed, especially along lines of labor and technical efficiencies. A great many firms now have appliances for checking up quality of gas, amount of coal used, and temperature control. At last, manufacturers are realizing that a gas producer cannot be run efficiently without competent men.

Surface combustion is reviewed in a paper by Prof. C. E. Lucke, the inventor and original patentee of the process. When air is perfectly mixed with gaseous fuel, in chemically combining proportions, the products of combustion are free from both fuel and oxygen. The mixture burns at the maximum possible rate because of the absence of flame volume and regardless of the nature of the surrounding atmosphere. For the commercial applicability of the combustion of such explosive mixtures, a definite localization of combustion zones is necessary, and means must be provided to prevent "back flash" and "blow off" due, respectively, to inferior and excessive flow velocity as compared with that of flame propagation. Back heating from the combustion zone along the walls of the feed passages to the mixture supply point, must also be prevented, either through thermal resistance or cooling by circulation of air around the passages. Perfect cooling prevents "back flash" regardless of flow velocity; with imperfect cooling it is prevented by a drop in pressure through supply exits varying from 0.1 in. water column to larger values, according to the size of the passages and burning rates of the mixtures.

"Excess exit velocity from the passages, which is normally necessary to prevent back flash, must be promptly reduced to prevent blow off, by spreading the mixture stream just beyond exit from the passages by baffles of solid refractory surfaces or by porous beds such as layers of granular refractory material, loose or bonded. These refractory spreaders become incandescent, permanent fire beds, converting a maximum of the heat generated into the radiant form, and they incidentally act also as accelerators of the combustion reaction.

"Accordingly the combustion zone may, it has been found, be definitely and permanently localized by utilizing the properties of the explosive mixtures themselves, and as a result there is now available for commercial application a new method or system of gas combustion, characterized by maximum possible rate of combustion, by maximum possible temperature of gases, because of minimum weight of products per pound of fuel, and by products containing normally no free oxygen and no unburned fuel, though by adjustment of proportions the products may be made either oxidizing or reducing."

Experiments on Sewer Pipe and Drain is the subject of Bulletin No. 7 of the Utah Engineering Experiment Station, Salt Lake City. The author is Prof. E. H. Beckstrand. Pipes were tested under all sorts of stresses, internal and external, and very complete information is given.

The **Brown Instrument Company**, Philadelphia, Pa., has just let a contract for an addition which will furnish nearly 50 per cent additional floor space. The factory, which a year ago seemed sufficiently large, has been outgrown, due to the large demand for Brown pyrometers for high-temperature control.

Opportunities for the American Chemical Industry*

BY EDWARD EWING PRATT

Chief Bureau of Foreign and Domestic Commerce, Department of Commerce, Washington, D. C.

The Department of Commerce is deeply interested in the chemical industry and aims to facilitate its development in every way. The department realizes that no other branch of American industrial activity has been forced to deal so swiftly and effectively with a great variety of extremely difficult problems. The chemical industry of the United States along with other industries found a very serious situation at the outbreak of the European war, and the last year has been a period of readjustment and reorganization.

The National Exposition of American Chemical Industries is significant because it illustrates the fact that American chemists and American chemical manufacturers have, through their own inventive skill, their own talent for organization, and their own thorough knowledge, been able to accomplish a great deal during the last twelve months. It can be fairly said that at the present time the American chemical industry is well established and that American firms need no longer be dependent for chemicals upon any foreign country. This is a tremendous accomplishment and it is extremely significant in the development of American industries.

The effects of the great European war have been noteworthy in our American industrial life. On the whole, they have been of a twofold nature; there are direct, visible results, essentially of a transitory nature and destined to disappear with the approach of peace. There are other results less evident to the eye but increasing with every added day of the conflict and bound to be of far-reaching import in the development of our industries.

Among the more important temporary effects of the war are those which have to do with the furnishing of supplies for the various belligerent activities in Europe. We are furnishing not only large quantities of foodstuffs and live stock, but considerable quantities of shoes, wearing apparel, saddlery, motor trucks, railway supplies, iron and steel in all kinds of shapes and forms; lead, zinc and copper; fire-arms and ammunition. For the time being these specialties are stimulating considerable activity in our industrial plants. Whether it is an altogether healthy activity, and whether it will not lead to serious economic consequences is a question. In so far as our manufacturers count on this activity as definite increases in their business and as a permanent increase in production, so far will they be unprepared for the cutting off of this activity at the end of the period of hostilities.

A review of the chief industries ministering particularly to the temporary needs of the belligerents across the Atlantic shows clearly the final outcome will be a very material addition. Part of this plant will be simply anticipatory of the normal growth of the company's mechanical equipment. Part must lie idle in time of peace, but is a distinct asset in the national preparedness for an adequate defense against attack. The remainder furnishes at once products needed in the healthful expansion of our industries, and particularly of the chemical industry.

Less conspicuous and spectacular, but of far greater permanent value, is the impulse given to the manufacture on American soil with American raw materials of a variety of articles for which we have heretofore been dependent upon foreign skill and enterprise. In a more

---

* An address made before the First National Exposition of Chemical Industries at New York City on Sept. 25, 1915, slightly abstracted.

or less uncomfortable way we have suddenly been brought to recognize the folly of shipping vast amounts of crude material of our farms, forests and mines 3000 miles across the ocean and buying it back in a manufactured form at a vastly enhanced price. We have likewise come to recognize the absurdity of allowing many natural products of the tropics, of South America, of the Far East, to find their way to Europe and of paying foreign intelligence and skill to transform them into articles of daily need in our lives.

The complete cessation of imports from Germany and Austria and the serious restriction in our purchases from many other countries have taught us these two lessons. It is in the practical application of these lessons that the American people will derive their fullest benefit from this otherwise so deplorable world conflict. American skill, ingenuity, adaptability, inventive talent, scientific attainment and general enterprise have promptly rallied to meet widespread demands to establish on our own soil the permanent manufacture of a number of wares, some of minor, others of major importance. The return of peace will see them well rooted and able to withstand foreign competition.

There are a number of industries which might be cited where we have heretofore been dependent upon Europe and have since the outbreak of the war begun to manufacture for ourselves—the curved faces of our clocks and watches, fine brushes for water-color use, chloride and carbonate from domestic barium minerals, chemical porcelain and optical glass are cases in point.

Prior to the war we imported from Europe, chiefly from Germany, coal-tar dyes valued annually at nearly $10,000,000. Our vast textile interests, the great industries producing paper, ink, varnish, pigments, etc., were dependent upon these importations for the element of color in their wares. To every tailor, to every milliner, in fact, to every consumer of colored articles, it has been a matter of vital necessity that there should be no interruption of the regular arrival of the hundreds of varying hues produced upon the banks of the Rhine from prosaic coal tar.

There was a limited production of these artificial dyestuffs in the United States. Unfortunately the domestic production has been dependent hitherto upon Europe, and again chiefly Germany, for its raw materials, the semi-manufactured so-called intermediates, such as aniline, salicylic acid, etc.

The supplies of intermediates ceased with the outbreak of the war. The importations of finished dyes from Germany were intermittent and finally stopped altogether in March of the present year. Conditions threatened to paralyze the activities of our textile interests and of allied industries. There has been a certain amount of displacement in the mechanism of production, unavoidable under the circumstances, as the available stores of artificial dyes steadily disappeared from the storerooms of textile and other mills.

Thus far the disaster has been less serious than we feared it might be four months ago. Forced to make material changes in designs and in processes with more or less incidental losses, there is little doubt but that the sum total of the losses borne by American industries during the year 1915 in consequence of the cessation of the importations of foreign coal-tar dyes will far exceed the amount of capital needed to establish upon our own soil a complete self-contained American coal-tar dyestuff industry, using exclusively American crude materials and meeting adequately all the nation's needs for artificial colors.

In this connection the users of dyestuffs in this country should have the co-operation of every consumer. Up to the present time manufacturers have been using the stores of dyes which were left on hand or which have been meagerly supplied since the opening of the great war in Europe. Before our own industry can produce the necessary amount of dyestuffs there will be a certain hiatus during which it will be impossible to get the same kind of colors and the same qualities and shades of colors as has been possible heretofore. Garment wearers—men. women and children—will have to be content with plainer and more prosaic standard colors. Consumers will have to forego the use of the more intense and delicate colors which were obtainable from the various coal-tar products. This applies not only to outer garments, but to shirts, women's waists, neckties, hosiery and underwear. In fact, to everything in which dyes are used for the production of fine colors in the daily wear of people.

It therefore behooves the people of this country to be considerate, and if only plain colors are obtainable, or if colors are used which do not stand the test of exposure to weather and climate, not to blame the manufacturer of the garment or the manufacturer of the colors.

American industry, however, has taken hold of this problem in a particularly rapid and satisfactory manner. Each week witnesses the addition of new firms engaged in solving the problem of a domestic supply of coal-tar colors either by furnishing crudes or intermediates for finished dyes. Increasingly large amounts of capital are being devoted to this new industry, and there is an intelligent awakening of both capital and enterprise to the opportunity offered for establishing a fairly complete coal-tar chemical industry on American soil.

One of the especially interesting features of this exposition is that of a pioneer company in Buffalo, which has been able to prove that the United States can create a complete comprehensive and self-contained coal-tar chemical industry, fully capable of meeting the demands of the great textile industry and the scores of allied interests in which these colors are of vital importance. In fact, American chemists have concentrated their efforts upon the solution of the dyestuff problem, and, noting the creative ability which is being applied to these problems, I am sure that a solution will be reached.

The United States has also been dependent upon Europe for its supplies of potash. These supplies have been used exclusively for fertilizers which are especially needed in the cotton plantations of the South and are indispensable to the crystal products of our glass works. The United States has been content to receive its supplies from Europe. These supplies were suddenly cut off. Under these conditions the American manufacturer has turned to the resources of his own country and has been able to arrive at a practical solution of this very difficult question, for a method has been discovered by which the tons of kelp on our Pacific coast can be utilized as a means for securing potash supplies. It is therefore with peculiar satisfaction that I have learned from the official of the Bureau of Foreign and Domestic Commerce who has been in charge of the investigation in this field that several processes of real economic promise have been discovered, and there is no doubt that the securing of potash from the kelp fields of the Pacific will soon be established upon a broad industrial basis.

It would be scarcely in accord with the usual development of industry to recommend that we should slavishly imitate the example of any foreign country. It is worth while, however, to consider the methods and success of Germany in developing her chemical industry. In 1860 the chemical industry of the world was developed to its highest extent in England, with France a close second.

It was not until about 1875 that Germany began to show great activity in this industry. Her development, however, was as rapid as it was unforeseen, and in the face of serious obstacles. Even for many years after this date Germany had to rely upon imports for many of the principal staple materials required by the chemical industry, such as soda ash, bleach, coal tar, ammonia compounds, etc., from other countries, especially England. Even as late as 1879 Germany's imports of soda amounted to 24,000 tons, which constituted the entire consumption for that year. In 1910 the imports of soda had fallen to 154 tons, while the exports had amounted from zero to 62,500 tons, representing the excess of production over consumption.

Similar instances illustrating the growth of the German chemical industry can be quoted in any number. Not only did England and France have the start of Germany in the matter of raw materials, but those countries also to a considerable extent had a corner on the market for technical skill which was required in the development of the chemical industry. In spite of these handicaps, Germany went forward to such a point that before the opening of the European war she controlled many branches of the chemical industry and other countries of the world went to her for their supplies. This is particularly true of the coal-tar industry and the manufacture of synthetic dyes.

Chemistry has truly been called "The Intelligence Department of Industry," and it is therefore peculiarly important that we should develop a chemical industry in the United States. It is not merely a matter of a single industry or the matter of attaining increased efficiency or a wider variety of products in one industry, but applied chemistry is largely the successful utilization of by-products and, therefore, the development of a chemical industry in the United States means increased efficiency and increased economy in every industry in this country.

It is also pertinent to point out that perhaps the fundamental reason for the peculiar success of the German chemical industry has been the willingness to devote years and years of effort, of careful scientific experimentation to the development of a process or a new product. It is this long-time investment for the future, the idea of unceasing experimentation, that American industry must learn.

The progressive development of industry—this is particularly true of the chemical industry—parallels the development of science and knowledge. The nations whose natural products are the most intense and the best utilized are also those which attain industrial supremacy.

The United States should be independent of all foreign sources for all its chemicals, for the United States has within its own boundaries the raw materials for the production of such chemicals. This exposition tonight illustrates the fact that chemical manufacturers are alive to the possibilities of the present situation. It shows, too, that the national government is earnestly seeking to encourage and facilitate the growth of the nation's chemical industry. The Bureau of Foreign and Domestic Commerce, which has had such an active share in this exposition and through the work of its own commercial agent is attempting to solve some of the difficulties which have confronted some of our chemical industries, feels that the chemical manufacturers of the United States are opening up a new epoch in American industry, and that as a result of the transformation which is taking place the United States will not only be a producer of its own chemical needs, but that the United States will undoubtedly secure a large share in the chemical markets abroad.

Accident Prevention in the Chemical Industries*

BY FREDERIC W. KEOUGH
National Association of Manufacturers

A recent bulletin of the Bureau of Labor Statistics of the U. S. Department of Labor, presents an estimate that 25,000 fatal industrial accidents occur annually among American wage earners and approximately 700,000 accidents occur which involve a disability of more than four weeks' duration. The industries which contribute to the greatest number of fatal accidents are railroad and agricultural work, each causing about 4200 fatalities per year. Coal mining causes more than 2600; building and construction work only 1900, and general manufacturing about 1800.

In an effort to get some statistics on accidents and accident prevention in the chemical industries, I wrote to some sixty concerns and to my first letter received only three acknowledgements of any sort. A second letter to the same parties brought little more in the way of results. From this one might assume that chemical establishments are not interested in accident prevention. There is, however, excellent testimony from a few sources to the contrary. It may be concluded, nevertheless, that there are no particular hazards in the chemical industries, other than those of running machinery. Pains should therefore be taken to educate workmen when engaged on special jobs and proper remedies should be near at hand in case an accident should occur. For instance, as a special aid soda ash should be stored in convenient places in case of breakage of acid carboys or similar injuries to the men. A first-aid department should be installed to treat minor injuries, and if the size of the plant justifies, a physician should be on the house staff. For emergency use there is nothing better than the N. A. S. O. jar—N. A. S. O. meaning National Affiliated Safety Organizations, namely the National Founders Association, National Association of Manufacturers, National Metal Trades Association, and National Electric Light Association.

This jar was developed to meet all requirements of a compact, convenient, sanitary-first-aid outfit. It is structurally strong and its arrangement allows quick removal of any article without disturbing the rest. It includes every material which a large conference of physicians with an extensive experience in the treatment of injuries, agreed upon as necessary for effective first-aid treatment by laymen. The jar is especially useful as it can be transported readily from place to place. Some employers, in fact, place a jar on every truck or wagon used in connection with outside work. The jar, like the standardized safety goggles, foundry leggings and shoes, is sold at cost price as there is no intention to make a profit on the devices.

First aid, in order to result in the decrease of accidents and in the prevention of serious consequences following slight injuries, is dependent upon three factors, namely:

(1) Properly equipped and properly managed emergency rooms with competent first-aid man in charge in the smaller works; in the larger works, attendant physician and nurses are requisite.

(2) The intelligent and willing co-operation of every workman in the prevention of accidents. All workmen should familiarize themselves with, and put into practice, the company's rules requiring the immediate reporting to the emergency room of all injuries for treatment.

*An address delivered at the National Exposition of Chemical Industries at the Grand Central Palace, New York City, Sept. 22, 1915.

(3) The instructions of every man at the works to see that proper attention is given to his injuries in order to prevent their becoming serious. This may be accomplished by the organization of first-aid squads which, of course, should be properly instructed by the physician in charge in all the elements of emergency practice. One of these squads should be organized in each department, and it will be of decided advantage to arrange for a similar rotation of service as is operative in the work committees.

The timely treatment of injuries will always result in a rapid cure and consequently in a reduction of expenses.

Chemical companies, let us believe, are interested in accident prevention in a general way even though they have few recommendations of ways and means especially adaptable to their industry. It is a source of great satisfaction to learn that the safety department of *American Industries*, the magazine of the National Association of Manufacturers, has enjoyed the appreciation of the chemical industry. In the promotion of safety work we have issued a four-page supplement for the last three years, devoting each issue to some particular topic and showing in colored illustrations, innumerable devices that may be made in any shop.

As to causes of accidents in the group comprising manufacture of paints, oils, etc., an indication as to the principal sources is found in a bulletin of the New York State Department of Labor for 1912 and 1913, which shows in 2642 cases, 575 accidents caused by fall or weight of objects; 508 by miscellaneous accidents; 449 through heat or electricity; 341 by falls; 292 by working machinery; 168 by hand tools; 136 by conveying and hoisting machinery and 86 by power transmission.

The accidents directly related to the manufacture of chemicals are largely occupational diseases or burns from acids or poison by some mineral. Especially dangerous minerals are lead, arsenic, mercury and phosphorus. In addition we have the danger of acids which corrode the skin and act as caustic and in vaporous state attack teeth. Wood alcohol produces blindness if taken internally or even if breathed in large quantities; and gases such as carbon monoxide, methane or marsh gas are deadly. In fact, all of the hydrocarbons are more or less poisonous. One of the ever-present dangers is that if there is any corrosion of the skin or any skin disease which may arise from certain products, such as varnish, other diseases are engrafted on it. The principal thing is cleanliness of the hands, so wash basins are necessary and many times gloves. Some of the anilines are also poisonous. Dust is also a factor in the manufacture of some chemicals. There is danger in many lines of explosion, particularly now in the rapid manufacture of so much powder and high explosives. The principal lines of prevention are dust hoods, washing, etc.

The list of industrial poisons is a long one and since they attack from so many points, they must be studied closely. Here is the list that is entitled to special attention: Acetaldehyde ethylaldehyde, acridine, acrolein, ammonia, amylacetate, amylalcohol, aniline, aniline dyestuffs, antimony compounds, arsenic compounds, arseniureted hydrogen, benzine, benzol, carbon dioxide, carbon disulphide, carbon monoxide, chloride or lime, chlorine, chlorodinitro-benzol, chloronitrobenzol, chromium compounds, cyanogen compounds, diazomethane, dimethyl sulphate, dinitrobenzol or binitrobenzol, formaldehyde, hydrochloric acid, hydrofluoric acid, lead, manganese dioxide, mercury, methyl alcohol, methyl bromide nitraniline, nitrobenzol, nitroglycerin, nitronaphthalene, nitrous gases, oxalic acid, petroleum, phenol, phenylhydrazine, phosgene, phosphorus, phosphorus sesquisulphide, phosphureted hydrogen, picric acid, pyridine, sulphur chloride, sulphur dioxide, sulphureted hydrogen, sulphuric acid, tar, turpentine oil.

Since these attack through the respiratory organs, by absorption through the uninjured skin, through the digestive organs, specific measures for the protection of workers must be devised. The suggestions laid down by Dr. R. Fischer of Berlin, are comprehensive enough to repay study and application. These are:

1. Properly adapted buildings, thick walls of separation for dangerous rooms, good lighting, facilities for keeping the workshop clean and for effective ventilation.
2. Apparatus adapted to its special purpose, whenever possible, closing tight in every part.
3. Appliances for accomplishing the arrest of gases and dust at their place of origin, their removal (by exhaust fans) and in a suitable manner rendering them innocuous or collecting them, thus preventing them from entering the nose and mouth.
4. So far as possible, avoidance of direct contact with poisonous materials or substances injurious to health in working with, transporting, or packing them.
5. The displacement of particularly dangerous labor methods and materials by the introduction of less dangerous labor processes and materials, as well as by the employment of materials satisfactorily pure chemically.
6. Instruction of workmen just entering upon an occupation concerning the properties of the poisonous substances extracted, manufactured, used, or otherwise evolved, and, whenever possible, caution leaflets should be put into the hands of the workers.
7. The repetition of this instruction at frequent intervals.
8. Posting of precautionary regulations and warning placards containing admonitions for the exercise of special caution and enjoining the observance of measures for insuring safety. Constant supervision of all dangerous employments by expert and responsible persons.
9. Employment by appropriate means for personal protection as work clothes, caps, gloves, goggles, and, as necessary adjuncts, mouth and nose shields, respiratory masks and the like, in case the appliances named in rule 3 are inapplicable.
10. Practice of bodily cleanliness by the use of wash, bath and dressing rooms, the use of special rooms for eating, separate wardrobes for street and work clothes, and frequent, nonhazardous cleansing of the clothing.
11. Immediate report of symptoms of indisposition, attention to wounds of the skin caused by the handling of corrosive materials, the speediest employment of an unexceptionable antidote giving promise of success at the very first symptoms of poisoning, with the simultaneous summoning of a physician.
12. The installation of a healthy working force capable of withstanding exposure to the poison. Temporary or permanent exclusion of sick workmen from the dangerous departments of the industry. Medical examination of the workers in dangerous employments at suitable intervals. Under certain circumstances there should be a change of work in occupations giving rise to chronic poisoning.
13. The utmost possible reduction of the hours of labor in dangerous employments.

Satisfactory statistics are not available, showing the number of cases of poisoning resulting from the inhalation of poisonous fumes and vapors in the various industries of the United States. Physicians in this country have reported many cases that have come under their observation, insurance companies have had considerable similar experience, and other cases are brought to light through the reports on occupational diseases that are required by law in some of our States. These returns are incomplete, however, and they utterly fail to reveal the seriousness of the situation.

It is of the utmost importance that the men who are to work at dangerous occupations be carefully selected, because some persons, by reason of physical infirmities or deficiencies, are totally unable to withstand the unhealthful conditions that are sometimes associated, more or less unavoidably, with our manufacturing plants. Before engaging in hazardous work of this nature, each man should be carefully examined by a

competent physician, and similar examinations should be made thereafter, periodically and regularly. In plants making use of hazardous processes, there is no doubt that both the efficiency and the health of workmen are better when reasonably short hours are the rule, and when stated rest periods are allowed.

Heads of departments should co-operate with their men in having all thoroughly aware of the hazards of any special operations. They must impress on their workers that among them should be foremost the accident prevention spirit. They should realize as vividly as do the managers of the plant that accidents are bad business, aside from humanitarian and sentimental considerations. Accidents increase insurance premiums and it is only a common business principle that it is necessary to reduce expenses as far as possible in this and every other direction.

The accident insurance companies and the State factory inspectors are entitled to much credit for the reduction of accidents through their insistence that the requirements made by the inspector are complied with. Factory inspection and inspectors have grown into something like a burden in all lines of industry; in the direction of safety inspection can scarcely be too frequent or too searching.

In a chemical works there are machine shops in the buildings, woodworking and similar mechanical risks, that can be solved according to the best modern practice in safeguarding and safety appliances. All necessary precautions should be taken in chemical plants to install proper safeguards around machinery, elevators, boilers, railway tracks, etc.

Beyond these risks are those inherent in the processes of manufacture of the so-called heavy chemicals, sulphuric, nitric, muriatic, hydrofluoric acids and their by-products, sulphate of alumina and other alkaline products. There is a certain negligible risk from fumes in the operation in the manufacture of acids, but this is very remote, the most dangerous fumes being those produced in the manufacture of nitric acid, which are released only through the breaking down of some portion of the apparatus. The most dangerous of the acid burns are hydrofluoric, nitric and sulphuric. The burns caused by these acids getting on the skin are very severe and painful.

To protect the eyes of men working with these acids in any situation in which there is danger of splash should be obliged to wear rubber-lined goggles, fitting close to the face. All bad results from getting the acid on the person can be avoided entirely by thorough washing with plain water which dilutes and removes the chemical from the skin.

The General Chemical Company, which has an admirable safety organization, furnishes men working on acid pipe lines with a rubberized cloth hood with mica covered eye openings to be worn whenever they are loosening or tightening valves or separating flanges, to guard against a sudden squirt of acid which might strike them in the face and eyes. In working in the alkaline processes, the men wear rubber gloves furnished them.

Cooling pans containing hot liquids are railed off to a height of 3 ft. to prevent men from stumbling and falling into them. In dusty processes, as in other industries, men are obliged to wear respirators of some approved type.

In the heavy chemical industry the matter of ventilation of process buildings is simple, since in general they are large and high with ample openings near the roof for the escape of any gases or fumes. The chief means adopted by the General Chemical Company to prevent the industrial accidents inherent in the manufacture of chemicals is the careful education and supervision of the men.

An effective device for use in filling laboratory stock bottles for strong acids from carboys is forcing the acid, or the ammonia, from the carboy through a glass tube by means of compressed air. The air is freed from impurities by passing it down through a 5-ft. iron pipe filled with fairly fine coke. An attendant must always be present with the regular operator during the filling of these bottles.

Systematic schemes for preventing accidents are not new in the United States. Some large employers have had efficient systems for a number of years, but efforts were not sufficiently widespread and, as a national movement, accident prevention was in the United States up to a few years ago far behind other industrial nations. American statesmen, employers, economists, insurance experts and humanitarians of all classes have called attention to the need of greater and more concerted action and much has been done in the last three years.

The present time finds the people of our country far more active in accident prevention than any past period. This activity will continue and increase for years to come and those who have had the opportunity to investigate this subject here and in European countries believe that we are gaining headway and that within a few years will overtake some of the nations who have preceded us in the movement from fifteen to twenty-five years.

In the face of all the safety work that is being done by societies, by associations, by manufacturing plants, by individuals and the press, it is strange that one finds Secretary Frank Morrison of the American Federation of Labor, in a speech last Labor Day, uttering for obvious effect this grave misrepresentation: "Let us not forget that 30,000 of our fellow-countrymen engaged in gainful occupations are killed every year. Men talk about preparedness, but never a word of protest at the annual loss of these thirty regiments that are silently swept into unknown graves *that dividends may continue.*"

An investigation made of a large number of concerns that have reduced their accident records an appreciable per cent, proves conclusively that mechanical safeguards only prevent from 25 to 40 per cent, while the remaining 75 per cent can be prevented only by education, inspection and co-operation of the workmen. Even in the smallest plants, it is necessary to have some form of a safety organization in order to keep employees interested and on the look-out not only to safeguard themselves from injury, but their fellow workmen as well. One of the greatest means of getting the desired co-operation is that of allowing men to serve on committees and give them some responsibility in the work. Where this plan has been followed, 95 per cent of the suggestions for safeguarding submitted, have been found practical and were adopted.

The central committee should have as a member at least one of the executive heads of the concern, not only to give it prestige but authority as well. It should serve as a general clearing house for all safety matters and devise ways and means for keeping safety interest aroused and obtaining the co-operation of employees. Regular meetings should be held, preferably monthly, at which time all serious accidents should be discussed and measures taken to prevent their future occurrence. Proceedings of the shop committee should be considered and action taken on recommendations offered, and guards ordered installed that are deemed necessary. The report of periodical inspection made by the safety man should be considered and investigations made of dangerous conditions reported.

The shop committee should meet at least monthly and all dangerous conditions discussed and suggestions made to remedy them. The personnel of the committee should be changed at least every three months so that as many as possible can be drawn into intimate touch with the work and the interest aroused. Since workmen make the best inspectors, they should be encouraged to report conditions in their departments that they usually see in the course of their regular duties, as with plants of the size here discussed, it is hardly necessary to devote a definite period of time to inspection work.

Even in plants of the smallest size, some one person should be detailed to see that safeguards are constructed in accordance with various standards adopted and report to the central committee, when the work has been completed on the progress that is being made. Such a man can usually be found in the drafting or mechanical departments and should be required to make periodical inspections of the entire plant and report on conditions found.

One of the greatest factors is keeping employees interested in a regular "booster" or get-together meeting. A "smoker" often serves the purpose, at which time stereopticon or motion pictures relating to safety can be shown and by the aid of talks by various members of the firm or an authority on accident prevention, the subject can be impressed on their minds and their co-operation obtained. At these meetings the cause and prevention of accidents should be freely and frankly discussed which will tend to bring a closer relationship between employer and employee, which will not only aid in accident prevention, but will aid in disseminating any industrial discord that may have a tendency to arise. The solution of the whole accident problem is to get the men with you, then do your part, and accidents will take care of themselves.

It is conceded generally, says a well-known safety engineer, that the older employees resent the safety idea more than the younger men, and it is only natural that this be true. After a man has operated a machine for a number of years without sustaining an injury, he naturally would feel as though it was a reflection on his ability to have safeguards applied. This condition is particularly found in small shops, and it requires some tact in approaching the employees and gaining the desired confidence. After such an employee is once won over to the side of safety, he will usually prove a very ardent "booster" not only in preventing accidents, but in pointing out dangerous conditions.

First National Exposition of Chemical Industries

To supplement our report of the exhibits given in our issue of Oct. 1, we herewith give an account of a few exhibits which were omitted through error of the printer in our last issue.

Condensite Company, Bloomfield, N. J.—Exhibit of the various products made from "condensite," among which were the Edison records, switch board meters, the Remy ignition generator, golf clubs, automobile steering wheels and numerous other articles of all kinds. Their exhibit also included Hallowax, which is made from chlorine and napthalene and used for fire extinguishers and in places where a high specific inductive capacity is required. Mr. Sanford Brown was in charge.

L. O. Koven & Brother, Jersey City, N. J.—Showed small models of water still and benzol still, and also a large size Kelly filter press manufactured by them. Dr. Emil E. Lungwitz was in charge.

Standard Aniline Products, Inc., New York City.—Showed samples of nitraniline, beta naphtol, permanent red, sulphur black and para-nitraniline.

Werner & Pfleiderer Company, Saginaw, Mich.—Exhibited four small models of their kneading and mixing machines and one large "Universal" mixing machine was shown with the top removed so that inside mechanism could be seen. Mr. F. H. Banbury was in charge.

The following list comprises the names of those who registered either at the booth of the American Electrochemical Society or at the booth of METALLURGICAL AND CHEMICAL ENGINEERING. Where no address is given New York City is understood:

Paul O. Abbé; Wm. H. Abeling; Aberman & Son; Jerome Alexander; B. Alperowitz; M. E. Alpers, Dover, N. J.; L. T. Alton; H. S. Amer, Bloomfield, N. J.; American Alkali & Acid Company, Bradford, Pa.; Wm. C. Andrews, Orange, N. J.; D. W. Armstrong; Louis V. Aronson, Newark, N. J.; D. Irving Ashworth, Wappinger Falls, N. Y.; L. H. Baekeland, Yonkers, N. Y.; Robt. J. Ball, Newark, N. J.; Will H. Baltzell, Pittsburgh, Pa.; John H. Banks; E. J. Bartlett, Hanover, N. H.; Chas. Baskerville; J. W. Beck, Rosiclare, Ill.; A. E. Bellis, Chicopee Falls, Mass.; R. C. Bergen; H. S. Blackmore, Washington, D. C.; D. M. Bliss, Kingsland, N. J.; J. E. Bloom, Brooklyn, N. Y.; E. Blough, Pittsburgh, Pa.; P. L. Blumenthal, Lexington, Ky.; Walker Bowman; W. H. Baynton, Grasseli, N. J.; Chas. S. Bradley, Linn Bradley; Walter M. Bradley, New Haven, Conn.; William Brady, Chicago, Ill.; H. B. Branerr, Seattle, Wash.; E. J. Bremnesen, Elmhurst, L. I.; T. Lynton Briggs, Flushing, N. Y.; W. H. Broadhurst, Brooklyn, N. Y.; H. E. Brown, Kingston, N. Y.; C. L. Bryden, Scranton, Pa.; Lucien Buck, Rochester, N. Y.; Robt. H. Buckie, Mechanicville, N. Y.; R. Buisemeister; W. G. Bullard, Dover, N. H.; D. G. Bunicke, Philadelphia, Pa.; C. F. Burgess, Madison, Wis.; J. W. A. Butler, Brooklyn, N. Y.; Alison Butts, Chrome, N. J.; J. R. Cain, Washington, D. C.; Harry S. Calvert, Pittsburgh, Pa.; R. P. Calvert, Henry Clay, Del.; Arthur J. Campbell, Bridgeton, N. J.; Frank W. Cann, Newark, N. J.; Jessie Y. Cann, Urbana, Ill.; H. Carmichael, Boston, Mass.; H. M. Carter, Norwood, Mass.; George S. Cary; C. F. Chandler; P. L. Charter, Bridgeport, Conn.; J. B. Churchill, State College, Pa.; G. W. Clarke, Cleveland, Ohio; E. A. Colby, Newark, N. J.; Albert A. Cory; Alfred H. Cowles, Sewaren, N. J.; J. R. Crocker; W. L. Cummings, Philadelphia, Pa.; F. W. Cunningham, Orange, N. J.; Thos. Darlington; Ralph W. Deacon, Chrome, N. J.; C. F. De Ganoke; J. R. de la Torre Bueno, White Plains, N. Y.; Demaras Bros., Athens, Greece; C. H. Demproolf, York, Pa.; H. C. Diercks, Ithaca, N. Y.; Carl Dittmar; Wm. Donald, Ridgefield Park, N. J.; Chas. A. Doremus; L. B. Drekerson; Gustav Drobegg, Brooklyn, N. Y.; J. W. Drummond; Wm. R. Duggan; E. N. Dukern, Monte Carlo; Arthur J. Dwight; Thos. A. Edison, Orange, N. J.; L. A. Ehnhardt; August Eimer; Carleton Ellis, Montclair, N. J.; N. H. Emmons, 2d, Englewood, N. J.; Henry C. Enders; H. W. Engle, Marietta, Pa.; H. W. Faint, New Brunswick N. J.; E. W. T. Faint, Roselle Park, N. J.; J. Wm. Fehnel, Bethlehem, Pa.; P. B. Fehl, Reading, Pa.; Colin G. Fink, East Orange, N. J.; Staats L. Fink, Newark, N. J.; Chas. B. Foley, Ann Arbor, Mich.; W. A. Forbes; Albert Ford, Bridgeport, Conn.; Chauncey E. Foster; C. Fuld Frank; M. M. Franklin, East Orange, N. J.; H. A. Frasch; F. W. Frerichs, Jr., St. Louis, Mo.; R. C. Gardner, York, Pa.; David S. Giles, McKeesport, Pa.; J. S. Goldbaum, Philadelphia, Pa.; H. A. Goldman; S. M. Goldsmith; W. E. Gray, Elyria, Ohio;

TWO MORE EXHIBITS FROM FIRST NATIONAL EXPOSITION OF CHEMICAL INDUSTRIES

F. W. Green, Little Falls, N. J.; Martin L. Griffin, Rumford, Me.; Elmer S. Grymes, New Brunswick, N. J.; C. A. Hall, Philadelphia, Pa.; W. T. Hall, Jr.; J. C. Halpenny; Fred J. Hambly, Buckingham, Que.; Wm. J. Hammer; Wm. H. Hampton; James O. Handy, Pittsburgh; J. W. Hansen, Troy, N. Y.; C. A. Hanson, Schenectady, N. Y.; C. K. Harding, Chicago; R. F. Harrington, Boston; Edward Hart, Easton, Pa.; Frank Hartwick, West Orange, N. J.; W. B. N. Hawk, Elyria, Ohio; W. P. Hayden, Perth Amboy, N. J.; Carl Hegstrom, Perth Amboy, N. J.; Elwood Hendrick; S. T. Henry; Chas. H. Herty, Chapel Hill, N. C.; J. B. F. Herreshoff; B. C. Hesse; Henry D. Hibbard, Plainfield, N. J.; Harold Hibbert; John Wm. Hield; J. F. Hinckley, Newark; Dr. J. M. Hirsh, Chicago; Lea S. Hitchner, Newark, N. J.; Irving Hochstadter; R. A. Holbrook, Chicago; M. L. Holcroft, Chicago; A. P. Hollock; A. Honery, Oak Park, Ill.; M. S. Hopkins, Reading, Pa.; Henry Howard, Brookline, Mass.; E. J. Hubaux; W. F. Hubley, East Orange, N. J.; M. A. Hunter, Troy, N. Y.; H. H. Hurt; J. W. Incusty, St. Louis, Mo.; W. T. Ingraham, Dover, N. J.; Chas. Ingram; Daniel D. Jackson; W. A. James, Buffalo, N. Y.; A. W. Jenkins; W. H. Jennings, Jr., Phoenix, N. Y.; J. E. Johnson, Jr.; Grinnell Jones, Cambridge, Mass.; C. H. Jouet, Roselle, N. J.; J. C. Jurgensen, Lodi, N. J.; E. C. M. Keby, Washington, D. C.; Thos. J. Keenan; John E. Keller, Jr., Litchfield, Conn.; E. J. Kelley; J. S. Kennedy; Chas. W. Kern; J. Kilpatrick, Brooklyn; C. J. Kinzie, Niagara Falls, N. Y.; F. W. Kitterer, Jersey City; H. F. Klemfeldt, Newark, N. J.; W. A. Klipstein; A. F. Kumberger, Philadelphia; P. J. Kurg, Jr., Ithaca, N. Y.; Theo. Kuthier; W. D. Landis, Niagara Falls, N. Y.; Clement L. Le Boutillier, High Bridge, N. J.; Kurt Ledig, Newark, N. J.; L. Lefferts, Brooklyn, N. Y.; X. M. Lehmann, Boston; H. R. Lesser; Wallace G. Levison; F. A. Lidbury, Niagara Falls, N. Y.; Hugo Lieber; Morton Liebschutz, Newark, N. J.; A. T. Lincoln, Troy, N. Y.; G. L. Lindsay; F. M. Linnhard; A. D. Little, Boston; L. I. Loghry, Stoneboro, Pa.; A. Ludwigs, Irvington, N. J.; W. E. Lummus, Boston; J. Lunsman, W. Orange, N. J.; C. N. Manfred; A. S. Manning; O. S. Marckworth, Columbus, Ohio; C. P. Marsh; Gustav Martin, Boston; W. J. Matheson, Newark, N. J.; J. C. Matthews, Arlington, N. J.; Max Mauran, Niagara, N. Y.; A. S. McDaniel, Rochester, N. Y.; James C. McGuire; Parker C. McIlhiney; M. R. McKeown, Pittsburgh, Pa.; Wm. H. Meadowcroft, Great Neck, N. Y.; Wm. S. Miller; H. S. Miner, Gloucester, N. J.; H. K. Moore, Berlin, N. H.; Russel W. Moore; C. B. Morey, Buffalo; Stephen R. Morey; Wm. E. Morrissey; Wm. Roy Mott, Cleveland, Ohio; Emil Mueser, Niagara Falls; J. M. Muir; W. A. Nealy, Boston; E. M. Neil; H. B. Nichols; E. F. Northrup, Princeton, N. J.; L. H. O'Donnell, Jersey City; W. J. Graphite.—The two uses of graphite that seem to have shown the greatest gains in 1914 are its application to lubrication and as a preparation to lessen boiler scale.

Monazite, Thorium and Mesothorium is the title of Technical Paper 110 of the Bureau of Mines. The author is Mr. Karl L. Kithil. This paper describes the properties, occurrence and methods of mining and milling monazite, and methods of preparation of thorium and mesothorium.

A New Electrolytic Method of Sewage Disposal*

BY J. C. OLSEN

The process of sewage disposal described in this paper has been in operation at Elmhurst in New York City for more than a year.

At the plant in New York City a 25,000-gal. unit was in operation for several months and was very thoroughly tested by several chemists, sanitary and electrical engineers. The results were so satisfactory that a 500,000-gal. unit was built and has been in continuous operation since early in April. During this time an average of about 750,000 gal. of sewage has been treated daily, although the unit was constructed for 500,000 gal. For about three months after it was installed, tests were carried out almost continuously by the author, in conjunction for most of the time with Prof. William P. Mason, Dr. C. O. Mailloux and Mr. P. M. Travis. Dr. Mailloux made most of the electrical observations and deductions, while the chemical and bacteriological tests were made by Professor Mason, Mr. Travis and the author, assisted by Mr. William H. Ulrich. The work involved the taking of about 200 samples and their chem-

*A paper read at the Los Angeles meeting of the American Institute of Chemical Engineers, in joint session with the Southern California section of the American Chemical Society.

ical and bacteriological analyses as well as a very large number of observations of current consumption.

The process and apparatus used was invented and patented by Mr. C. P. Landreth of Philadelphia and will, no doubt, become known as the Landreth electrolytic process of sewage disposal. The electrical purification of sewage has been attempted before in various ways and is or has been in use at a number of localities notably Oklahoma City, Okla., and Santa Monica, Cal.

Mr. Landreth's process seems to be new in that he uses lime together with electrolysis for the treatment of sewage and also in that he uses a much smaller quantity of electricity per gallon than others have employed.

Electricity alone has been used before as well as lime alone, but the combination of these two agents accomplishes what neither of them alone can effect. The Landreth process also employs a very thorough system of agitation.

The process as in use at Elmhurst comprises the following principal stages of operation: (1) screening; (2) electrolytic treatment with addition of lime; (3) sedimentation; (4) filter pressing of sludge.

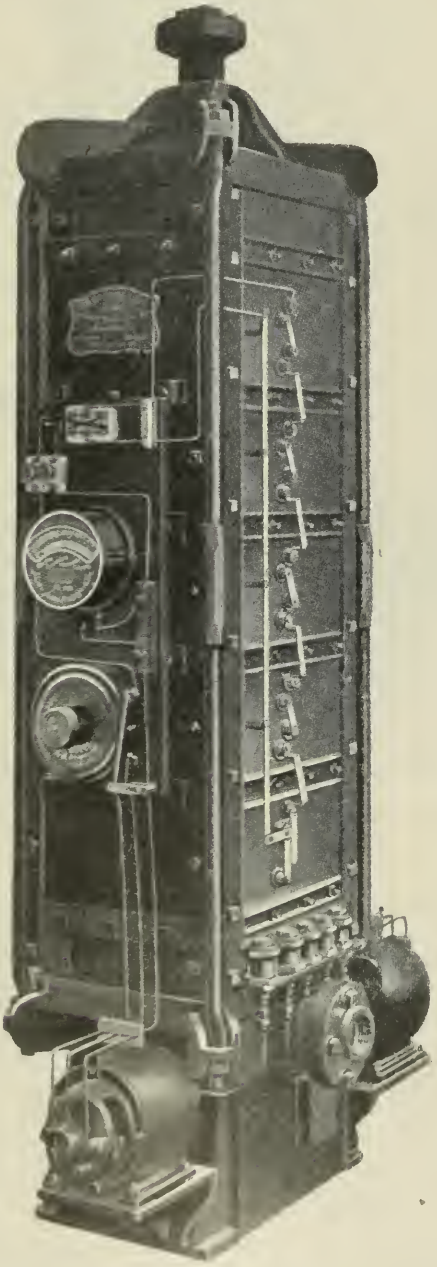

FIG. 2—OUTSIDE VIEW OF ELECTROLYTIC APPARATUS 25,000 UNIT

The raw sewage is delivered by the mains into a receiving well from which it is pumped through quarter-inch screens by means of a centrifugal pump through the electrolytic machine.

The electrolytic machine consists of a horizontal wooden box 23 ft. 3 in. long, 3 ft. in width, and 2 ft. 8¾ in. in depth. It rests upon a masonry foundation 18 in. high. The sides, top and bottom of the box are stiffened by means of angle irons. The top of the box is in two equal sections bolted on, the joint being made tight with a rubber gasket. The top may be removed for cleaning or for the inspection of the electrolytic apparatus.

A series of valves at the bottom serve to remove any sludge which may accumulate in the box.

The sewage to be treated is forced through the apparatus by the pump which takes it from the receiving well and delivers it to the inlet of the apparatus at one end. In passing from the inlet to the outlet (at the other end) of the apparatus, the sewage flows between numerous plates which are placed parallel and close to each other inside the closed box. Consequently the liquid does not flow in one mass, but is subdivided into a large number of relatively thin "sheets." The plates which separate these sheets of sewage from each other also serve as electrical conductors or "electrodes" by means of which electrical currents capable of producing electrolysis are conveyed across the liquid sheets, through the sewage with the result that one side of each liquid sheet is in contact with an "anode" surface, and the other with a "cathode" surface. To insure thorough agitation of the sewage, as it flows in the spaces between the electrode plates, mixers in the form of paddles placed between these plates are rotated in the plans of each liquid sheet.

The plates inside the apparatus are all in a vertical plane, parallel with the sides of the tank, so that the "liquid sheets" of flow between the plates are all vertical. These liquid sheets are not continuous from the inlet to the outlet ends of the apparatus, because the plates are arranged in groups with spaces left between them.

The plates are of iron, and are all of the following dimensions: length, 16 in.; height, 10 in.; thickness, from ¼ in. to 3/16 in. The plates are grouped and assembled in sets, like the plates for an "element" or cell of a storage battery. The plates in each group are all parallel to each other, and they have equal spaces between them (5/16 in. to ⅜ in.). They are held together by bolts, which pass through all the plates, and through the insulating separators between them, and clamp them into a solid unit.

When the groups are in position in the tank, these bolts extend across the tank horizontally and support the plates, which are then all in a vertical position, parallel with the sides of the tank, and occupy the entire available space across the tank. A group contains fifty plates (except in a few cases where the number is one or two less). There are groups at eleven places or divisions in the tank between the inlet and the outlet; and there are two groups at each place, one above the other.

This makes a total of twenty-two groups and (nearly) 1100 plates.

The two bolts just mentioned are also utilized as electrical terminals and conductors for the plates. This is done by insulating the even-numbered plates from one bolt and connecting the odd-numbered plates with it, and doing the opposite for the other bolt.

This is the arrangement used for the groups in the

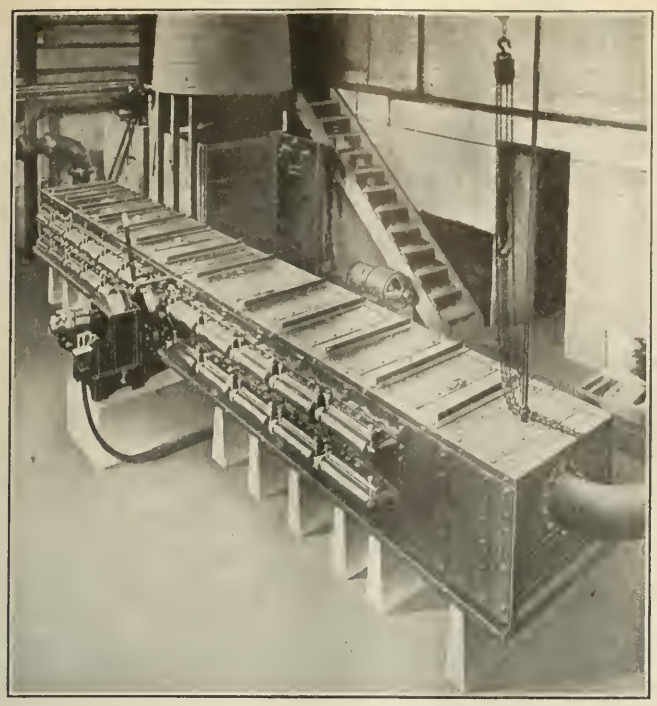

FIG. 3—HORIZONTAL ELECTROLYTIC APPARATUS 500,000 UNIT INSTALLED AT ELMHURST, NEW YORK CITY, MOTOR AND REDUCTION GEARING FOR THE MECHANICAL STIRRERS SHOWN ON LEFT-HAND SIDE OF MACHINE

first section (counting from the inlet) and in the last six sections, or for a total of fourteen groups. In these groups the plates constitute, in each case, an "electrolyzing element" of twenty-five pairs of plates.

In the other four divisions the arrangement is less simple. The fifty plates of each group are not electrically grouped and connected into a single element of twenty-five pairs of plates, but into three elements, each of eight pairs (or more), which are connected in series. It follows that the total number of "elements" in these four sections is twenty-four (*i.e.*, twelve for the four upper groups and twelve for the four lower groups). Adding these to the fourteen elements in the other divisions, the total is thirty-eight elements.

In most of the tests the thirty-eight elements were all connected in a simple series; in one test the nineteen elements in the upper tier were connected by themselves in series, and likewise the nineteen elements in the lower tier; and the two series were then connected in multiple. Various other combinations of series and multiple connection may be made and were made in some of the tests.

When all the thirty-eight elements are connected in series, there is a difference of three to one in the current density at the "large" elements (composed of twenty-five pairs) and at the "small" elements (composed of eight pairs). The same current passes (theoretically) through all the elements, and as the electrode surface is three times greater at the large elements than at the small elements, the current per unit of surface will be only one-third as great at the large elements as at the small elements.

SOURCE OF CURRENT

The current supply required for producing electrolysis is obtained from a direct-current generator of 5-kw. capacity, which is direct driven by an alternating-current induction motor.

The maximum current capacity of the generator is

FIG. 4—HORIZONTAL ELECTROLYTIC APPARATUS INSTALLED AT ELMHURST, SHOWING ELECTRICAL CONNECTIONS ON RIGHT-HAND SIDE OF MACHINE

40 amp. and its maximum voltage is 125 volts. A watt-hour meter was especially connected in the mains between the generator and the switch board for the purpose of the test to enable the direct-current output in watt-hours to be computed for given periods of time in connection with the test.

AGITATION OUTFIT

In addition to the two holes in the electrode-plates for the bolts which serve to hold them together there are two other holes which make openings for the shafts upon which the paddles rotating in the spaces between the electrode-plates are mounted. There are two rotating shafts passing through each group of plates, and each shaft carries forty-nine paddles. This makes ninety-eight paddles per group of plates, or a total of 2156 paddles for the twenty-two groups. The forty-four shafts are supported in bearings mounted in the sides of the tank. They pass through the side of the tank, and are driven by bevel gearing from four horizontal shafts, which receive power from a 3-hp. induction-motor through reduction-gearing.

There is a double reduction-gear by which the speed of the clutch-shaft is reduced to seventy-eight when the motor speed is 1800. The horizontal shafts are geared to run at half this speed, and the paddle shafts are geared to run at half the speed of the horizontal

FIG. 5—SEDIMENTATION TANKS AND OVERFLOW OF PURIFIED SEWAGE

shafts. Hence, if the motor ran without slip the paddle shafts would have a speed of 19.5 r.p.m. Actual test showed that the speed of the paddle shafts was from 18 to 19 r.p.m., according to the "load" on the motor, which at times appears to be relatively heavy, as indicated by the rise of temperature of the motor. The increase in load appears to be due to increased friction between the paddles and the electrode plates, owing to deposits on the plates.

The amount of flow of sewage through the machine was measured by a Venturi indicating and recording meter connected in the discharge pipe leading from the machine to the sedimentation tank.

The milk of lime added to the sewage is prepared by putting quick-lime or hydrated lime in a vat with water and agitating the mixture by electric power, produced by a ½ hp. motor. The electric current supply required for operating the pump motor, the lime vat motor and the motor generator is taken from the street mains through watt hour meters.

METHOD OF OPERATION

The milk of lime is introduced into the sewage in several different ways. A small centrifugal pump operated by an electrical motor was at times used to force the milk of lime into the inlet of the electrolytic machine through a suitable pipe, the amount of flow being regulated by a valve on this pipe. A pipe was also provided by which the milk of lime could be forced into the sewage at the outlet of the machine.

The milk of lime was also at times forced into the sewage through a pipe leading to the inlet of the sewage pump. In the latter case the mixture of the milk of lime with the sewage was affected by the action of the pump.

The electrolyzing current was maintained as nearly constant as practicable, the voltage of the direct-current generator being regulated at the switchboard whenever any variation in the current is observed. The "polarity" of the current was reversed about every hour, with the object of equalizing any chemical action that may be produced on the iron electrodes, and preventing the formation of deposits there. A very considerable drop in voltage occurred on reversing the polarity after which the voltage increased again and after about 15 min. was again normal. The volume of electrical current (amperes) sent through the apparatus, varies with the mode of connection of the electrodes. With all the thirty-eight elements connected in simple series, the current through the circuit was generally maintained at about 30 amp. This is the way in which the apparatus has been principally operated.

On one occasion, the elements in the upper and lower tiers were respectively connected in series, and the two series were connected in parallel. This would give nineteen elements in series, each element being composed of two elements in multiple. The current passing through these series on that occasion was maintained at 40 amp., which was the limit of current output of the direct-current generator.

The voltage of the generator must be equal to the sum of the "voltage-drops" at all points in the entire working circuit, including the leads, the electrolyzing elements, and their connections. The voltage-drop at the electrolyzing elements is the factor which, multiplied by the current (amperes) passing through the elements, gives the electrical energy expended directly upon the liquid. The voltage, or potential difference, per element, depends upon the counter-electromotive force, and the polarization incidental to the electrolysis produced, and upon the electrical resistance of the liquid. These conditions, in turn, depend and are affected by the chemical constitution, the density ("strength"), and the temperature of the liquid.

Theoretically the voltage per element should be the same for all sets of electrodes of the same kind (*i.e.*, having the same number and size of plates, etc.), under the same working conditions. Practically, it is found that the voltage per element varies even with plates of the same kind and size, in consequence of changes in the conditions. Deposits are produced on the plates, which alter the amount of active surface of the electrodes, or decrease the thickness of the sheet of liquid flowing between the plates; and chains and bridges of solid matter may at times form between plates of opposite polarity, causing the current to be shunted in part or even short-circuited entirely. Tests made while the apparatus was in operation show that the voltage per element varies appreciably from such causes.

ELECTROLYTIC ACTION PRODUCED PER UNIT VOLUME OF SEWAGE TREATED

The total quantity of electric current sent through a unit volume of the sewage passing through the machine depends (a) upon the total volume of current or the aggregate sum of the electric currents passing through the elements and (b) the speed of flow of the liquid to the apparatus.

The total quantity of current is equal theoretically to the product of the number of elements connected in series by the current in amperes passing through the series. Thus, with a current of 30 amp. passing through all the thirty-eight elements in series, the total quantity of current would be equal to 1140 amp. on the assumption that there is no loss by leakage or shunting past any of the electrodes in the middle portion of the series.

The length of time that the liquid is subjected to electric action depends upon the length and sectional area of the path through which the sewage flows in passing through the apparatus and the rate of pumping, or the speed of flow through the apparatus.

The time of flow through the apparatus, when in operation, under given actual conditions, was determined by injecting a coloring substance into the liquid at some point ahead of the inlet, and then noting the time which elapsed until the color appeared at the outlet of the apparatus. It was found that when the speed of flow through the apparatus (as indicated by the Venturi flow-meter) was at the rate of 765,000 gal. per day, the time of flow through the apparatus was 1 min. 8 seconds, or 68 seconds. Allowance should be made for the time elapsing while the liquid is passing through the inlet and outlet, and through portions of the apparatus at which there are no electrodes. The actual time that the liquid was passing through the machine did not probably exceed 1 min. (60 seconds).

A rate of flow of 765,000 gal. per day is equal to 531.2 gal. per minute. Allowing for 10 per cent leakage, a current of 1140 (or 1026 net) amperes acting during 1 min. represents 61,560 coulombs. The quantity of electric current applied, in 1 min., to the liquid, is

$$\frac{61{,}560}{531.2} = 116 \text{ coulombs per gallon.}$$

This quantity will obviously vary inversely with the rate of flow. Thus, if the rate of flow were increased to 1,000,000 gal. per day, the coulombs per gallon would fall down to 88; and if the rate of flow were decreased to 600,000 gal. per day, the coulombs per gallon would increase to 148. Under these conditions, and taking into account all causes of variation, the quantity of electric current per unit volume of sewage treated may range, in round numbers, between 80 and

150 coulombs per gallon, or 21 to 40 coulombs per liter. In the tests actually made, the electric current ranged between 19.5 and 40.9 amp. according to connections and other conditions of the tests; and the current per unit volume was from 85 to 169 coulombs per gallon (22.5 to 44.7 coulombs per liter). When extreme and unusual conditions are excluded, the figures are likely to remain within the limits just mentioned.

This quantity of electricity will, theoretically, liberate from 0.00174 to 0.00332 grams or 1.21 to 2.31 cu. centimeters of oxygen per liter of sewage treated.

CURRENT-DENSITY

In fourteen sets of electrode-plates all the plates of the set (forty-eight to fifty in number) are connected electrically so as to make one single electrolyzing element of twenty-four (or twenty-five) pairs of plates. In the other eight sets the plates are connected electrically so as to constitute three electrolyzer elements of eight pairs of plates, and the three elements are connected in series. The theoretical active electrode surface in the "single" elements (of twenty-four pairs) is three times greater than in the "triple" elements (of eight pairs). Hence, with the same current passing through "single" and "triple" electrodes (as when they are connected in single series) the current-density in amperes per square foot of active electrode surface, is only about one-third as great at the "single" as at the "triple" electrolyzer elements.

Each electrode-plate is 16 in. in length and 10 in. in height which gives an active surface of 160 sq. in. on each side, from which must be deducted the loss of active area due to holes in the plates (for the shafts on which the "paddles" are mounted) and to insulating separators. An allowance of 10 sq. in. is made for this deduction, which leaves 150 sq. in. per side. Both sides of each plate are active, except at the two outside plates, which have only one active surface. The active surface of the larger electrolyzer elements (of twenty-four pairs of plates) is $23\frac{1}{2} \times 300$ or 7050 sq. in., equivalent to 48.9 sq. ft. The active surface of the smaller electrolyzer elements (of eight pairs of plates) is $7\frac{1}{2} \times 300$, or 2250 sq. in., equivalent to 15.6 sq. ft.

When all the electrolyzer elements in the apparatus (C-24) were connected in series (making thirty-eight in series), the electrolyzing current is maintained at about 30 amp. The maximum current capacity of the direct-current generator is 40 amp. With an electrolyzing current of 30 amp., the current-density will be equal to the following values:

For large units:
30/7050 = 4.25 milli-amp. per square inch, or,
30/48.9 = 0.61 amp. per square foot.
For small units:
30/2250 = 13.33 milli-amp. per square inch.
30/15.6 = 1.92 amp. per square foot.

With 40 amp. these values would be one-third greater.

For large units:
40/7050 = 5.67 milli-amp. per square inch.
40/48.9 = 0.82 amp. per square foot.
For small units:
40/2250 = 17.8 milli-amp. per square inch.
40/15.6 = 2.56 amp. per square foot.

The range of variation of current-density in round numbers is within the following limits:

For large units:
From 4 to 6 milli-amp. per square foot.
From 6/10 to 8/10 amp. per square foot.
For small units:
From 13 to 18 milli-amp. per square foot.
From 1.9 to 2.6 amp. per square foot.

SEDIMENTATION

In the operation of the process, two sedimentation tanks are used. The sewage, after it has passed through the machine (or through the by-pass, if that be used), is discharged into a flume about 3 ft. wide, which connects with the inlet of the sedimentation tanks in the tank room.

After the sewage has received its dose of lime and has been electrolyzed in the machine, it is passed through the above-mentioned flume in a stream, about 6 in. deep, into two settling tanks (each 82 ft. 6 in. x 20 ft. x 5 ft. 3 in., of about 65,000 gal. capacity, and provided with a baffle at the center rising from the bottom, and also with a deep hanging baffle at the entrance and a skimming baffle at the exit, and from the second of them the settled effluent is finally discharged). These tanks are connected in tandem. The sewage enters the first tank at one end and passes through a gate into the second tank at the farther end. The time for sedimentation in each tank is nearly two hours or four hours for total time of sedimentation, dependent upon the rate of sewage flow. The effluent is discharged from the second tank through a flume by which it is conveyed to the discharge pipe.

It is proper to note that these sedimentation tanks were constructed for sewage disposal by the septic process previously in use at Elmhurst. Suggestions have been made for a new type of sedimentation tank and a model embodying some of them has been constructed, with which it is expected that more rapid and perfect sedimentation will be obtained.

FILTER PRESS

Pipe connections of suitable diameter, leading from the bottom of the sedimentation tank, serve to convey the sludge to a receiving basin in the press room whence it is pumped to the filter press, which is of the Johnson type. Attention should be called to the fact that the filter press is not an essential part of the apparatus as other methods of disposing of the sludge may be adopted.

(*To be concluded in issue of Nov.* 1.)

Alloy Steels*

BY GEORGE L. NORRIS

Steel can broadly be defined as an alloy of iron and carbon that can be forged and rolled. From expediency and necessities of manufacture, certain impurities beneficial or otherwise are present, but not in sufficient amounts to materially alter the characteristics of the pure alloy of iron and carbon.

Under this definition, steel, or as it is now often referred to, carbon steel, is usually within the following maximum composition: Carbon, 1.50 per cent; manganese, 1 per cent; silicon, 0.35 per cent; phosphorus, 0.05 per cent; sulphur, 0.05 per cent.

An "alloy" steel is alloyed with one or more metals, in sufficient amounts to influence or change the characteristics of steel, and still possible of forging or rolling.

The usual steel alloying metals are manganese, silicon, nickel, chromium, tungsten, and vanadium. As these metals will all alloy with each other, it is evident that it is possible to obtain a great variety of alloy steels.

Steel containing upward of 1.50 per cent manganese is not commonly considered an alloy steel, although this

*A paper read before the International Engineering Congress in San Francisco, on Sept. 21, 1915, as part of the Symposium on Iron and Steel, arranged and edited by Prof. Henry M. Howe.

percentage of manganese undoubtedly has some effect on the characteristics of steel. This is due no doubt to the fact that manganese is always present in steel.

The alloy steels are usually divided into two groups: "ternary" steels, with one metal alloyed, and "quaternary" steels, with two metals alloyed. The more complex alloy steels are practically limited to high-speed tool stees.

The general characteristics of alloy steels are high elastic limit and great strength, combined with a high degree of toughness, as compared with the carbon steel with which they are alloyed. The strength and hardness can be enormously increased by heat-treatment (quenching and tempering) and still have the steel retain great toughness.

Alloy steels are not as a rule placed in service in the condition as forged or rolled. The forging and rolling temperatures are usually so high that the steel requires heat-treatment to refine the grain and develop the exact combination of strength, hardness and toughness desired. It is frequently necessary to anneal after forging in order to facilitate machining operations. This, of course, necessitates subsequent heat-treatment.

Most of the alloy steels are of medium or low carbon content. The corresponding simple or carbon steels are only slightly or moderately improved in strength by heat-treatment.

The use of alloy steels in cutting tools dates back nearly a hundred years, although it was not until after 1850 or 1860 that alloy steels for this purpose became firmly established.

With the advent of iron-clad warships began the struggle for supremacy between projectile and armor plate that has been so fruitful in the development of alloy steels. Chromium, nickel, and nickel-chromium steels are largely the result of this struggle.

The publication in 1888 by Hadfield of the results of an extensive research of the alloys of manganese and steel, which resulted in the discovery of a remarkable new alloy steel, marks a period of active investigation into the effect of other metals on steel. The most important of these were the investigations on nickel steels by James Riley in 1889, which demonstrated that a mild open-hearth steel, such as used for structural, general forging and machinery purposes, when alloyed with 3 per cent to 4 per cent nickel had considerably higher elastic limit and tensile strength, with practically the same or greater ductility. One of the earliest and most extensive applications of nickel steel was for armor plate. For many years nickel steel was the principal alloy steel in use.

During this same period referred to, Hadfield made investigation of the effects of silicon on steel, and also a very complete study of chromium steels, which for some time had been used in a small way for springs and special forgings, but principally for tools and armor-piercing projectiles.

The development of high-speed steel about 1900, making it possible to readily machine heat-treated alloy steels, and the advent of the automobile with its demand for superior steel, have brought about the present extensive use and development of alloy steels.

The automobile industry, with its demand for steel of high strength and durability, has been undoubtedly the most important factor in the development of commercial alloy steels, and the largest consumer. Alloy steels are used extensively for transmission gears, and shafting axles, steering levers and spindles, springs, chassis frames, crank shafts, cam shafts, connecting rods, valves and many other parts of automobiles.

They are also extensively employed in forgings for high-speed engines, marine engines, locomotives, electrical machinery, mining machinery, and other mechanical engineering structures.

The use of alloy steels in bridge construction has been limited, but there is undoubtedly a field in long-span bridges for an alloy steel of high strength that can be used in the condition as rolled, preferably, or at most with a simple annealing.

Coincident and having a marked influence on the development of alloy steels, was the discovery of large deposits of vanadium ore in Peru, thus assuring a source of supply at a reasonable cost of this rare metal, which is the most powerful yet discovered for alloying with steel, that is, in small amounts.

The most important of the engineering or constructural alloy steels are those containing nickel, chromium, and vanadium, singly or in combination. With all these steels it is possible, through heat-treatment, to obtain a tremendous range in strength, in round numbers varying from 100,000 to 250,000 lb. per square inch, depending also, of course, upon the size of the section.

It is not possible nor within the province of this paper to go deeply into the technology of alloy steels, but only to briefly describe the principal alloy steels and their characteristics.

MANGANESE STEEL

This steel usually contains 10 per cent to 13 per cent of manganese and approximately 1 per cent of carbon. It is practically non-magnetic and has a peculiar hardness, to which it owes a remarkable resistance to abrasion. It is extremely difficult to machine. It has high strength and toughness, but relatively low elastic limit. With care it can be forged and rolled.

It has found its principal application in castings for crushing and grinding machinery and railroad crossings.

Manganese steel has the peculiar property of being toughened and softened by quenching in water, resembling copper in this respect. All manganese steel castings are subjected to this treatment to remove brittleness.

SILICON STEEL

There are two types of silicon steel, one of which has found some application as an engineering steel. This steel, frequently called silico-manganese steel, is generally covered by the following limits of composition: Carbon, 0.45 per cent to 0.65 per cent; silicon, 1.50 per cent to 2 per cent; manganese, 0.50 per cent to 0.80 per cent.

The manganese is normal, contrary to what is indicated by the name. The principal application of this steel is for automobile springs, and to some extent for gears. It fibers readily through heat-treatment, and is very brittle in the direction at right angles to rolling. It is very sensitive to heat-treatment, and a relatively small variation in annealing temperature after quenching has a strong effect on the results obtained.

The other type of silicon steel contains 3 per cent to 5 per cent silicon, is low in carbon and manganese, and is extensively used for electrical transformer sheets on account of its high permeability and electrical resistance. Structurally, it is weak and has no constructural value.

NICKEL STEEL

Nickel alloys with steel in all proportions, but by far the most important nickel steel, from an engineering standpoint, is the low- and medium-carbon steel with 3 per cent to 4 per cent of nickel, commonly known as 3½ per cent nickel steel.

The presence of manganese in nickel steel is very essential, as it has a marked effect on the mechanical properties. The amount of manganese should range from 0.50 per cent to 0.80 per cent.

This steel has been extensively used since its introduction in 1889, and is a good all-round engineering and structural steel with considerably higher elastic limit and tensile strength than the corresponding carbon steel, and with practically the same degree of ductility.

The low-carbon steel, 0.10 per cent to 0.20 per cent, is used extensively for case-hardening parts. It case hardens more readily than carbon steel and gives a harder casing with a strong, tough, fibrous core.

A great deal of nickel steel with carbon from 0.20 per cent to 0.35 per cent has been used in shapes and plates as rolled and in annealed eye-bars for bridge construction. In this condition, which is not to be recommended for forgings, the following are typical physical properties.

Elastic limit, lb. per sq. in.	45,000 to 60,000
Tensile strength, lb. per sq. in.	80,000 to 100,000
Elongation in 2 inches, per cent.	20 to 15
Reduction of area, per cent.	40 to 25

Annealed nickel-steel forgings have only slight advantage in strength over carbon steel, and consequently are not advantageous either from an engineering standpoint or commercially unless heat-treated. With heat-treatment it gives considerably higher strength than carbon steel, combined with greater ductility or toughness. It does not give as high values as the nickel chromium and chromium-vanadium steels.

Nickel steel rolls and forges readily and machines easily. It develops a very thick, hard scale which is apt to give considerable trouble in drop-forging and is hard on the dies. Nickel steel is also very liable to develop seaminess, especially when made in large heats and cast into large ingots, as is now customary. It requires a larger discard to insure soundness. The use of nickel steel in forgings, and particularly drop-forgings, is falling off in favor of other alloy steels with greater values.

CHROMIUM STEEL

The use of this steel is confined principally to a few specialties and it is not in general use as an all-round engineering steel. One of the principal uses is for balls and ball races. The great mineralogical hardness obtained by quenching is very desirable for this purpose. The steel for this application contains approximately 1 per cent each of carbon and chromium.

Chromium steel is also used for stamp-mill shoes, and in combination with soft steel in laminated plates for construction of burglar-proof safes, and in the same combination in bars for jails.

The low- and medium-carbon types, containing 0.80 per cent or less of chromium, have somewhat higher mechanical properties than the corresponding carbon steel. It is not used to any great extent, other alloy steels being superior, both in static and dynamic strength. Chromium steel is also very liable to crack and check in heat-treatment.

NICKEL-CHROMIUM STEEL

The addition of chromium to nickel steel has a marked effect, greatly increasing the strength and resistance to shock and particularly the mineralogical hardness. It is more difficult to forge and heat-treat and harder to machine, and is also liable to the seaminess frequently present in nickel steel. There are three types of this steel, differing both in the percentage of nickel and chromium, and all with low or medium carbon:

	Nickel, Per Cent	Chromium, Per Cent	Carbon, Per Cent
1st	3.5	1.50	0.25 to 0.45
2d	2.0	1.00	0.10 to 0.45
3d	1.5	0.50	0.10 to 0.45

The first type is used principally for armor plate and armor-piercing projectiles and came into use about 1895, superseding the nickel plates and chromium projectiles.

The other two types were developed by the automobile industry. The second type is largely for automobile forgings. It gives high strength with heat-treatment, has great hardness and good shock and fatigue resisting qualities.

The third type is a largely used all-round engineering steel. It is used for automobile forgings and for a variety of miscellaneous drop-forgings and machine parts. It is an excellent case-hardening steel, carbonizing readily. This type is more tractable in working, heat-treating and machining than the other two. It is also somewhat lower in tensile strength.

VANADIUM STEEL

The addition of small amounts of vanadium, generally under 0.25 per cent, to simple carbon steel or any of the alloy steels increases very considerably—about 30 per cent or more—the elastic limit and breaking strength, without materially affecting the ductility. To an even greater extent it increases the resistance to shock and fatigue.

The vanadium steel which has been up to now most generally used is a chromium-vanadium steel of the following typical compositions:

Carbon, 0.10 per cent to 0.55 per cent.
Manganese, 0.50 per cent to 0.80 per cent.
Chromium, 0.80 per cent to 1.00 per cent.
Vanadium, over 0.15 per cent.

The lower carbon type, 0.10 per cent to 0.20 per cent, is used mainly for case-hardening and is the best steel for this purpose. It carbonizes readily, gives the highest maximum carbon and finest grain. The casing is very strongly coherent to the core, very hard, tough, and strong, and practically free from any tendency to flake or powder. The core is remarkably strong and tough.

The higher limits of carbon, 0.45 per cent to 0.55 per cent, are extensively used for automobile and locomotive springs, giving remarkable resiliency and endurance. It is also extensively used for oil-tempered gears.

The range in carbon from 0.35 to 0.45 per cent is largely employed for crank shafts, locomotive axles, crank pins, connecting rods, hammer piston rods, automobile transmissions and rear axle shafts.

The range from 0.25 per cent to 0.35 per cent carbon is used for automobile forgings of all kinds and a great variety of miscellaneous work requiring the best combination of static and dynamic strength.

As illustrating the wonderful shock and fatigue enduring qualities of chrome-vanadium steel, drop-hammer piston rods of this material are giving many times the length of service of carbon, nickel, and chromium-nickel steel rods.

Vanadium steels have a much wider heat-treatment range than other steels. The desired physical properties can be obtained with a higher draw-back or annealing temperature, which is very advantageous as more completely removing quenching strains, and also as a manufacturing proposition.

Chromium-vanadium steel forges and machines better than nickel-chromium steel, is not as liable to injury in heating for forging, is not so liable to crack or check in heat-treatment and is free from the scamy tendency of steel containing nickel.

Carbon steel with a small percentage of vanadium, from 0.15 per cent to 0.20 per cent, has been used extensively for locomotive-frame castings with great success. The failure of these frames from all causes over a period of nearly ten years has been only a fraction of 1 per cent.

In tool-steel grades this steel has better cutting qualities, hardens deeper and more uniformly, and has remarkable toughness. In what are termed battering tools, chisels, cutters, dies, etc., it gives several times the length of service of ordinary carbon tool steel.

The handicap of high cost of vanadium has almost disappeared, and simple carbon-vanadium steel in the ordinary forging grades will undoubtedly soon become very widely used as an all-round engineering steel, when a better steel than carbon is required. It is remarkably clean and is as easily worked as carbon steel. It is free from the seaminess and ugly scale of nickel steels and the tendency to check and crack of the chromium steels, particularly nickel-chromium.

Tests of carbon-vanadium steel rails in curves are showing about 20 per cent less wear than rails with 0.15 per cent to 0.20 per cent higher carbon, and are also considerably stronger. This difference in wear will doubtless be much greater when the carbon percentage in the vanadium rails is increased to that of the standard rails.

In simple annealed forgings, plain vanadium steel has physical properties well above those specified for heat-treated (quenched and tempered) carbon steel.

This type of vanadium steel has a wider range of quenching temperature than nickel or nickel-chromium steels; and for mechanical properties after heat-treatment is practically on an equality with 3½ per cent nickel or the low nickel-chromium steels in general use, and apparenty has higher fatigue-resisting qualities.

While nickel and chromium interfere seriously with the welding quality of steel, vanadium does not, but on the contrary improves this quality. Vanadium steel wire is in common use for autogenous welding.

TUNGSTEN STEEL

This is principally used for magnets for magnetos and to some extent in hack saws and special tool steels. Tungsten is seldom used in engineering constructional steels, and then usually in combination with chromium.

Table I shows the typical engineering alloy steels and their tensile properties for the same heat-treatment draw-back temperature. This is in all cases 600 deg. C. (about 1100 deg. Fahr.). The specimens in most cases were heat-treated in the form of inch rounds and were machined after treatment.

Table I.—Typical Engineering Alloy Steels

COMPLEX ALLOY STEEL

Practically none of the constructional steels contain three or more alloy metals. The only steel in this class to be considered is what is commonly known as high-speed steel.

Robert Mushet developed and patented about 1860 an air-hardening steel that was very much superior to carbon steel for machining hard material. Mushet steel, as it was known, had about the following composition:

Carbon, 2.00 per cent.
Manganese, 1.75 per cent.
Silicon, 0.75 per cent.
Chromium, 0.40 per cent.
Tungsten, 5.50 per cent.

At the Paris Exposition in 1900 the Bethlehem Steel Company exhibited a new tool steel that took wonderfully heavy cuts at high speeds, the point of the tool heating up to a strong blue color without losing its edge.

This steel, which immediately became known as high-speed steel, was the culmination of the research work carried on for many years by Mr. F. W. Taylor and later published in his monograph "The Art of Cutting Metals." The difference between this steel and Mushet steel is apparent from the following typical composition:

Carbon, 0.60 per cent.
Manganese, 0.20 per cent.
Silicon, 0.10 per cent.
Chromium, 4.00 per cent.
Tungsten, 18.00 per cent.

With this steel, cutting speeds of over 90 ft. per minute were obtained.

Within three or four years it was found that the addition of vanadium to high-speed steel made it possible to still greatly increase the speed and size of cut. At first only about 0.30 per cent vanadium was added, but this has been increased until now 1.00 per cent is practically the standard amount in most high-speed steels, and speeds of 140 ft. and upward per minute have been attained.

Lately the addition of cobalt to high-speed steel has been meeting with favor as still further improving the endurance of the steel. The amount of cobalt generally used is 3 per cent to 4 per cent, with no change in the percentage of the other metals—tungsten, chromium and vanadium.

Pittsburgh, Pa.

Stearic Acid.—The price of this commodity has increased very materially since the beginning of the European conflict. It is largely used in the manufacture of the highest grades of Tripoli and white finish composition, and forms one of the chief ingredients. Due to its continued advancing tendency, it seems very evident that the price of good Tripoli and lime composition must be increased to meet the increased raw material costs. A movement is contemplated by several of the largest manufacturers of Tripoli composition to form a company and erect a rendering plant for the manufacture of stearic acid (from its tallow basis) and in sufficient magnitude to take care of their own and some outside requirements. This would enable the Tripoli manufacturers to offer the best and most uniform product and at the lowest possible cost. Members of the Metal Finishers Equipment Association, which is primarily interested in the good and standardization of the industry, speak very encouragingly of the project and will no doubt give it their enthusiastic support.

The **Federal Dyestuff & Chemical Co.** has been incorporated in Delaware on Oct. 4 as a $15,000,000 concern of New York. The incorporators are Blair Frazier, Newton James, and George A. Harrington, all connected with White & Co., bankers of 30 Pine Street, New York. Further information is not yet available.

The Co-operative Metallurgical Exhibit at the Panama-Pacific International Exposition

BY A. E. WELLS AND G. H. CLEVENGER

The co-operative metallurgical exhibit forms an important part of the United States Bureau of Mines exhibit at the Exposition and is of particular interest to those connected either directly or indirectly with the metallurgical industry. Although this display appears as a Government exhibit and is directly under the management of the Bureau of Mines, it was only made possible by the generous co-operation of the metallurgical industry and the manufacturers of metallurgical machinery and laboratory apparatus who have contributed the funds and equipment necessary for the installation and operation of the exhibit.

The metallurgical exhibit had its inception with the formation of a committee upon metallurgical participation by Charles E. Van Barneveld, Chief of Mines and Metallurgy. This committee consisted of F. G. Cottrell, pyrometallurgy, G. H. Clevenger, hydrometallurgy, and D. A. Lyon, electrometallurgy. Conditions arose which made it impossible to proceed with the plans of the electrometallurgical section of the exhibit, but the work

FIG. 1—EASTERN FAÇADE, PALACE OF MINES AND METALLURGY

of procuring subscriptions from the mining industry and manufacturers for the hydrometallurgical and pyrometallurgical exhibit was at once proceeded with and met with such a ready and liberal response that it was possible to proceed with the plans for the exhibit without delay.

The object of the exhibit has been three-fold. First, to present an attractive and instructive exhibit which would serve to interest the general public in the metallurgical industry. Second, to bring about a closer relationship between the metallurgical industry and the Bureau of Mines and thus enable the Bureau to most effectively assist the industry in the solution of its problems. Third, to begin and, so far as possible, complete the investigation of certain definite metallurgical problems.

The exhibit occupies about 7000 sq. ft. floor area, directly opposite the north entrance of the Palace of Mines, and is in two sections, the east half of the block being devoted to a working display of hydrometallurgical machinery, while the west half of the block is devoted to working laboratories.

The work in the laboratories is under the general direction of Dr. F. G. Cottrell, Chief Chemist of the Bureau of Mines. The chemical research laboratory is under the direction of Dr. L. H. Duschak, Chemical Engineer of the Bureau of Mines. Pyrometallurgical investigations are under the direction of A. E. Wells, Metallurgist of the Bureau of Mines. The hydrometallurgical research work is under the direction of Professor G. H. Clevenger of Stanford University, Consulting Metallurgist to the Bureau of Mines.

Some of the problems under investigation may be enumerated as follows:

(1) The chemistry of roasting sulphide ores in the presence of water vapor and other gases, with the view of devising means of recovering the sulphur. This investigation is being conducted in both the chemical research laboratory and in a small multiple-hearth furnace in the pyrometallurgical laboratory.

(2) Microscopic examination of slags from copper and lead smelting plant, and investigation to determine the possibility of recovery of the metals from the slag.

(3) Investigation of the chemistry and commercial possibilities of the wet thiogen process for the recovery of sulphur from smelter flue gases.

(4) A preliminary investigation of the mechanism of slime settling.

(5) An investigation of the chemistry of the cyani-

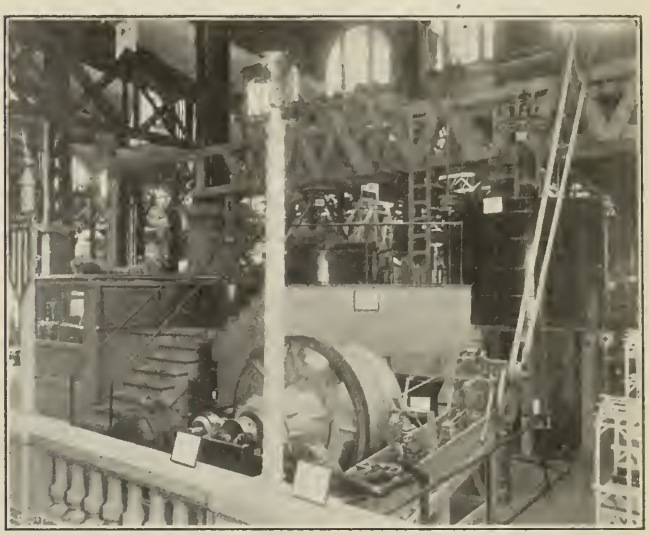

FIG. 2—EXHIBIT OF HARDINGE MILL AND DORR CLASSIFIER AND THICKENER

dation of silver minerals and its bearing upon the treatment of complex silver-gold ores.

(6) Standardization of the methods of analysis and assaying used in hydrometallurgical plants.

(7) The behavior of aluminium compounds in cyanide solutions.

The results of these investigations will be published in the bulletins or technical papers of the Bureau of Mines, and eventually will be available to all who are interested.

Starting at the northeast corner of the block is a model ore sampling mill which is an exact reproduction of the Colorado Springs sampling plant of the Portland Gold Mining Company.

Adjoining this is a $4\frac{1}{2}$-in. Hardinge tube mill, arranged in a closed circuit with a small Dorr simplex classifier. The overflow from the classifier is elevated to a Dorr thickener by means of a Byron Jackson direct-connected centrifugal pump. The overflow from the thickener is returned to the classifier sand and to the tube mill discharge. The underflow from the Dorr thickener is transferred by diaphragm pump to a Dorr agitator.

The pulp, after treatment in the agitator, is pumped by a single stage direct-connected Byron Jackson pump to a Merrill 10-frame, 3 x 4 in., automatic sluicing slime press, where it is washed by solution introduced by the same pump. The press is sluiced by means of a four-stage direct-connected Byron Jackson pump. The clear solution effluent from the press during the filling and washing is delivered by gravity to a 4 x 6 ft. sump tank.

The cloudy solution overflowing from the thickener is delivered by gravity to a second sump from which it is pumped to a Merrill 20-frame 3½ x 3½ ft. automatic sluicing clarifying filter. The clear solution from the clarifying press is delivered by gravity to the sump which received the slime press effluent.

At intervals of from 6 to 8 hr. or more, the deposit on the filter cloths of the clarifying press is removed by sluicing with high-pressure jets of water introduced through a rotating sluicing pipe, this operation being similar to that of sluicing the slime press, except that in the clarifying press the sluicing pipe is located at the center of the plates and frames and rotates in one direction only, whilst in the slime press the sluicing pipe is located at the bottom of the plates and frames and is reciprocated back and forth.

The clear rich solution in the first tank is pumped to a Merrill 10-frame 36-in. agitating precipitation press, the precipitant being delivered into the suction of the pipe between the tank and the pump by a specially designed feeder which can be readily adjusted to feed a varying amount of precipitant. The dry finely powdered precipitant drops from this feeder into a grinding pan or emulsifier, into which is also fed enough water or solution to form an emulsion with the precipitant. The clear effluent barren solution is delieverd to a third sump to be used as a wash for the pulp collected in the slime press. The precipitant is retained in the filter press until it becomes time for a "clean-up."

As it is not feasible to secure a continuous supply of fresh ore in the model cyanide plant, the same pulp is kept in circulation by returning the discharge from the Merrill press to a second Dorr thickener. The overflow from the second thickener is returned to the filter effluent sump, while the underflow is pumped up to the agitator tank by means of a second diaphragm pump. In this way continuous operation is made possible with a minimum amount of material in circulation.

An alternate system of filtration is represented by the Oliver filter. This is the smallest size of standard Oliver filter manufactured, having a drum 3 ft. in diameter by 2 in. in width. A 25 in. to 28 in. vacuum is maintained by a 3½ in. Root rotary wet vacuum pump. Air at 5 lb. pressure from a Baker-Hansen rotary blower is used for the release of the cake and agitation. A 1½ in. Krogh centrifugal pump returns the pulp from the agitator to the Dorr thickener.

This filter is being used in the exhibit for demonstrating the dewatering of flotation concentrate from the Anaconda Copper Mining Company's Washoe plant. The concentrate is fed to the filter from a 4-ft. Dorr thickener at a consistency of one part of water to one part of solids, and is discharged as a ¾-in. cake containing 6 per cent moisture. The discharged cake is carried by belt conveyor to an agitator, where it is broken up and returned to the circuit. In practice this conveyor would probably discharge into a briquetting machine.

The west half of the block is devoted to laboratories, models and charts. In the assaying and general laboratory are installed Braun laboratory crushers, pulverizers, mixers and samples, Abbe ball mill, Tyler Ro-Tap sieve shakers, a complete set of Tyler standard screens, Braun combination gas furnace, gasoline crucible furnace, two muffle assay furnaces for burning crude oil, constant temperature roller agitator, Féry radiation pyrometer, Bristol recording thermometers, and the other accessory equipment necessary in such a laboratory. A balance room, completely enclosed in glass, contains Ainsworth assay and analytical balances and a Keller assay balance. A feature which has proven of unusual interest to the general public in this section is a special chart which shows all the operations of fire assaying.

Adjoining the assay and ore testing laboratory is the pyrometallurgical laboratory. At the present time the equipment of this laboratory consists of the following pieces of apparatus:

(1) A Wedge multiple-hearth roasting furnace, especially designed for experimental work. This furnace has a capacity of 500 lb. of ore per day, and is now being used for experimental work in connection with the distillation of sulphur from sulphide ores, and also for the reduction of barium sulphite and sulphate in connection with an investigation of the thiogen process.

(2) A Monarch tilting furnace. This is being used in connection with the work upon the thiogen process. Bristol indicating and recording pyrometers are used for showing the temperature of the Wedge furnace and the tilting furnace.

(3) A working unit of an electrical precipitation apparatus having a capacity of about 500 cu. ft. of gas per minute. This is complete with transformer, rectifier and precipitation units, and is so arranged that it may be used in conjunction with the experimental Wedge roaster.

(4) A cooling tower, designed by Hunt & Fogg, is being used in connection with the Wedge furnace.

The research laboratory at the other end of the space is surrounded by glass partitions on account of the delicate nature of the work. The experimental work in this laboratory is for the purpose of determining the fundamental chemical principles involved in certain of the metallurgical processes under investigation on a larger scale in the pyrometallurgical and hydrometallurgical laboratories.

The equipment used in this laboratory includes Siemens & Halske indicating and recording pyrometer, a Tycos recording pyrometer and special apparatus designed and constructed in the laboratory. Further equipment includes a complete installation of Leitz micro-metallograph and accessory equipment for microscopic examination of ores, metals and metallurgical products. In connection with this there is also a band saw especially constructed for cutting rock sections, as well as two polishing machines for preparing sections for microscopic examination.

An analytical laboratory, fully equipped with hoods, fume cupboards, gas, compressed air, vacuum and running water, is located adjoining the research laboratory and is used for the analytical work which arises from the various investigations which are being made. Electric furnaces and hot plates of the Electric Heating Apparatus Co. have also been installed.

Facing the main entrance to the exhibit are illuminated charts showing the typical operations of lead and copper smelting. In the same space is a model of an electric precipitation installation, a small working model of a bag house, and also a small model of a Dwight and Lloyd sintering machine. In a glass case is shown a collection of products from both lead and copper smelters, and in another case is shown a complete set of products representative of the Homestake metallurgical practice. Directly back of this space is a small office and conference room.

The funds necessary for the installation and maintenance of the exhibits have been supplied by the following: American Smelting and Refining Company; Anaconda Copper Mining Company; Dorr Cyanide Machinery Company; International Nickel Company; Nevada Mine Operators' Association; Oliver Continuous Filter Company; Phelps-Dodge & Company; Portland Gold Mining Company; the Thiogen Company; W. S. Tyler Company.

The metallurgical Exhibit Fund is deposited with The Union Trust Company of San Francisco, and is administered by the following trustees: F. G. Cottrell, E. B. Braden, Charles E. Van Barneveld, Albert Burch and C. L. Ely.

The following have loaned equipment or donated supplies for the exhibit:

Paul O. Abbe, New York City: Pebble mills, including accessory equipment and cost of installation.

Wm. G. Ainsworth & Sons, Denver, Col.: Assay balance and analytical balances and weights.

Baker-Hansen Company, Oakland, Cal.: Rotary air compressors, rotary vacuum pump, including complete installation.

J. T. Baker & Co., Phillipsburg, N. J.: Laboratory reagents.

Bausch & Lomb Optical Co., Rochester, N. Y.: Microscopes; arc lamp for microscopic work.

Braun Corporation, Los Angeles, Cal., and Braun-Knecht-Heimann Co., San Francisco, Cal.: Laboratory crushers, pulverizers, samplers and mixers, cupel machine, assay furnaces, crucibles, flues and chemicals for assaying, assay chart, roller agitator, apparatus and glassware for ore testing laboratory, including cost of installation.

The Bristol Company, Waterbury, Conn.: Recording and indicating thermometers and pyrometers.

Byron Jackson Iron Works, San Francisco, Cal.: Centrifugal pumps.

Crocker-Wheeler Co., San Francisco, Cal.: Electric motor.

Dorr Cyanide Machinery Co., New York City: Classifier for fine ground ore, continuous thickener, continuous agitator, including accessory equipment and complete installation.

Dwight & Lloyd Sintering Co., New York City: Model sintering machine.

Edison Storage Battery Supply Co., San Francisco, Cal.: Storage battery.

Electric Heating Apparatus Company, New York City: Electric hot plates, electric crucible furnace.

Charles Engelhard, New York City: Recording and indicating pyrometers.

Guernsey & Company, San Francisco, Cal.: American Blower Company exhauster.

Hardinge Conical Mill Company, New York City: Conical tube mill, including complete installation.

H. W. Johns-Manville Co., San Francisco, Cal.: Fireproof cements and asbestos.

Krogh Pump Manufacturing Co., San Francisco, Cal.: Centrifugal pumps.

Keller Manufacturing Co., Salt Lake City, Utah: Assay balance.

Ernst Leitz, New York City: Micro-metallograph and automatic arc lamp, microscopes.

Mammoth Copper Mining Co., Kenneth, Cal.: Operating model of bag house.

Merrill Metallurgical Company, San Francisco, Cal.: Automatically sluiced filter press, automatically sluiced clarifying filter, agitating precipitation filter, zinc dust feeder and emulsifier, including complete installation.

Monarch Engineering Co., Baltimore, Md.: Tilting furnace.

Oliver Continuous Filter Co., San Francisco, Cal.: Continuous filter, including complete installation.

Pacific Tank and Pipe Company, San Francisco, Cal.: Redwood tanks, including installation.

Portland Gold Mining Co., Colorado Springs, Col.: Operating model of sampling mill.

P. H. & F. M. Roots Co., Connersville, Ind.: Rotary vacuum pump.

E. H. Sargent Company, Chicago, Ill.: Water still.

I. C. Smith, Los Angeles, Cal.: Air compressor.

Spencer Lens Company, Buffalo, N. Y.: Microscopes.

H. B. Squires Manufacturing Co., San Francisco, Cal.: Cutler-Hammer air-pressure control apparatus.

Taylor Instrument Companies, Rochester, N. Y.: Féry radiation pyrometer, thread recorder and thermoelement.

W. S. Tyler Company, Cleveland, Ohio: Ro-Tap sieve shaking machine and standard sizing screens.

Union Oil Company of California, San Francisco, Cal.: All fuel oil, gasoline distillate, lubricating oils, used in the exhibit during the Exposition.

Utley Wedge, New York City: Mechanical roasting furnace.

Fred. Ward & Sons, San Francisco, Cal.: Carborundum grinding powder.

Western Precipitation Company, Los Angeles, Cal.: Electrical precipitation apparatus and model of installation.

Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.: Electric motors.

G. E. Witt Co., San Francisco, Cal.: Pressure reducing valve.

The United States Geological Survey have co-operated through the detailing from their staff of F. B. Laney and E. S. Bastin, who have charge of the microscopic and mineralogical work.

The University of Utah has detailed Prof. R. H. Bradford and Fellow H. J. Morgan to co-operate in the investigations which are being made.

Prof. Welton J. Crook of the South Dakota State School of Mines has contributed his services in connection with some work upon the cyanidation of silver minerals.

The following men have been detailed by the United States Bureau of Mines, largely from the San Francisco Station: G. H. Clevenger, consulting metallurgist; F. G. Cottrell, chief chemist; L. H. Duschak, chemical engineer; W. Freeman, junior chemist; R. E. Head, skilled laborer; G. N. Libby, assistant metallurgist; A. E. Wells, metallurgist; E. H. Zeitfuchs, junior chemist.

The following men have been employed with the co-operative fund: C. E. Brandt, analytical chemist; R. Buhman, assistant chemist; H. S. Coe, assistant metallurgist; H. B. Jordan, assayer; G. A. Linhart, analytical chemist; E. A. Madison, draughtsman; E. I. Oberlightner, laborer; K. Pyle, assistant metallurgist; H. W. Young, assistant metallurgist.

Graphite brushes for use upon commutators are being furnished by the Joseph Dixon Crucible Co. of Jersey City. It has been found that they are free from grit and are self-lubricating.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in March, 1915, was 63. The total quantity of ore milled during that period was 2,123,465 tons. There were 9745 stamps in operation, with an average duty of 9.22 tons per 24 hours. Tube-mills in commission numbered 309. The yield for the month was 676,221 fine ounces gold. The working profit per ton milled was only 8s. 4d., as compared with 9s. in February, 1914.

Vulcanized Fibre

BY CHARLES ALMY, JR.

Despite the fact that the annual production of Vulcanized Fibre in this country exceeds 15,000,000 lb., comparatively little is known either of the method of manufacture or the properties of this widely used material. Books on Industrial Chemistry or Cellulose Products, as a rule, dismiss the subject with a few words, often inaccurate or misleading, and give in many cases the impression that Vulcanized Fibre is still largely in a visionary stage, interesting chiefly from the theoretical standpoint.

FIG. 1—MACHINE TURNING OF VULCANIZED FIBRE SHOWING ITS TOUGHNESS

The purpose of this brief article is to explain in a few words the main facts regarding its manufacture and to outline some of the properties that have made it so widely useful to the engineering professions.

Vulcanized Fibre was invented by an English chemist named Taylor about the year 1869, but its commercial development dates from 1873 when the American Vulcanized Fibre Company was established in Wilmington, Del. Although the original patents included the use of sulphuric or nitric acids with or without the addition of various metallic salts, the process as practised to-day is confined to the action of zinc chloride on an all cotton cellulose paper, unsized and unloaded.

This paper is passed over heated cylinders through a bath of zinc chloride maintained at about 70 deg. Baume and 40 deg. C., depending upon the quality of the paper and the atmospheric conditions. It is then rolled up over large heated drums to the desired thickness, the zinc chloride hydrolyzing the cellulose and gelatinizing the surface to such an extent that the paper unites together and forms an almost homogeneous mass. Fibre tubes are made in a similar manner by substituting for the large drums, mandrels of the proper size to give the desired inside diameter.

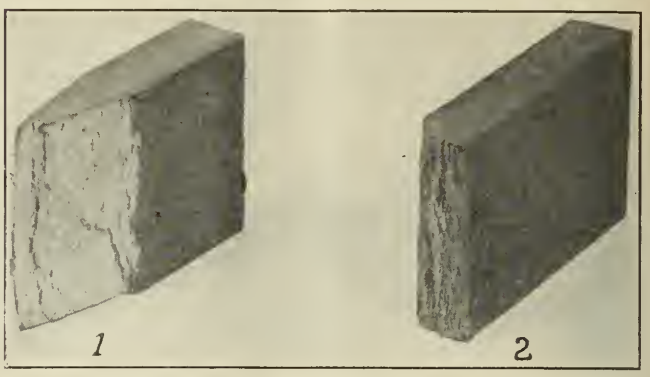

FIG. 3—TENSILE TEST—NO. 1, SP. GR. 1.25, FRACTURED AT 8650 LB. PER SQUARE INCH—NO. 2, SP. GR. 1.37, FRACTURED AT 12,250 LB. PER SQUARE INCH

The "green fibre" is then washed in zinc chloride baths of progressively diminishing concentration until it is commercially pure, i.e., contains less than 0.15 per cent chlorine. This process is of necessity very slow, and any attempts to expedite it are apt to result in an inferior grade of fibre or in blisters due to the increased osmotic pressure. One-quarter inch fibre, for instance, requires three to four weeks for washing, and 2-in. fibre six to eight months. The wet pure fibre is dried at a temperature of 40 deg. to 60 deg. C., after which it is pressed and usually calendered.

The finished product which has shrunk to one-half its original thickness is a homogeneous, tough, horn-like material which can be readily machined, threaded, embossed, etc., and which can be given a high polish. Fig. 2 shows cross sections of two pieces of gray vul-

FIG. 2A—GRAY VULCANIZED FIBRE, SP. GR. 1.45

FIG. 2B—GRAY VULCANIZED FIBRE, SP. GR. 1.20

canized fibre photographed across the laminations at a magnification of about 150 diameters, and illustrates very forcibly the homogeneity of the material.

Vulcanized Fibre is not waterproof, but is not injured by immersion in water, either hot or cold, and on re-

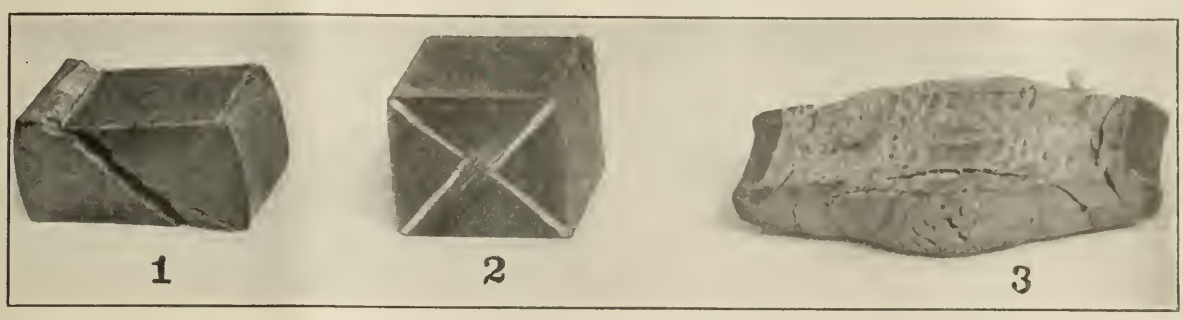

FIG. 4—COMPRESSION TESTS—NO. 1, 38,000 LB. APPLIED ON NATURAL FACES OF 1-IN. FIBRE CUBE—NO. 2, 9000 LB. APPLIED ON EDGE OF 1-IN. FIBRE CUBE—NO. 3, 90,000 LB. APPLIED ON EDGE OF 1-IN. CUBE AS IN NO. 2—NOTE HOMOGENEITY AS SHOWN BY 45-DEG. FRACTURE

drying resumes its original dimensions and properties. Neutral salts are also without any harmful effect, but most mineral acids in time cause disintegration. Organic solvents, such as ether, carbon tetrachloride, etc., and all oils are absolutely without effect on fibre, and are not absorbed in the slightest degree.

The mechanical and physical properties may be varied between fairly wide limits by proper manipulation of the chemical treatment and by varying the quality of the original paper. This fact is little appreciated by the public, and, in fact, only too little appreciated by some of the fibre manufacturers themselves. Consequently a man believing that "fibre is fibre" may purchase a grade absolutely unsuited for his particular needs, and without further investigation conclude that all fibre is worthless to him. To illustrate this point more strongly, we give in Table I the properties for two samples of material both of which sell under the name of Vulcanized Fibre.

FIG. 5—SECTION OF TRACK 4400 FT. IN LENGTH AT McKEE'S ROCKS, ON THE P. & L. E. R. R., WHERE 3000 STEEL TIES WERE INSULATED WITH AMERICAN VULCANIZED FIBER SHIMS THAT HAVE LASTED OVER FIVE YEARS

TABLE I—PROPERTIES OF TWO KINDS OF VULCANIZED FIBRE

	No. 1	No. 2
Thickness	⅛ in.	⅛ in.
Specific gravity	1.100	1.480
24 hours' absorption of water	70%	25%
Chlorine content	0.20%	0.03%
Hardness by scleroscope	25	50
Shearing strength, lbs. per sq. in.	9,000	13,000
Crushing strength, lbs. per sq. in.	33,000	43,000
Tensile strength, lbs. per sq. in.	8,000	13,000
Breakdown voltage	12,500	50,000

At a glance it will be seen that there are great differences in the properties of the two samples, and that the purchaser of fibre must take care how and where he buys in order to be sure that the manufacturer is able to and actually does give him the grade best adapted to his purposes.

Vulcanized Fibre is used in all kinds of electrical insulation; in trunks, roving cans, waste baskets and similar receptacles; and in a great variety of mechanical parts such as gears, valves, washers, bushings, etc. One of its principal applications is in railroad insulation for automatic block signals, shims, etc. Fig. 5 shows an installation of the latter and illustrates the extreme durability of the material. Vulcanized Fibre gears are noiseless and oil-proof and on account of their toughness and elasticity will outwear two or three sets of brass gears. Vulcanized Fibre valves have given continuous service for over three years in feed-water pumps, pumping hot water at 212 deg. Fahr., against 150 lb. pressure, and are far superior to rubber or composition valves for water or any neutral solution.

The tensile strength of Vulcanized Fibre which is three times that of leather, and its high dielectric strength of 200-400 volts per mil, are constantly leading manufacturers as they become more familiar with this interesting material, to adopt it for new uses, and it is hoped that this article may prove of value by suggesting to some puzzled engineer the answer to the frequent query, "What material can I use?"

The **Titanium Alloy Manufacturing Company** has prepared an illustrated booklet entitled "How Titanium Bronze Is Produced." It is profusely illustrated with photographs of the various departments of its works.

The Electrolysis of Copper Sulphate Liquors, Using Carbon Anodes*

BY LAWRENCE ADDICKS

Through the courtesy of Dr. James Douglass, I am permitted to give the results of quite an extended research conducted at Douglas, Ariz., on the possibilities of electrolytic recovery of copper from liquors resulting from sulphate leaching.

Starting with sulphide copper ores or concentrator products therefrom, which was the particular case under consideration, the simplest form of the proposition is to make sulphuric acid from concentrates by the usual roasting procedure, use this for leaching, electrolyze with lead anodes and precipitate upon iron sufficient of the liquor to maintain a reasonable degree of purity in the electrolyte. Such a method is commercial when there is no serious competition by other processes, as where concentrator tailings are very rich in values or where some local handicap to smelting exists, or where there is a profitable market for a surplus of sulphuric acid.

A very different way of attacking the problem was the old Siemens-Halske process, where ferric sulphate was used for the direct consumption of sulphides, the resulting ferrous-cupric sulphate liquor being electrolyzed in a diaphragm cell, obtaining a copper cathode and regenerating the ferric sulphate at the same time. This failed, partly due to the non-existence of a satisfactory diaphragm and partly to the shortcomings of the leaching agent.

Then Tossizza attacked the question by applying the long known action of sulphur dioxide gas as a depolarizer, introducing it directly into the cell, making sulphuric acid in accordance with the inclusive reaction.

$$CuSO_4 + SO_2 + 2H_2O + \text{current} = Cu + 2H_2SO_4$$

and reducing the voltage in proportion to the energy of oxidation at the anode. The direct use of sulphur dioxide as a depolarizer is undesirable for three reasons: (1) The escaping gas makes the atmosphere of the cell room unbearable and the ventilating problem, while perhaps not insurmountable, would be a very serious matter; (2) the gas escapes so readily from a warm liquor in motion that the consumption would be prodigal and there are limits, even though rather liberal ones, upon the quantity available; (3) it is a difficult matter to obtain a sufficient absorption for efficient depolarization, using roaster gas, unless compressors or other complications are resorted to.

The research work finally developed a process based upon the depolarizing value of ferrous sulphate, using a carbon anode, the sedative value of aluminium sulphate (U. S. patent No. 1,138,921) thereby restraining the redissolving of the cathode copper, and the reduction of the ferric sulphate by sulphur dioxide outside of the cell room. It is the purpose of this paper to discuss the various factors involved in this scheme of procedure.

While it is not possible to divorce entirely these different factors, for clearness' sake they will be taken up individually as follows:

1. Circulation and agitation.
2. Anodes and depolarization.
3. Cathodes and corrosion.
4. Sulphur dioxide and reduction of ferric sulphate.
5. Efficiencies.

Circulation and Agitation

In any electrolytic process the constituents of the electrolyte taking part in the oxidation at the anode and the corresponding reduction at the cathode must be continually supplied at the electrodes by some method of circulation at a rate sufficient to satisfy the demands of the current at the density employed. If this is not done the voltage will rise until the next reaction in line occurs, or if the voltage is limited, the current will fall, or flow spasmodically. In our particular case ferrous sulphate must be supplied at the anode fast enough to take up the oxygen released and copper at the cathode in sufficient quantity to prevent the liberation of hydrogen or precipitation of impurities. A relatively low rate of circulation suffices at the cathode if the liquor is reasonably rich in copper sulphate, as demonstrated in ordinary refining with a soluble anode. At the anode, on the other hand, a violent circulation is necessary, and this is best obtained by agitation with compressed air, apart from the relatively low circulation necessary for replenishment.

The reason for this behavior of the anode is doubtless due to the fact that a gas is liberated on a rather rough surface and more or less of a mechanical scouring action is necessary as well as a sufficient concentration of ferrous iron. In ordinary refining work the liquor is circulated at a rate which displaces the contents of a cell in several hours. In this work, at a current density

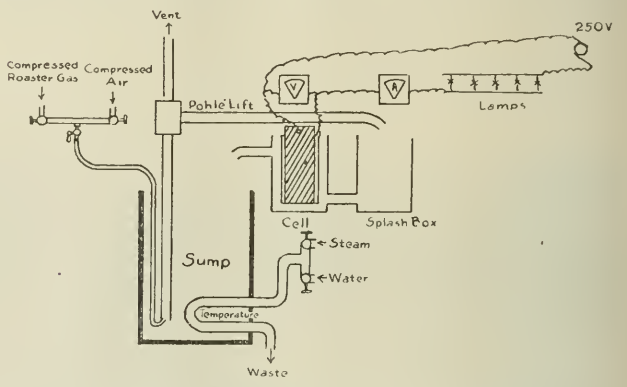

FIG. 1—CELL ARRANGEMENT FOR VOLTAGE TESTS

Carbon anode, 3½ x 4 in. (9 x 10 cm.). Copper cathode, 4 x 4 in. (10 x 10 cm.). Electrodes 1 in. apart (2.5 cm.).

of 4 amp. per square foot (44 per square meter) a relatively low rate of circulation proved adequate, but at 8 amp. per square foot (88 per square meter) the contents of the cell, in small scale experiments, had to be displaced every thirty seconds, and at 16 amp. every twenty seconds, in order to obtain voltages indicating satisfactory depolarization, although these were readily reached by stirring or agitation. Any method of agitation which affords rapid movement of the electrolyte over the face of the anode may be used, but the introduction of compressed air at the bottom of the cell seemed the most practical application.

Fig. 1 is a diagram of the apparatus first used in making these experiments. As the first runs were purely voltage determinations, agitation was dispensed with, a stirring rod being vigorously used at the time a reading was taken. Compressed roaster gas was at first used in the Pohlé lifts, but later air was substituted. After complete voltage records had been obtained for varying current density, composition of electrolyte, temperature, etc., the question of current efficiency was studied, several cells being connected in series and compressed air being introduced through a perforated false bottom in each cell.

Finally large cells were operated, using 600 amp., as shown in Fig. 2, and compressed air was introduced at the bottom of each cell, through a 1½-in. (3.8-cm.) lead pipe, coiled in a spiral and perforated at regular intervals with eighty 3/64-in. (1.2-mm.) holes. Measurements showed that the pressure necessary started

*A paper read at the San Francisco meeting of the American Electrochemical Society Sept. 17, 1915.

FIG. 2—FULL SIZE CELLS

FIG. 4—ANODE PARTS FIG. 5—COMPLETED ANODE

barely above that of submergence or about 1½ in. (3.8 cm.) of mercury. Then as these holes gradually became choked by crystals or sediments, the pressure rose to about 3 in. (7.6 cm.) of mercury. This would take several hours. Then steam was introduced into the air system for several minutes, which fully cleared it. The quantity of air used was about 500 cu. ft. (14 cu. m.) an hour, and as each cell deposited over a pound (453 gr.) of copper an hour, it will be seen that the power for compressing this air was very small.

The general plan of operation adopted was, therefore, a circulation sufficient to replenish the liquor at a rate which would hold the anode oxidation product—ferric sulphate—at a concentration which would not seriously corrode the cathode, and compressed air agitation sufficient to obtain a minimum voltage by depolarization. An idea of these effects may be obtained from Fig. 3, which shows the voltages in one of the small cells with and without agitation for different current densities and temperatures. It will be noted that rising temperature assists the depolarization while rising current density impedes it.

Anodes and Depolarization

Three commercially possible materials are to-day available for use as insoluble anodes in sulphate liquors:

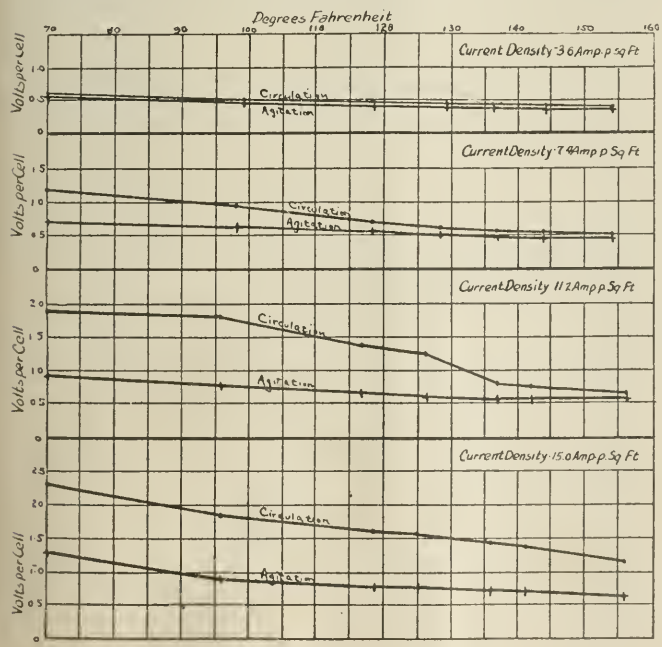

FIG. 3—EFFECT OF AGITATION UPON CELL VOLTAGE

Electrolyte—3.7 per cent Cu, 2.0 per cent Fe, 4.3 per cent Al_2O_3, 4.2 per cent H_2SO_4.

Lead, magnetite and carbon. There are two objections to lead, viz., it does not work at low cell voltages even in the presence of depolarizers, and its life is more or less limited, due to the flaking off of the sulphate and peroxide formed on its surface.

Magnetite is fragile and expensive and it remains to be seen whether it will hold its own in large-scale work. The showing made at Chuquicamata will settle this point.

Carbon has been used for many years as an anode in chloride electrolytes and has given satisfactory service. In many of these cases free chlorine gas has been evolved at the anode, so that the disintegration of the carbon conglomerate in sulphate solutions must be due to the chemical properties of the oxygen formed, rather than to any physical attack. We know that charcoal, for example, has the property of absorbing large volumes of gases and we find that oxygen evolved at a carbon anode will react markedly with depolarizing agents, while oxygen liberated in the same way at a lead anode gives but partial response. It seems likely, therefore, that something akin to ozone is formed at the surface of the carbon anode, and that in the absence of substances susceptible of more ready oxidation, the carbon itself or its more or less carbonized binding material is oxidized and the anode breaks down.

The early work done with electrolytes weak in either sulphur dioxide or ferrous sulphate, showed a very decided softening of the surface of the anode. The later work, after ferrous sulphate was definitely adopted as the depolarizing agent, and a minimum of 1½ per cent ferrous iron kept in contact with the anode by agitation, showed no sign of any deterioration of the anode after several months' use. Nearly all of the work was done with Acheson graphite slabs, but some tests were made with baked carbon slabs and as far as these tests went, no difference was found in the behavior of the two.

The construction of a practical anode out of the ½ x 4 inch (1.25 x 10 cm.) slabs used gave some trouble. After several trials the design shown in Figs. 4 and 5 was developed and gave satisfactory service. The carbon strips were first trued up and the necessary holes drilled. Then they were electroplated with a thin film of copper at the upper end and the copper contact strips attached with copper bolts and nuts. The exposed copper parts were then given a coat of asphaltum paint and a lead apron burned around the entire upper end. This construction prevented the electrolyte from reaching the copper parts and dissolving them either chemically or electrolytically and the voltage drop between bus bar and active anode surface was negligible.

When a piece of carbon and a strip of copper are immersed in an acidulated copper sulphate solution, a voltmeter indicates an open circuit voltage of 0.29 volt,

the carbon being, of course, electro-negative to the copper. This counter e.m.f. has, therefore, to be overcome when using carbon as an anode. The data given in Fig. 3 can be rearranged to show this; this is done in Fig. 6, and brings out clearly the effect of agitation, temperature and current density. No attempt has been made to measure actual polarization voltages or figure the theoretical voltages possible, but the solid lines in this diagram represent the actual voltages obtainable under corresponding working conditions. The liquors used in many of these measurements contained a few hundredths of a per cent of free sulphur dioxide, but it is not believed that this has any bearing on the voltages obtained. All percentages by analysis given in this paper represent grams per 100 c. c., except when measuring the percentage of sulphur dioxide in roaster gas, which is stated by volume.

Next a series of investigations was undertaken on the effect of varying quantities of free acid, iron and alumina in the electrolyte upon the voltage obtainable. In order to keep this paper within reasonable length, but a few representative diagrams will be given from the great number of measurements made and tabulated. Fig. 7 shows the general relation between power and voltage and current efficiency in the electrolysis of cupric sulphate, for convenience in considering the possible recovery per kw.-hr. under various conditions.

Figs. 8 and 9 show the effect of varying the quantity of free sulphuric acid in the electrolyte at a constant temperature of 120 deg. Fahr. (49 deg. C.). As increasing temperature was found of material assistance both in reducing the ohmic resistance of the cell and in rendering efficient depolarization more easily obtainable, a cell temperature of about 115 deg. Fahr. (46 deg. C.) was determined upon when large scale work was taken up. Too high a temperature, on the other hand, increased cathode corrosion, a matter which will be discussed later on. Fig. 10 shows the working voltages obtained with varying acidity in large scale work. It is evident that the acid assists somewhat in the mechanism of depolarization and lowers the resistance of the electrolyte, but that there is no warrant for carrying the high percentage of acid used in regular refining work. The enormous quantity of salts present in the electrolytes used is doubtless the cause of this difference. Most of the work was, therefore, done at an acidity of not less than 4 per cent. Too high an acid content impeded the solution of sulphur dioxide, as will be shown later. The temperature in Fig. 10 was 119 deg. Fahr., the electrolyte contained 4.3 per cent Cu, 3.5 Al_2O_3, 2.4 Fe.

Next the effect of aluminium sulphate was taken up and the results obtained at a temperature of 120 deg. Fahr (49 deg. C.) with varying current densities are shown in Fig. 11, and similar data for a fixed current density with different temperatures in Fig. 12. These two sets of curves have been selected as representative of the general effect alumina has of interfering with depolarization. It was found in regular work that 4 per cent was the maximum which could be carried in the electrolyte without excessive voltage, disproportionate agitation or the production of soapy froth. On the other hand, it is desirable to carry as much as possible on account of its restraining effect upon cathode corrosion. It may be said here that a current density of 13 amp. per square foot (143 per sq. m.) was decided upon as causing about as rapid a production of oxygen at the anode as could be properly handled by the depolarizing agent. Alumina also reduces the absorbing power of liquor for sulphur dioxide.

Next the effect of ferrous sulphate was studied. Fig. 13 shows that in the absence of agitation the voltage decreases in proportion to increasing concentration of ferrous iron but that except at high temperatures even

very concentrated solutions give but partial depolarization. On the other hand, with agitation, the voltage drops immediately as iron is introduced, to a minimum

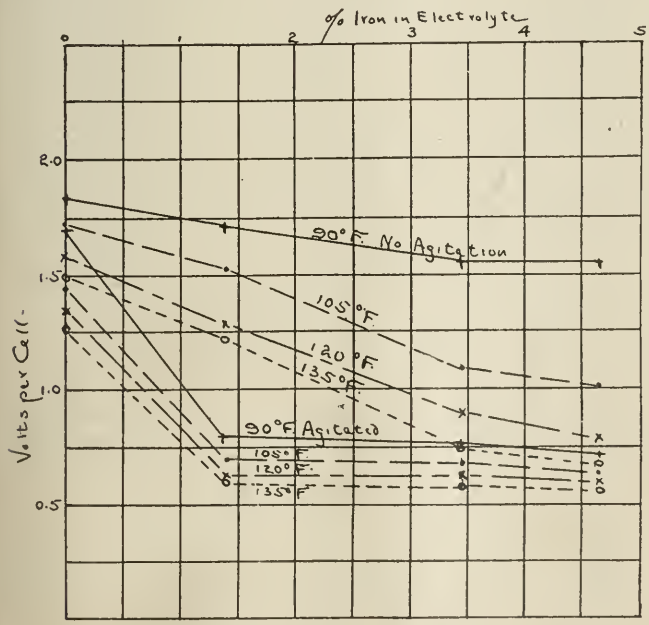

FIG. 13—VOLTAGE VS. IRON

2.6 per cent Cu, 4.4 per cent Al_2O_3, 4.2 per cent H_2SO_4, 12.5 amp. per square foot (137 per square meter).

which is practically unaffected by further additions. No ill effect is produced by very high iron. The reason that agitation slightly lowers the voltage on the zero iron line is probably that the small quantities of sulphur dioxide present in the solutions have a slight depolarizing effect.

The relative values of sulphur dioxide and ferrous sulphate as depolarizing agents are taken up in Fig. 14. A solution showing but the merest trace of iron present by analysis was examined with varying proportions of sulphur dioxide added. Then sufficient ferrous sulphate was added to make the iron content 1.35 per cent. At 90 deg. Fahr. (32 deg. C.) and 13.2 amp. per square foot (145 per square meter), and in the absence of either ferrous iron or sulphur dioxide a voltage of nearly 1.9 is observed. Agitation drops this slightly, to about 1.8 volts. Adding SO_2 up to a content of 0.35 per cent has but little effect in the absence of agitation, but when agitated the cell voltage drops steadily as the strength of SO_2 increases; 0.35 per cent, however, brings the voltage down to but 1.25, and apparently a high content would be necessary to effect anything like the depolarization corresponding to the complete utilization of the anode oxygen. On the other hand, the moment any ferrous sulphate is added, the voltage drops to the value expected. It was, therefore, concluded that the presence in the liquor of the small quantities of sulphur dioxide which it is possible to absorb from relatively weak roaster gases, afforded no gain in depolarizing, while introducing various handicaps in other directions, so that ferrous sulphate was settled upon as the depolarizing agent and a minimum of 1.5 per cent ferrous iron determined upon.

Cathodes and Corrosion

Two problems were encountered at the cathode. The corrosive effect of the ferric sulphate produced at the anode made it difficult to obtain a high current efficiency, and under certain conditions the deposit would be tarnished by a film of copper sulphide.

The first difficulty is expressed by the reaction

$$Cu + Fe_2(SO_4)_3 = CuSO_4 + 2FeSO_4$$

Fig. 15 shows the corrosion rate to be expected in an acid solution of ferric sulphate. It is self-evident that the corrosion may be expressed in terms of weight lost per unit of superficial area of copper exposed to the wash of the liquor. It will be noted that the speed of the reaction is proportioned to the concentration of ferric iron and is greatly accelerated by heat.

The rates of corrosion were measured in a motor-

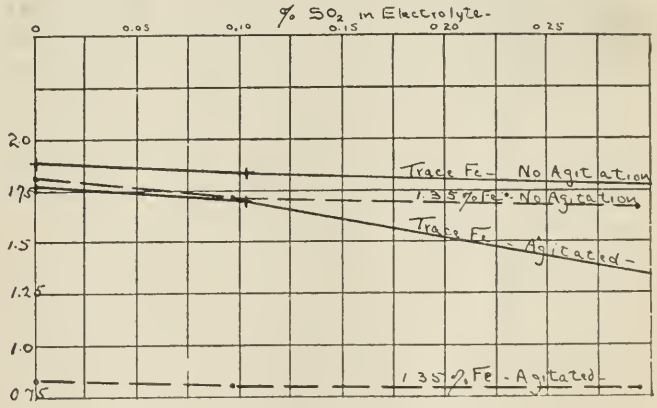

FIG. 14—VOLTAGE VS. SULPHUR DIOXIDE

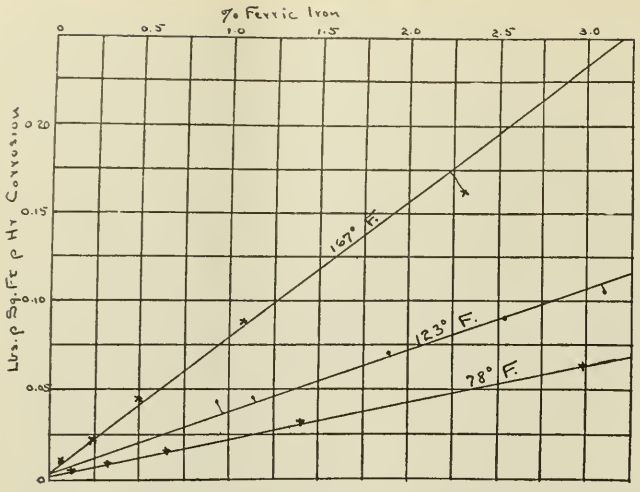

FIG. 15—REDUCTION OF FERRIC SULPHATE BY COPPER

Liquor: 4 per cent H_2SO_4 + × $Fe_2(SO_4)_3$.

driven shaking machine. This same apparatus was also used in the determination of the ferric iron in liquors. When simply a rate of corrosion was desired, the liquor was taken in such quantity that a measurable loss in the weight of the copper strip was obtainable without serious change to the strength of the liquor. When the ferric iron contents of the liquor was to be determined, on the other hand, the quantity of liquor was chosen so that complete exhaustion would not take an unreasonable time. Fig. 16 gives the characteristics of the machine. The oxidation error shown by constant loss in weight of the strip after twenty hours is very small.

The corrosion rates shown in Fig. 15 are very large. Thirteen amperes per square foot (143 per sq. m.) would deposit 0.034 lb. on a square foot (169 gr. per sq. m.) in an hour. From the diagram it appears that about 0.75 per cent ferric iron at 123 deg. Fahr. (51 deg. C.) would corrode as fast as the current deposited. A study was, therefore, made of the possible effects of the other components in the solution with quite remarkable results.

Fig. 17 shows the effect upon corrosion by adding either cupric, ferrous or aluminium sulphate to a liquor carrying 0.2 per cent iron as ferric sulphate and 4 per cent sulphuric acid. The copper and iron have but a slightly depressant effect upon the speed of reaction of the ferric iron upon the copper strip; the alumina, however, has a most marked effect and when the solution is practically saturated with aluminium sulphate the corrosion is almost completely arrested. Fig. 18 shows this same relation for a liquor carrying 3 per cent of both cupric and ferrous sulphates, being within the range of composition of a practical electrolyte. Fig. 19 shows that the amount of free acid present has but very slight effect. It, therefore, was determined to use aluminium sulphate as an antidote to ferric sulphate and it is believed this property of alumina may have wide application. No explanation is offered of the mechanism of this effect. It seems to slow down various reactions; for example, copper appears to cement upon iron with more difficulty. With alumina present, it is more difficult to depolarize, less sulphur dioxide can be absorbed, etc.

The second general difficulty, that of obtaining a bright deposit, was found to be due to the operation of several side reactions depositing either cupric sulphide or cuprous chloride upon the cathode. In the first place the work was done where the climatic conditions caused a tremendous amount of evaporation—some 200 units of water per unit of copper deposited had to be replaced—and the local water was full of salts, mainly chlorides. The electrolyte, therefore, rapidly built up in chlorides

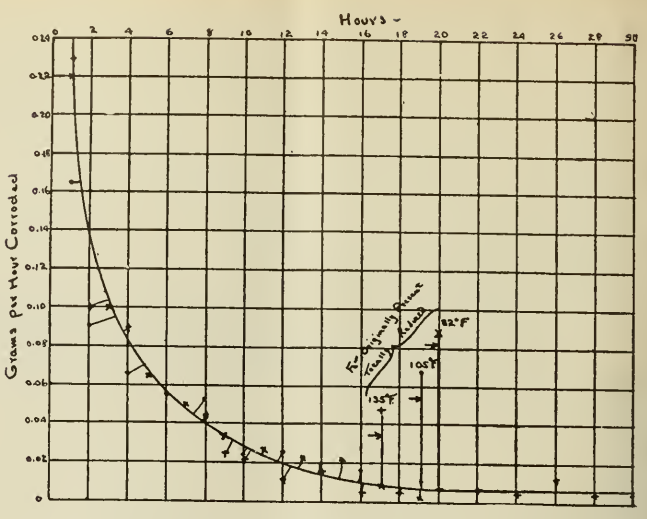

FIG. 16—OXIDATION ERROR OF SHAKING MACHINE

until about 0.1 per cent Cl was found to be present by analysis. This resulted in a precipitation of cuprous chloride on the cathode which, owing to its actinic property, caused a tendency to blacken upon exposure to the light. Chlorine further reacted with the SO_2 when it was present in the liquors to form a cupric sulphide

film on copper. Finally unless the reduction of ferric sulphate by sulphur dioxide was carried out under proper conditions, some unknown practical products of reduction were formed which appeared to reduce to cupric sulphide at the cathode.

A brilliant deposit can easily be obtained where the liquor in the cells is free from chlorides or sulphur dioxide and any previous reduction of ferric sulphate has been properly carried out.

Sulphur Dioxide and Reduction of Ferric Sulphate

In Fig. 20 is given some data regarding the solubility of sulphur dioxide. In common with other gases its

solubility varies directly with the pressure and diminishes with increase of temperature until practically none remains in solution at the boiling point of the solvent. The curves in Fig. 20 are all for pure SO_2 gas at atmospheric pressure. The top curve is plotted from data in the published handbooks for the solubility of 100 per cent SO_2 in water at various temperatures at sea level and the next one corrects these data to the 26.25 in. (668 mm.) barometer under which the local experiments were made. The next lower curve shows the results obtained by simply bubbling gas through water until no further increase in dissolved SO_2 could be found by titration with iodine. The bottom curve gives the results of similar work using electrolyte as the solvent and a great decrease in the amount of SO_2 which can be absorbed will be noted. Of course, if the gas used runs less than 100 per cent SO_2, a corresponding diminution of the absorption value will be noted and Fig. 21 is a rearrangement of some of the data in Fig. 20, which shows just what can be expected with various strengths of roaster gas.

Figs. 22 and 23 are examples from a complete set of tests made, showing the effect of copper, iron and aluminium sulphates and free acid upon the solvent power of the liquor. It will be noted that the first two have but little effect, while the last two diminish markedly the amount of gas which can be dissolved. Supposedly 100 per cent gas was used in these tests. Fig. 24 shows the actual absorption obtained in practice, using a roaster gas in a tower some 6 ft. (1.8 m.) in diameter and 25 ft. (7.5 m.) high, packed with coke. In general it will be seen that we cannot hope to get more than a maximum of 0.2 per cent free SO_2 by analysis in electrolyte under operating conditions, unless compression of the roaster gas is resorted to. The furnace used was an ordinary six-hearth, 18-ft. (5.4 m.) MacDougall, arranged for metallurgical work, sending gases to waste so that 6 per cent SO_2 by volume was the maximum richness of gas obtainable.

We have three available reducing agents for ferric sulphate—sulphur dioxide, cement copper and the calcines leached as a source of copper.

For complete reduction, about 0.5 unit of sulphur as SO_2 is required for each unit of copper deposited, the iron sulphate acting as a carrier of oxygen from the anode to the SO_2 tower. As copper-bearing sulphide minerals generally carry about 2 units of sulphur per unit of copper, we have a margin of 75 per cent of the sulphur contents to cover losses in calcines, escaping tower gases and free SO_2 absorbed but later blown out of the liquors. The 0.5 unit utilized will add approximately 1.5 units free sulphuric acid to the system, which represents the amount of acid which would have to be

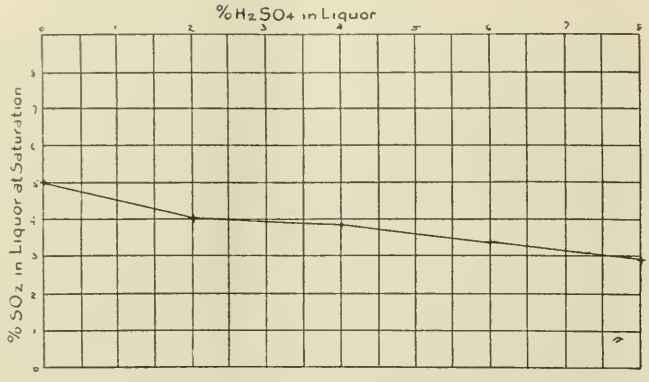

FIG. 23—EFFECT OF FREE ACID UPON SOLUBILITY OF SO_2

Liquor: 0.2 per cent Fe", 3 per cent Cu, 3 per cent Fe", 3 per cent Al_2O_3, 62 deg. Fahr. (17 deg. C.).

run away in purifying the electrolyte were SO_2 the sole source of reduction utilized.

There are several difficulties involved in the use of sulphur dioxide as a reducing agent, aside from the impossibility of obtaining a concentration stronger than 0.15 to 0.20 per cent in the liquors. When an acidified solution of ferrous sulphate is made up, it is a very pale green in color. Copper sulphate added to this at once masks this green entirely and the liquor appears a true blue. When this liquor is oxidized by anodic oxygen or by hydrogen peroxide, for example, the ferric sulphate formed turns it a bluish green. Now when SO_2 is bubbled through, it would be expected that the original blue would be restored, but unless the liquor is quite warm this is not the case, and if the liquor is hot the amount of gas absorbed is so small that but a small amount of reduction will exhaust its power. In a cool liquor the SO_2 turns the liquor a brilliant grass green, and it requires either heating to about 160 deg. Fahr. (71 deg. C.) or a period of rest of some sixteen hours to restore the blue color indicative of complete reduction. Neither of these methods are commercially practicable and the way of escape appears to be to use warm liquors, circulating them through the cells at such a rate that but about 0.1 per cent Fe is oxidized in transit, which small quantity a very small amount of free SO_2 seems capable of quickly reducing.

The next step is to use a certain proportion of cement copper as a reducing agent after the liquor leaves the tower. This not only readily reduces any traces of ferric iron or partial reduction compounds remaining, but precipitates any chlorides as cuprous chloride as

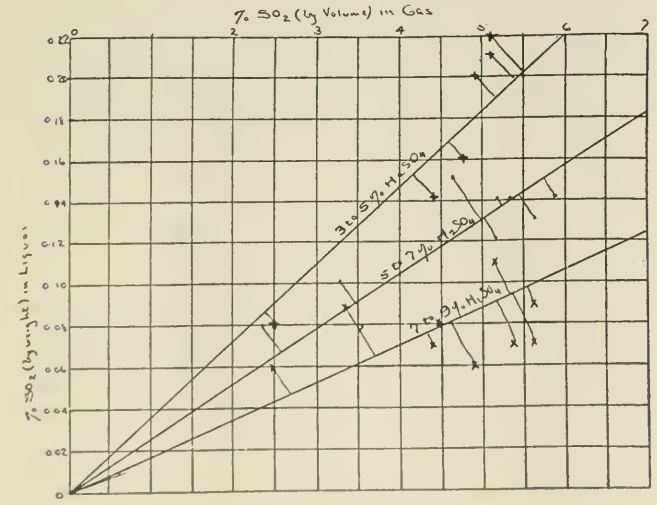

FIG. 24—SO_2 ABSORBED FROM ROASTER GAS IN PRACTICE

Liquor about 3 per cent Cu, 2.5 per cent Fe", 0.3 per cent Fe''', 3.7 per cent Al_2O_3, 85 deg. Fahr. (29 deg. C.).

well. Whatever iron, alumina or other impurities are dissolved from the calcines in leaching will have to be removed by systematic withdrawals of electrolyte which can be cemented upon iron. Perhaps 15 per cent of the copper leached will pass through this channel, and the method proposed forms an easy way of converting it to cathode copper.

The calcines to be leached are a fairly effective reducing agent for ferric sulphate, and at least half of the ferric iron contents of a liquor are reduced when passed through the leaching plant.

Efficiencies

We are interested in four efficiencies:

(1) *Current efficiency of cathodes.*
(2) *Quality of cathode.*
(3) *Efficiency of oxidation at anode.*
(4) *Sulphur efficiency.*

CURRENT EFFICIENCY AT CATHODE

About fifty separate runs were made in the cells shown in Fig. 2, during which some 4 tons of cathodes were deposited. The anodes shown in Fig. 5 were held rigidly in place on the cells, eight anodes and seven pairs of cathodes being used in each cell. In most of the work the liquor was circulated through four cells in series. The cathodes shown in Fig. 25 were freely suspended from their supporting bars by hooks made from insulated wire, but spacing blocks were so arranged that when the cathodes rocked under the influence of the compressed air agitation employed, they could not touch the anodes and cause short circuits. As mechanical short circuits were supposedly impossible, and as the agitation resulted in a beautifully smooth deposit without any tendency to form trees, we will assume that any deficiency from 100 per cent efficiency at the cathode was due to redissolving of the copper by ferric sulphate formed at the anode.

We have six factors influencing the rate of corrosion at the cathode; the concentration of ferric sulphate in the electrolyte, the temperature of the electrolyte, the concentration of aluminum sulphate in the electrolyte, the efficiency of contact with the cathode due to agitation, the surface exposed to corrosion and the offsetting effect of the rate of deposit, or, in other words, current density.

The influence of the first of these factors, the concentration of ferric sulphate, under operating conditions, is shown in Fig. 27, where the average of the ferric sulphate entering and leaving the cells in the large scale runs is plotted against the current efficiency obtained. The existence of other variables scatters the points more or less, but the relationship is clearly indicated.

The temperature of the electrolyte was held at about 120 deg. Fahr. (40 deg. C.) entering the cells in most of the large scale runs. In the presence of aluminum sulphate the effect of temperature upon corrosion is not very marked.

The aluminium sulphate was consistently held above 3 per cent and in general the protective relationship established in the small tests was verified.

The rate of agitation employed was determined entirely by the voltmeter readings. The higher the alumina the greater the agitation called for and a limit around 4 per cent Al_2O_3 was reached where the cells foamed badly.

The surface exposed to corrosion enters in rather an unexpected way. As long as the current efficiency is 65 per cent or over, the corrosion seems quite uniform and the cathode remains relatively smooth. Below this efficiency, however, the corrosion cuts grooves or furrows in the cathodes. These furrows present increased

surface to corrosion and an unstable condition ensues which causes the efficiency to fall day by day until a very low value is reached. The difference in appearance between cathodes which have been operating above and below this critical value is shown in Figs. 25 and 26.

The current density in the large scale runs was held at 13 amp. per square foot (143 per square meter) because it was found difficult to obtain thorough depolarization at higher rates.

QUALITY OF CATHODE

Physically, most beautiful cathodes were made when the rate of corrosion was properly controlled. This was, of course, due to the burnishing effect of the agitation in the cells. Chemically, three possibilities have to be considered—fouling by cuprous chloride, contamination by copper sulphide and plating out of arsenic, etc.

Cuprous chloride is purely a local problem where the water supply or the calcines carry chlorides and the use of cement copper appears to be an adequate remedy. Some cathodes made without the use of cement, analyzed 2.9 per cent Cl, while others made where cement was used showed 0.4 per cent Cl, indicating that a more thorough use of the cement would eliminate the cuprous chloride without difficulty. This same problem is being handled at Chuquicamata by precipitating upon shot copper.

The proper reduction of ferric sulphate by sulphur dioxide will not leave partial compounds which blacken the cathodes. While some of the earlier copper showed the presence of sulphur, the later runs gave out 0.002 to 0.003 per cent.

Small scale experiments, using an electrolyte to which 1 per cent arsenic as As_2O_3 had been added, yielded cathodes running but 0.0011 per cent As.

ANODE EFFICIENCY

The anode efficiency was ascertained for twenty-seven of the large-scale runs, as follows:

The theoretical oxidation of ferrous sulphate was calculated from the cell—ampere—hours for each run. The gain in ferric sulphate was then figured from the quantity of liquor circulated and the shaking machine determinations on the entering and leaving liquors. To this was added the quantity of ferric iron reduced at the cathode as shown by the current efficiency, the sum being the iron actually oxidized electrolytically at the anode and chemically by the air used in agitation. The results ran in general from 90 to 115 per cent. Some runs, to determine the amount of oxidation due to the air, indicated perhaps 15 per cent, so that the depolarization was apparently perfect.

SULPHUR EFFICIENCY

We have available, in general, 2 units of sulphur per unit of copper. We lose perhaps 10 per cent in the calcines and some, let us say another 10 per cent, must be lost in the exhausted tower gases. We have an anode efficiency of oxidation of say 110 per cent, including that due to the agitation. This will call for 0.55 unit sulphur per unit of copper, in the form of SO_2, to reduce the equivalent ferric sulphate. We have, therefore:

Lost in calcines	0.20 unit
Lost in tower gases	0.20 unit
Used in reduction	0.55 unit
	0.95 unit
Total available	2.00 unit
Possible loss in liquor	1.05 unit S per unit Cu.

If we assume 0.15 per cent free SO_2 in liquor leaving the tower, this 1.05 units will supply 700 units of liquor. We must, therefore, remove 1 unit of copper by deposition from 700 units, or less, of liquor. This corresponds to an oxidation of 1.77 units of iron, or 0.25 per cent increase in ferric iron in passing through the cells. This comes within the danger limit shown by Fig. 27. If we wish to run at lower ferric iron increase we must recover some of the free excess SO_2 in the liquor and use it again in a secondary tower, or figure on less than 0.15 per cent in the liquor leaving the tower.

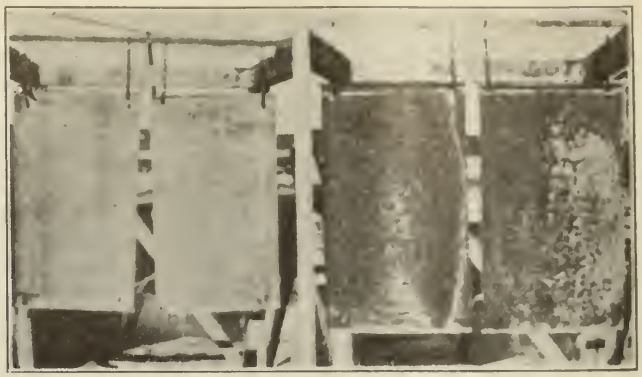

FIG. 25—SMOOTH CATHODES FIG. 26—FURROWED CATHODES

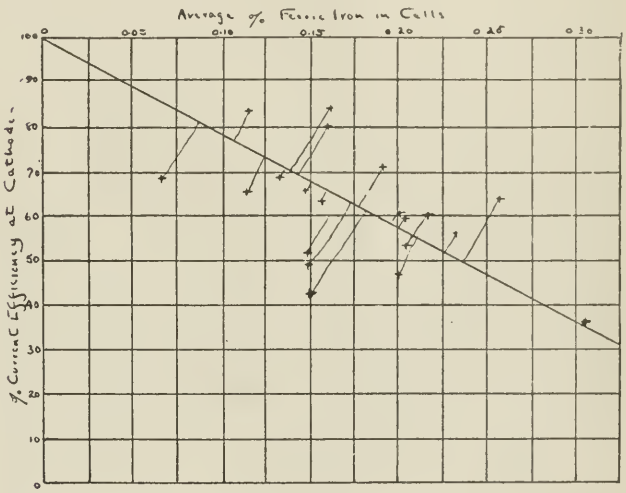

FIG. 27—EFFECT OF FERRIC SULPHATE UPON CURRENT EFFICIENCY IN PRACTICE

Liquor about 5 per cent H_2SO_4, 3 per cent Cu, 2.5 per cent Fe", 3.7 per cent Al_2O_3, 118 deg. Fahr. (48 deg. C.).

CONCLUSIONS

Carbon anodes will stand up in sulphate liquors if they are properly depolarized.

Aluminium sulphate can be used as a substitute for a diaphragm.

2.25 lb. (1.019 kg.) of copper per kilowatt-hour can be recovered under proper operating conditions.

Great quantities of various sulphates present as impurities do not foul the cathodes.

Three or possibly 3.25 units of acid are made per unit of copper, of which 1.5 to 1.75 units are new acid from the tower gases.

No mechanical difficulties are experienced in the tower, but a thorough study remains to be made of the chemistry of reduction of ferric sulphate by sulphur dioxide in order to utilize the roaster gas to best advantage.

The New Jersey iron mines in Morris County are reported to be very active, foremost among these being the Empire Steel & Iron Co. at Mount Hope and the Thomas Iron Co. at Richard Mine. The former is shipping about 17,000 tons of ore per month and the latter 6000 tons.

Recent Advances in the Manufacture of Cyanogen Compounds*

BY J. E. CLENNELL

Fixation of Atmospheric Nitrogen

Much activity has been shown of late in the study of methods for the fixation of atmospheric nitrogen, and a number of products are now made on a large scale both for direct use and as a basis for the production of other nitrogenous substances. The most remarkable development has been in the manufacture of calcium cyanamide, $CaCN_2$. Impure commercial products consisting mainly of this substance are now extensively used as fertilizers under the names of "lime nitrogen" and "nitroline." Alkali cyanides and other cyanogen compounds are obtained by further treatment of cyanamides in a variety of ways. Other processes are used to transform cyanamide into ammonia, ammonium salts and other nitrogenous compounds of commercial value.

The earlier attempts at the fixation of atmospheric nitrogen were mostly based on the reactions taking place between barium oxide, carbon and nitrogen at high temperatures. An important investigation of this process has been published by Thomas Ewan and Thomas Napier,[1] who summarize the chief data obtained by previous investigators in this field. The formation of cyanides from a mixture of BaO, C and N requires a minimum temperature of 1200 deg. C., but proceeds best at 1400 deg. C., when 40 per cent of the Ba may be cyanized. Hempel (1890) showed that the percentage of Ba cyanized may be increased by pressure. Readman (1894) applied the electric furnace for this process, which has been carried out on a large scale by the Scottish Cyanide Company. Frank and Caro showed (1898) that a large part of the nitrogen is fixed in the form of barium cyanamide, $BaCN_2$. Caro also found (1907), that the addition of alkali and alkaline earth fluorides accelerates the reaction, and enables it to proceed at temperatures of 900 deg. to 1100 deg. C. Snodgrass (1907) showed that potassium carbonate has a similar action.

Ewan and Napier (1909) studied the action of catalysts to obtain the reaction at lower temperatures. In their first experiments, mixtures of barium carbonate and charcoal were placed in an iron boat in a porcelain tube, and heated in a current of dry nitrogen. The products finally obtained were barium cyanide $Ba(CN)_2$, barium cyanamide $BaCN_2$, carbon monoxide CO, and unaltered $BaCO_3$, C and N. The following reactions are supposed to occur:

$$BaO + 2C + N_2 \rightleftarrows BaCN_2 + CO$$
$$BaO + 3C + N_2 \rightleftarrows Ba(CN)_2 + CO$$

They summarize their results as follows:

1. Absorption of nitrogen begins at 900 deg. to 930 deg. C.

2. The amount absorbed increases rapidly from 1 per cent Ba combined at 930 deg. to 40 per cent at 1000 deg., in tests made under the conditions that four molecules of N act on one molecule of $BaCO_3$ for a period of two hours.

3. The greater part of the nitrogen is fixed as cyanide $Ba(CN)_2$ and not as cyanamide. When calcium is used in place of barium, the nitrogen is fixed almost exclusively as cyanamide, $CaCN_2$.

4. At 960 deg. about 2½ per cent of the nitrogen is fixed; at 1000 deg. about 10 per cent.

5. Addition of K_2CO_3 seems to improve the result, but the difference obtained falls within the limits of error in estimating temperatures.

6. No cyanide is produced until about 30 per cent of the $BaCO_3$ is converted into BaO, and until the percentage of CO has fallen to 30.

It is commonly supposed that barium carbide (BaC_2) is formed as an intermediate product, but Ewan and Napier find no evidence of this. From theoretical considerations BaC_2 could not be formed at all in presence of mixtures of CO and N from which N is freely absorbed by BaO and C. It is probable, however, that when calcium is used instead of barium the reaction:

$$CaC_2 + CO \rightleftarrows CaO + 3C$$

is a necessary intermediary.

Cyanid Gesellschaft[2] reports that nitrogen has no action on a mixture of CaO and C at 1100 deg., and that the reaction $CaO + 2C + N_2 = CaCN_2 + CO$ takes place best at 2000 deg. At this temperature nearly all the nitrogen is absorbed.

K. Kaiser[3] observes that if barium oxide or carbonate, intimately mixed with carbon, be heated to 900 deg. to 1400 deg. C. and allowed to cool in a dry atmosphere of nitrogen under pressure, as much as 90 to 95 per cent of the theoretical amount of nitrogen combines with the barium.

A French patent[4] of 1913 describes a method of carrying out the reaction between barium carbonate, carbon and nitrogen in an electric furnace. Tar is used as binding material for the ingredients; these are molded into balls and part of the bar recovered by distillation. The residue is then heated to 1600 deg. C. in the electric furnace and acted on by "producer gas" or other gas containing nitrogen, to form barium cyanide. The electrodes consist of two rings of carbon placed at the ends of the middle reaction zone of an inclined cylindrical furnace; the fused mass serves to conduct the current. Barium oxide may be regenerated by decomposing the barium cyanide by means of steam:

$$Ba(CN)_2 + 3H_2O = BaO + 2NH_3 + 2CO$$

When calcium is used instead of barium as the vehicle for the fixation of nitrogen, it was found by Barzano and Zanardo[5] that the yield of calcium cyanamide is increased by mixing calcium carbide with sufficient calcium cyanamide from a previous operation to form a friable mass, before subjecting it to the action of nitrogen.

The manufacture of cyanamide by the process of Frank and Caro is carried out on a large scale at the works of the American Cyanamide Company, Niagara Falls, Ontario.[6] Nitrogen is obtained by passing air over heated copper. The copper oxide thus formed is again reduced by the action of natural gas, so that it may be used repeatedly. Operations began in January, 1910, with a 10,000-ton plant, which has since been largely extended.

Cyanides and cyanamides of the alkali metals may be produced without the preliminary formation of a calcium or barium compound. E. A. Ashcroft[7] proposes to do this by using an alloy of the alkali metal with some heavy metal such as lead, and first fusing this with a portion of the product sought (e. g., NaCN or Na_2CN_2) at about 600 deg. C., to separate the alkali from the heavy metal. The resulting melt, freed from the heavy metal, is now caused to react with cyanogen or a substance yielding cyanogen, with or without electrolysis of the melt.

*The second part of a paper entitled "Recent Advances in the Chemistry of the Cyanogen Compounds," to be presented at the New York City meeting (February, 1916) of the American Institute of Mining Engineers. The first part of the paper deals with advances in the chemistry of ore treatment by cyanide.

Conversion of Cyanamides Into Cyanides, Etc.

We must now mention some of the recently proposed methods for converting calcium cyanamide into cyanides or other nitrogenous substances of commercial value. These may be roughly classified as fusion methods and wet methods.

Among the former, probably the best known is that of Erlwein and Frank[8] by which the crude calcium cyanamide is converted into a product containing the equivalent of 25 to 30 per cent KCN, by fusing with carbon and common salt. Careful regulation of the temperature appears to be necessary. I have found that the process is not easily imitated in laboratory experiments. The product has been placed on the market under the name of "surrogat." For extraction of precious metals, it appears to be as effective, per unit of cyanogen contained, as ordinary sodium cyanide. It requires, however, to be digested with water and the insoluble carbonaceous residue filtered off before use.

J. C. Clancy[9] proposes to heat calcium cyanamide with its own weight of a mixture of equal parts of sodium sulphide and chloride in presence of carbonaceous matter.

E. E. Naef[10] treats crude calcium cyanamide at a temperature of 300 to 500 deg. C. with sulphur or a substance yielding sulphur:

$$2CaCN_2 + S = CaS + Ca(CN)_2 + N_2$$

The product is then stirred with water and filtered from the residue of $CaS + C$. The filtrate is boiled gently with zinc dust, and the zinc cyanide formed converted into alkali cyanide by known methods.

Calcium cyanamide may be used as a source of ammonia by acting on it with steam under pressure at a temperature of 170 deg. C., using an agitator to prevent formation of lumps. C. Manuelli[11] observes that under favorable conditions nearly theoretical yields of ammonia can be obtained at a cost of about 1.7 cents per pound of nitrogen utilized. Another method (E. E. Naef)[12] is to pass a current of dry hydrogen, either alone or mixed with CO_2, CO or N, at ordinary or higher pressure, over a heated mass of calcium cyanamide.

The wet methods are based on the fact that cyanamide compounds, such as $CaCN_2$, are transformed by water into the sparingly soluble crystallizable salt dicyandiamide $(CN{\cdot}NH_2)_2$. At a temperature of 13 to 14 deg. C. about 90 per cent of the nitrogen of calcium cyanamide may be dissolved in twenty-five times its weight of water, in eight hours, the extraction proceeding rapidly at first but very slowly later (C. Manuelli)[11]. Various salts of dicyandiamide may be prepared by digesting the substance in presence of acids with the oxides of the metals whose salts are required. The polymerization of cyanamide in aqueous solution is promoted by addition of fixed alkalis or ammonia. According to Grube and Krüger,[13] the reaction appears to be due to the union of undissociated cyanamide $(CN{\cdot}NH_2)$ with cyanamide ions $(CN{\cdot}NH)'$, to form monobasic dicyandiamide ions $H{\cdot}(CNNH)'_2$, presumably in the following stages:

(*a*) Formation of cyanamide by hydrolysis of calcium cyanamide:

$$CaCN_2 + 2H_2O = Ca(OH)_2 + CN{\cdot}NH_2$$

(*b*) Dissociation of a part of the cyanamide:

$$CN{\cdot}NH_2 = H' + (NC{\cdot}NH)'$$

(*c*) Combination of dissociated with undissociated cyanamide:

$$(CN{\cdot}NH)' + CN{\cdot}NH_2 = H(CN{\cdot}NH)'_2$$

(*d*) Formation of dicyandiamide:

$$H(CN{\cdot}NH')_2 + H' = (CN{\cdot}NH_2)_2$$

It is found that at a given concentration of total cyanamide, polymerization proceeds most rapidly when the concentrations of cyanamide and of dissociated cyanamide ions are equal.

For the preparation of dicyandiamide from commercial calcium cyanamide, the addition of a foreign base is unnecessary; the conversion may be brought about by precipitating the lime at intervals so as to maintain approximately equal concentrations of $CN{\cdot}NH_2$ and $(CNNH)'$.

Alkali salts of dicyandiamide are produced by heating the substance with caustic alkalis in presence of an absorbent of water:[14]

$$4NaOH + (CNNH_2)_2 = (CN{\cdot}NNa_2)_2 + 4H_2O$$

If the water is not absorbed, part of it reacts with the melt thus:

$$Na_2CN_2 + 3H_2O = Na_2CO_3 + 2NH_3$$

The absorbents used are alkali or alkaline earth metals or their oxides, amides, nitrides, carbides or alloys.

Dicyandiamide is converted into cyanide by fusing with alkaline carbonates and carbon

$$(CN{\cdot}NH_2)_2 + Na_2CO_3 + 2C = 2NaCN + NH_3 + N + H + 3CO$$

or it may be converted into a variety of nitrogenous products suitable for manures, explosives, etc.

The conversion of cyanamide into dicyandiamide may also be brought about by heating its solution with a catalytic agent. H. Immendorf and H. Kappen[15] propose to carry out this process by means of ferric oxide on hydrate, manganous or manganic oxides or their hydrates, stannic acid, chromic oxide or hydrate, hydrated silicic acid or similar substances. The products obtained are ammonia, urea and dicyandiamide. During the process the catalyst absorbs the bases liberated and loses its efficiency. This may be restored by treatment with acid or with water. Commercial calcium cyanamide contains calcium chloride, which hinders the separation of urea and dicyandiamide. This difficulty may be avoided by converting the calcium chloride into sulphate or carbonate, which may be separated by reason of their insolubility in alcohol.

H. Kappen[16] obtains thiourea by treating dilute aqueous solutions of cyanamide with hydrogen sulphide at high temperatures, in closed vessels under pressure. The addition of acid and alkaline reagents and of soluble compounds of arsenic, antimony or tin increases the efficiency of the process.

Production of Cyanogen Compounds from Nitrogenous Gases by Catalysis and Otherwise

Another method for the manufacture of cyanides and related compounds, which has been largely developed of late years, consists in the contamination, under suitable conditions, of volatile carbon and nitrogen compounds. Usually this takes place at a high temperature under the influence of a "catalyst," *i.e.*, of some substance which does not undergo any permanent chemical change in the process.

It has long been known that hydrocyanic acid or ammonium cyanide could be produced by passing mixtures of carboniferous and nitrogenous gases over heated platinized pumice, as for example in Wolterech's process:[17]

$$CO + NH_3 = HCN + H_2O$$

C. Beindl[18] proposes to form hydrocyanic acid and

[18]German Patent 254,068, Feb. 15, 1912.

cyanogen compounds by catalytic combination of gaseous and volatile carbon compounds with gaseous and volatile nitrogen compounds, by the use of a contact material consisting of a metallic oxide or a mixture of metallic oxides. The gaseous mixture should contain not more than 7 volumes of the carbon compound to 1 volume of the nitrogen compound. It is claimed that oxides of metals of the iron group have the property of inducing the rapid formation of hydrocyanic acid at relatively low temperatures, from dry mixtures of these gases.

It has been found[19] that the yield is increased by introducing into the arc of an electric furnace the vapors of metals and metallic compounds, such as those of copper or iron and their salts.

W. Moldenhauer and O. Wehrheim[20] describe a method by which nitric oxide can be obtained by catalytic combustion of cyanogen compounds. Ammonia may also be used as the source of nitrogen, but the yield of nitric oxide is less than with cyanogen, and more attention must be paid to the condition of the catalyst and time of contact with it.

J. E. Bucher[21] proposes to produce alkali cyanides by the action of atmospheric nitrogen on alkali carbonate and carbon dissolved in iron, the iron acting as a catalytic agent. The alkali cyanide formed is removed from the reaction zone by distillation under diminished pressure.

The Deutsche Gold und Silber Scheide Anstalt[22] propose to pass gaseous mixtures containing nitrogen obtained by heating certain waste products such as "vinasses" through highly heated conduits lined with refractory material such as Dinas brick, fused quartz, or a fused mixture of zirconia and quartz which remains gas-tight and non-porous at the high temperature employed. It is said that practically the whole of the nitrogen is obtained in the forms of HCN and NH_3, the relative proportions of these varying with the raw material used.

In the process of Barzano e Zanardo[23] a mixture of nitrogen (say 60 per cent), hydrogen (32 per cent) and hydrocarbons (6 per cent) is raised to a high temperature, for example in the electric arc, and hydrocyanic acid absorbed by circulating the issuing gases through cooling and absorption apparatus. Sufficient nitrogen is added to maintain, with the hydrogen liberated, the concentration of these gases most favorable to the reaction.

Catalysis may be employed for the production of ammonia, not only from gaseous mixtures but also from solid organic nitrogenous compounds. F. Schreiber[24] proposes to act on the latter with contact masses containing hydrated iron oxide at temperatures below red heat. It is claimed that as much as 80 per cent of the nitrogen in pyridine and in cyanogen salts may be thus converted into ammonia, while ordinary destructive distillation yields not more than 20 per cent.

Production of Cyanogen Compounds from Gaseous Mixtures by Absorption with a Metallic Salt

The cyanogen contained in crude illuminating gas has for some years been utilized as a source of cyanides and cyanogen compounds on a commercial scale, as in the methods of Rowland[25] and Bueb[26].

[19]Konsortium f. Elektrochemische Industrie, G. m. b. H. German Patent 268,277, July 1, 1911. Addition to German Patent 263,692.
[20]Zeit. f. Angewandte Chemie, vol. 27, p. 334, 1914.
[21]U. S. Patent 1,094,976. Assigned to Nitrogen Products Co.
[22]German Patent 255,440, Nov. 9, 1911. French Patent 448,772, Sept. 5, 1912.
[23]French Patent 456,826.
[24]German Patent 257,188, June 2, 1911.
[25]U. S. Patent 465,609, 1891.
[26]English Patent 9,075, 1898.

L. Bergfeld[27] uses as purifying material dehydrated copper sulphate, or a mixture of salts, *e.g.*, alkaline earth sulphates or chlorides, which combine with NH_3 but not with H_2S, with metallic oxides capable of combining with H_2S. The mixture is treated with ammonia gas before use. The reaction is of the type:

$$H_2S + NH_3 + CaSO_4 \cdot NH_3 = CaS + (NH_4)_2SO_4$$

At the same time some SO_2 (which is fixed by the purifying material) and sulphur are also formed, thus:

$$SO_3 + H_2S = H_2O + SO_2 + S$$

When the purifying material is extracted it is heated, with regulated access of air, and ammonia liberated.

By gentle warming in presence of air, the ammonium sulphite deposited is rapidly oxidized to sulphate.

Cyanogen in the crude gas is fixed by the purifying material as cuprous ammonium cyanide. On heating with air this yields NH_3 and CO_2, and thiocyanate giving NH_3, CO_2 and SO_2. After passing the purifying material the coal gas may be further purified by leading it over alkali or alkaline earth sulphides, and if necessary over sodium amalgam.

C. A. Bergh[28] uses a solution of a zinc salt, containing also ferrous chloride, as an absorbent. The free acid formed is neutralized, and zinc sulphide and cyanide are precipitated, by addition of calcium carbonate, or some other sparingly soluble substance. This is added in quantity corresponding to the amount of H_2S and CN present. Iron remains in solution. By this method zinc is separated from iron and H_2S from CN by a single operation.

W. H. Coleman[29] passes coke-oven or other gases containing hydrocyanic acid through a tower packed with lumps of ferrous iron ore. A solution of sodium carbonate, or other suitable alkaline absorbent in solution or suspension, is circulated through the tower, and the resulting alkali or alkaline-earth ferrocyanicide liquor is treated for recovery of the ferrocyanide.

Foreign Markets for American Chemicals*

BY DR. THOMAS H. NORTON
Bureau of Foreign and Domestic Commerce.
Department of Commerce

Never before in our industrial history has the American manufacturer sought with more energy to gain a foothold in foreign markets. Never before have the opportunities for success in this field been so marked.

A titanic struggle is slowly sapping the strength of the chief European rivals of our country. Their power to maintain successful and prolonged competition is steadily diminishing, day by day.

Two nations, Germany and Austria-Hungary, are practically shut off from international markets. The ability to manufacture in other European nations is seriously impaired through the lack of workmen, through the difficulty of securing raw materials, through the more or less serious dislocation of the whole machinery for effecting the world's exchanges.

In the midst of this uncertainty this disorganization which prevails to a greater or less degree in the various European centers of production, it is a patriotic duty of American branches of manufacture to strive by every honorable means in their power to gain a permanent foothold in markets of all countries, neutral or belligerent.

What are the American manufacturers of chemicals doing to win new customers for their wares?

[27]German Patent 255,593, Aug. 24, 1910.
[28]German Patent 272,904, March 19, 1912.
[29]English Patent 27,908, Dec. 4, 1912.
*A paper read at the meeting of the American Institute of Chemical Engineers held in connection with the First National Exposition of Chemical Industries in New York City on Sept. 22, 1915. Slightly abstracted.

In order to answer this question we must first establish the extent to which American chemicals were purchased in foreign countries prior to the great war. Next we can note the temporary effect of the war on our trade in chemicals. Finally, we should ascertain along what lines of least resistance an export trade in American chemicals can most easily and effectively be built.

AMERICAN EXPORTS OF CHEMICALS PRIOR TO THE WAR AND DURING THE WAR

Table I gives the principal items of export, during the fiscal year, ending June 30, 1914 and 1915; enumerated under the head of "Chemicals, Drugs, Dyes and Medicines" in the statistical reports of the Bureau of Foreign and Domestic Commerce:

TABLE I

Articles	1914		1915	
	Quantity	Value	Quantity	Value
Acids:				
Sulphuric, lb	12,131,750	125,892	46,771,510	516,436
All other	.....	357,035	.....	2,611,741
Alcohol, wood, gal	1,598,776	652,486	944,374	438,846
Baking powder, lb	2,725,964	750,274	3,376,780	881,879
Bark, extracts of, for tanning	.....	639,941	.....	2,226,457
Calcium carbide, lb	32,845,649	962,040	35,772,867	1,097,952
Copper, sulphate of, lb	7,375,775	330,007	10,238,808	445,580
Dyes and dyestuffs	.....	356,919	.....	1,177,925
Ginseng, lb	224,605	1,832,686	103,184	919,931
Lime, acetate of, lb	68,160,224	1,560,933	24,673,247	486,405
Medicines, patent or proprietary	.....	6,721,978	.....	7,130,379
Petroleum jelly, etc	.....	661,889	.....	838,842
Roots, herbs, and barks, crude, not mixed	.....	513,071	.....	470,090
Soda salts and preparations	.....	.....	.....	3,141,022
Sulphur or brimstone, crude, tons	110,022	2,018,724	48,391	885,756
Washing powder and fluid, lb	12,761,958	535,635	14,695,317	635,476
All other	.....	9,019,582	.....	22,476,269
Totals	.....	$27,079,092	.....	$46,380,986

The variations in trade are somewhat more sharply marked if comparison is made of the exports during the months of June, 1914 and 1915. This is illustrated by Table II.

TABLE II.—EXPORTS DURING THE MONTH OF JUNE

Articles	1914		1915	
	Quantity	Value	Quantity	Value
Acids:				
Sulphuric, lb	647,498	5,948	5,931,208	63,516
All other	.....	23,102	.....	354,591
Alcohol, wood, gal	165,463	62,769	58,508	30,108
Baking powder, lb	249,446	74,634	320,953	85,142
Bark, extracts of, for tanning	.....	69,834	.....	506,289
Calcium carbide, lb	1,996,632	57,978	3,251,754	92,633
Copper, sulphate of, lb	281,445	12,265	144,268	9,115
Dyes and dyestuffs	.....	40,380	.....	204,732
Ginseng, lb	31,680	244,145	9,088	77,033
Lime, acetate of, lb	6,908,360	112,743	2,589,641	73,950
Medicines, patent or proprietary	.....	521,309	.....	780,811
Petroleum jelly, etc	.....	50,094	.....	88,923
Roots, herbs, and barks, crude, not mixed	.....	39,057	.....	77,149
Soda, salts and preparations	.....	.....	.....	684,355
Sulphur or brimstone, crude, tons	9,342	173,125	1,637	35,088
Washing powder and fluid, lb	1,508,698	59,402	1,322,231	59,715
All other	.....	876,409	.....	3,114,756
Totals	.....	$2,423,203	.....	$6,337,906

It will be noticed that the fiscal year recently elapsed, has witnessed notable increases in amount exported for the following articles: Sulphuric and other acids, calcium carbide, dyes and dyestuffs, petroleum jelly and other articles.

Decreases are noted in the case of wood alcohol, copper sulphate, ginseng, calcium acetate, sulphur.

There is little variation in the amount exported of baking powder, medicines, roots and washing powder.

As a whole the export of chemicals for 1915 shows an advance in value of 72 per cent over that of 1914.

The export of June, 1915, is 161 per cent greater than that of 1914.

The classification of the Department of Commerce does not include explosives, which increased in value from $6,272,000 in 1914, to $41,476,000 in 1915. It does not include also the heavy exports of cement, ink, mineral oils, paints, pigments, and varnish, perfumery, soap and a few other items, closely allied to the chemical schedule, but in which the variations in the volume of export were not of material importance.

It is quite evident that apart from munitions, the war has brought about a very pronounced increase of our chemical exports both in volume and in value. It is unfortunately impossible at present to have the complete data now being collected so that we may gain an adequate idea of the geographical distribution of the increase in exports during the past year. It suffices for the moment to note that the existing international conditions have very distinctly favored the expansion of the foreign market for American chemicals.

MARKETS OPEN TO AMERICAN CHEMICALS

And now, how can we most effectively build up an export trade in chemicals?

Evidently the existence of a world-wide war presents peculiar opportunities which can be utilized with perfect freedom, in the firm conviction that no ethical law is violated. With the friendliest of feelings toward Briton and Teuton, and the allies of both, we recognize that each of these two countries, normally so prominent in the export of chemicals, is now unable to meet fully the normal demands upon its productive capacity. A strong effort, on the part of American manufacturers of chemicals, to fill these demands is undoubtedly dictated by the circumstances, and it is likewise our duty to aim to build up permanent trade relations in those fields. It is most deplorable and unfortunate, from the standpoint of humanity, that such intense bitterness is awakened by the great conflict across the water. For years it will influence currents of trade; on the advent of peace, entire nations will apparently refuse to purchase the products of certain other nations.

The existence of such a factor of hostility and antagonism between nations hitherto closely related in international trade, is most regrettable. We can but hope that it eventually will disappear. In the meantime without encouraging any act on our part, we are legitimately free to do our best to meet the demands which may be made upon every branch of our national industry, and presumably upon our chemical industry, to an extent hitherto unknown.

Let us note what chemical products of the leading

TABLE III.—IMPORT OF CHEMICALS INTO DIFFERENT COUNTRIES

EUROPE			
Austria-Hungary	$20,386,000	Portugal	$1,864,000
Belgium	28,814,000	Roumania	1,191,000
Bulgaria	718,000	Russia	16,081,000
Denmark	3,897,000	Finland	306,000
France	32,900,000	Servia	245,000
Germany	79,394,000	Spain	10,224,000
Greece	1,180,000	Sweden	4,005,000
Itay	14,647,000	Switzerland	8,621,000
Netherlands	132,679,000	United Kingdom	75,113,000
Norway	1,039,000		
NORTH AMERICA			
United States	$78,207,000	Costa Rica	$113,000
Canada	10,933,000	Cuba	2,081,000
British West Indies	523,000	French Colonies	237,000
Mexico	4,688,000		
SOUTH AMERICA			
Argentina	$4,466,000	French Guiana	$27,000
Brazil	4,293,000	Peru	925,000
Chile	1,657,000	Uruguay	784,000
British Guiana	409,000		
ASIA			
China	$10,804,000	Japan	$13,536,000
India	9,245,000	Korea	202,000
Dutch East Indies	5,514,000	Siam	261,000
French Indo-China	1,149,000		
OCEANIA			
Australia	$589,000	New Zealand	$1,733,000
AFRICA			
British South Africa	$987,000	Tunis	$238,000
Mauritius	590,000	Egypt	3,307,000
Algeria	1,645,000		

European countries have entered most conspicuously into international trade.

IMPORTS OF CHEMICALS INTO THE VARIOUS COUNTRIES

Table III shows the value of the imports of chemicals, drugs, dyes and fertilizers, into each of the various countries, which keep careful statistics as tabulated for the year 1906.

Summarized, the countries of the world purchase chemicals, drugs, dyes and fertilizers to the following extent:

Europe	$433,304,000
North America	96,782,000
South America	12,561,000
Asia	40,731,000
Oceania	2,322,000
Africa	6,767,000
	$592,467,000

To this international market the United States brought for sale in 1906 wares to the value of about $41,000,000, or 7 per cent of the whole.

Such is the field in which our manufacturers of chemicals are to extend their trade. It is the trade with Latin America, with Asia, and with Oceania that they should seek to win. The potential purchasing power of these portions of the globe amounted in 1906 to over $74,000,000. Unquestionably in Europe itself markets will open to us which have hitherto been closed.

The Empire of Germany has contributed to the international traffic, chemical wares valued at $111,000,000 annually, or 17 per cent of the entire amount. The United Kingdom contributed chemicals valued at $63,019,000, or 11 per cent of the total amount.

The markets which have hitherto secured their supplies chiefly from Germany are naturally the ones, under existing circumstances, in which the most earnest efforts should be made to cultivate new trade relations.

It would lead me too far to analyze in detail the markets for chemicals in the non-European countries, more accessible to our commerce. The detailed statistics of German exports show, however, very clearly the great extent of the territory which at present must seek its supply of chemicals from new sources.

I would, therefore, urge upon the manufacturers of chemicals who distinctly desire to enlarge their foreign connections and establish themselves solidly and firmly in the markets of the countries to the south and west of our borders, a most careful and detailed study of the import statistics of Latin America and Asia.

In frequent cases, where European wares have dominated the world's markets, our own production has been restricted and remained in a half-developed state.

Here there is abundant reason for us to make a valiant effort to break out from the chrysalis-like condition, unfold our wings to the fullest extent and meet not only the demands of the home market, but sally forth into the markets of the world. Such a bold and vigorous line of action is dictated more especially when the raw material required is found in abundance within our own borders.

Two such fields of industrial effort and industrial evolution are, at the present moment, pre-eminently worthy of our notice. Potash and dyestuffs are terms haunting the waking hours and banishing slumber from thousands of manufacturers between the Atlantic and the Pacific. The fertility of immense tracts of our land will sadly suffer unless means are found to replace the supplies of potash salts hitherto received from the mines of Germany.

Hundreds of the textile mills throughout the eastern half of the republic are facing a dyestuff famine, resulting from the complete cessation of imports of artificial colors from Germany since the middle of March last. This threatens a more or less complete stagnation in production. It involves under the most favorable conditions, such a dislocation of technical and commercial relations along the whole chain of connecting links, between the producer of textile fibers and the ultimate consumer of knitted or woven fabrics, that the daily loss, direct and indirect can be measured only by hundreds of thousands of dollars.

POTASH

In the case of potash, it is an economic absurdity that the farmers and manufacturers of this country should be so absolutely dependent upon a single foreign source. The painstaking, exhaustive studies of the Bureau of Soils in the Department of Agriculture show beyond the shadow of a doubt that the vast amount of potash stored annually in the boundless beds of kelp, floating off our Pacific littoral, can amply meet the world's demands. My own studies on this subject reveal a handsome margin of profit, should the attempt be made, on a grand scale, to garner this valuable crop, and replace for use as a fertilizer, the $10,000,000 worth of potash which we bring across the ocean from the mines of Stassfurt. The methods of extracting from kelp the technically pure potassium chloride to serve as a starting point for the manufacture of a large variety of salts of potash employed in the arts has now been so far advanced that at an early date we may witness the complete disappearance from our markets of foreign salts in this category.

Highly perfected now are, also, the methods for extracting in a soluble condition the potash content of our vast deposits of feldspar. Of exceptional interest is the recent process for releasing from its rocky fetters the potash in the form of the carbonate, the most convenient salt to use in taking up the manufacture of the other compounds of potassium as well as in the glass industry.

The progress in the utilization of our Western deposits of alunite is also noteworthy. Large quantities of potassium sulphate are now shipped regularly from Marysvale, Utah. The recent discovery of enormous deposits of alunite in the State of Washington, adjacent to tidewater, is of great moment, as the question of freights is notably simplified.

Of great interest is the process recently perfected by a young chemist of this city for rescuing from distillery waste the notable quantities of potash at present allowed to go to waste.

The current daily loss throughout the United States in distilleries employing molasses as raw material is estimated at 106 tons of pure K_2O. This is now transformed into a dry powder containing over 9 per cent of potash and a considerable amount of nitrogen. It serves admirably for the manufacture of composite fertilizers. A large plant is now being equipped at Boston for the utilization of this distillery waste product on an extensive scale.

In view of all this may I not confidently look forward to the early date when the production of American potash will have reached a point that permits a large export after having met all domestic demands? Within a decade or two this country should easily compete in the world's markets with the salts of Stassfurt, which hitherto has been practically the only source.

DYESTUFFS

Equally hopeful is the outlook for the ultimate solution of our dyestuff problem.

When it became evident that a "color famine" was imminent, the situation was quickly sized up by the little band of American manufacturers of artificial colors.

With true American pluck and enterprise, emancipation from dependence upon foreign-made intermediates was declared the slogan. At an expense of hundreds of thousands of dollars the necessary plant was erected to transform American benzol, toluol, naphthalene, etc., into the numerous intermediaries directly required for color production. Not an hour was lost in completing the new equipment. To-day one establishment is manufacturing nearly 60 per cent more than was the case in July, 1914; another has trebled its output of that date.

The movement has not been limited to an enlargement of existing works. A large group of new firms has sprung into existence and is actively engaged in the production of coal-tar intermediates, notably of aniline, which can also be used directly in the production of aniline black on hosiery and yarn.

Thomas A. Edison is a brilliant example of what Yankee foresight and intelligence can accomplish in such a field. Consuming normally large amounts of carbolic acid in the manufacture of the records for his phonograph, he suddenly faced a crisis. The price of the article had soared from 10 cents per pound to $1.50, and but little could be secured at that rate. Promptly Mr. Edison assured an adequate supply of benzol, the primary coal-tar "crude," from which carbolic acid can be prepared synthetically. This was accomplished by erecting at considerable cost the requisite "scrubbers" for the removal of benzol from the waste gas of by-product coke ovens. He was then in a position to embark extensively upon the manufacture of carbolic acid. Finding the venture so successful, he constructed the necessary plant for the manufacture of aniline. This proved to be also most profitable.

In solving so simply and effectively two leading phases of the coal-tar problem, Mr. Edison has blazed the trail for other daring pioneers, and has shown how simple is the primary series of operations necessary to build up a self-contained American dyestuff industry. There are now quite a number of well-financed companies which are daily increasing the volume of the output of coal-tar intermediates and which are turning their attention to the manufacture of finished dyestuffs. Chemists, consumers, and economists have vigorously attacked the entire problem. There is an insistent inquiry, "Why are we not making ourselves all of the colors required by American consumers of dyestuffs?"

The Department of Commerce has taken an active interest in the working out of the problem. It has done all in its power to stimulate and encourage the efforts now directed to build up an independent, self-contained American coal-tar chemical industry. It has collected and disseminated the requisite information for those planning to enter the new field. It has carefully and exhaustively studied the question of how far existing law can protect the young industry against unfair competition on the part of foreign rivals, when normal international relations are restored.

Gradually the decisive factors in the situation have been determined and outlined. They may be summarized as follows:

The United States possesses all the needed raw materials in abundance—in such amount that it could meet the demands of the world's dyestuff industry. It offers the largest existing market for consumption of dyestuffs.

Enterprise, inventive talent, and technical ability are present in abundance.

Capital is ready to embark in the new field in ample amount, and is daily being invested.

On the other hand, we lack the few skilled, experienced captains of industry, well-trained in this special field, and thoroughly well-equipped to organize and conduct the manufacture of colors on essentially the same basis as now exists in directing the gigantic factories on and near the Rhine.

There is also some hesitation on the part of capital to build up the industry on a magnificent scale, fully commensurate with the country's needs, until there is absolute certainty that laws will find their way to our statute books capable of effectually preventing any attempt to destroy the young industry on the part of foreign competitors.

This is, in fact, the one great IF, which for the moment blocks to some extent the rapid and healthful expansion of the domestic industry. With or without the leadership of men equal in technical and scientific equipment to the brilliant galaxy of those directing the European factories, we are bound to have our independent American color industry. The moment is impatiently awaited when the President of this republic shall affix his signature to a law making as impossible in foreign trade as it is now in domestic trade any attempt to crush, stifle and throttle a new industry on the part of competing rivals beyond the seas. When this moment arrives, capital in abundance is ready to back American enterprise in swiftly but surely laying the foundations for a permanent American coal-tar color industry. It may take a year or two to furnish one-half of the artificial dyestuffs now in current use; it may take four or five years before nine-tenths of the colors now regularly used in American textile and other factories are made from American benzol, toluol, naphthalene, phenol, anthracene and carbazol. But the day is coming as certainly as the sun will rise to-morrow morning from the waves of the Atlantic.

It is most refreshing to note the utter indifference to minor side-issues manifested by the men who are determined to build up this new industry. But a few years ago discussion would have centered about the tariff. To-day the men who are ready to finance a color industry, or to throw into it the best of brain and nerve, are asking simply for a fair show—to prevent a competitor from hitting below the belt. The vast multitude depending directly or indirectly upon an abundant supply of coloring materials are fast losing patience with the class of publicists who fold their hands in the face of a profound industrial crisis, and grumble because the determined and persistent pressure brought to bear by our State Department has not yet succeeded in inducing our friends in Berlin to allow the free exportation of dyestuffs to our ports. They show as little interest in those who murmur, "Raise the tariff and it will be possible to plan for a genuine American color industry." Their sympathies are with the red-blooded men of action who have worked out the details of this most intricate of problems, recognize fully its manifold difficulties and the multitude of obstacles in the path, and yet are ready for the fray.

I cannot but admire men of the type of J. F. Schoellkopf of Buffalo, the pioneer in this branch, whose name will go down in our economic history as the father of the American coal-tar chemical industry. With what energy and strategy during the past twelvemonth has he multiplied the working features of the magnificent plant on the shores of Lake Erie, freed himself technically from all dependence in the future on foreign-made materials, concentrated his efforts on a few of the staple, most essential colors, and thereby vastly magnified his output. Such wisdom and resoluteness have meant salvation from heavy loss to many a mill man, hesitating whether he should close the doors and dismiss his operatives.

A year ago, a modest color factory was in operation in Brooklyn, sadly hampered by the sudden inability to

secure the customary intermediate compounds from across the sea. One night last November it was destroyed by an explosion, accompanied by sad fatalities. Did Dr. William Beckers decide to wait for further developments in the great struggle to our east, or for congressional action, before he laid his plans? Not he! A million dollars were promptly expended in new constructions and in the requisite mechanical equipment for eliminating all dependence henceforth on material from European works. To-day he also is able to contribute bravely his share towards lessening the hardships of the textile industry.

I might mention, in passing, the notable enlargement of the coal-tar dyestuff works in the great establishment of Heller & Merz at Newark, the spacious new buildings of the neighboring Central Dyestuff Works, and the noteworthy effort within the past few weeks to materially broaden the scope of the Consolidated Dye Works, in Newark, under the energetic direction of the Hon. Herman A. Metz, whose patriotic desire to contribute his part in building up an American dyestuff industry is equalled only by his achievements of a year ago in securing for our users of colors ample supplies from Europe when stocks were dangerously low.

I can dwell upon these aspects of the dyestuff situation in but a hasty and cursory manner. I cannot, however, close without referring briefly to promising and fascinating efforts to create an American dyestuff industry, in a new and very literal sense of the word. Two new projects have interested me extremely. The appearance at this exposition of the Pearsite and the Petracine colors may possibly mark new starting points in the evolution of the color industry. . . .

And now, let me revert to my original theme. May we not all look forward with a fair measure of confidence to the exposition of 1925, when the directors of American coal-tar chemical works will report to us their sales of American-made dyes in the world's markets?

What has been accomplished with the products of our iron mines and our pine forests, as well as with the many triumphs of American mechanical genius, can surely be attained in the field of coal-tar chemistry by a similar use of resoluteness and energy, supported by the helpful action of the nation's lawgivers, in granting full protection against unfair practices on the part of foreign competitors.

Centrifugal Pumps.—The Lea-Courtenay Company, Newark, N. J., has issued catalog H-2, containing illustrations and descriptions of their centrifugal pumps of the turbine type, double-suction, single and multi-stage types and single suction, multi-stage type for varied lines of work.

The **Pensacola Tar & Turpentine Co.** of Gull Point, Fla., has sent us its latest list of oils for flotations, comprising eight different oils. This company makes a specialty of producing oils for flotation purposes. "It seems that from 10 to 30 per cent of pine products are desirable, if not quite necessary, on most ores."

The **Specific Heat and Heat of Fusion of Ice** have been determined by the Bureau of Standards at the request of the refrigeration industries. The results are given in Paper No. 248, the authors being H. C. Dickinson and N. S. Osborne.

The **Bureau of Mines** has issued Bulletin 94, United States Mining Statutes Annotated, by J. W. Thompson. This is a large work in two volumes and shows the status of every Federal mining law, both relating to metal mining and coal, oil, and phosphate. It may be had for $2.50 by applying to the Superintendent of Documents, Government Printing Office, Washington, D. C.

Recent Chemical and Metallurgical Patents

Iron and Steel

Electric Steel Refining.—If the electric furnace is to become of widest use for the manufacture of large-tonnage steel products (rails, structural steels, etc.), it must be in a process in which electric-furnace refining succeeds Bessemer converter or open-hearth treatment, and it is of utmost importance to reduce the combined cost of such a combination process to a minimum. The principal problem of any such duplex process is to determine the exact point where to stop one step and begin the next step. In ordinary steel manufacture the manganese contained in the pig iron is almost wholly lost through oxidation in the Bessemer converter or open-hearth furnace. Mr. William R. Walker of the U. S. Steel Corporation avoids this loss by stopping the heat of the oenverter or open hearth while a major portion of the contained manganese (above 0.1 per cent) is still present in the metal. The metal is then tapped and fed into an intermediate mixer which equalizes the manganese contact. From this mixer charges of desirable size are taken to the electric furnaces in which the metal is deoxidized, largely through the action of manganese. (1,155,849, Oct. 5, 1915.)

Alloys

Alloy of Platinum and Osmium.—A substitute for platinum-iridium or "hard platinum" is patented by Dr. Fritz Zimmermann of Newark, N. J., the patent being assigned to Baker and Company. The limited supply of iridium and its high price have created a demand for another hard alloy. By a series of tests it was found that the addition of osmium to platinum greatly increases the hardness. The percentage varies between ½ of 1 per cent to 10 per cent. Alloys with 10 per cent are only workable with difficulty. As far as hardness is concerned, one part of osmium is equal to two and one-half parts of iridium; the tensile strength is high, and the alloy is ductile and is also more resistant to the action of acids than platinum-iridium. The alloy of 98 per cent platinum and 2 per cent osmium can be used for jewelry work, being hard and tough, while alloys containing 10 to 6 per cent osmium will replace alloys containing 15 to 25 per cent of iridium for contact points in electrical apparatus. The platinum and osmium must be refined to a high degree of purity to remove impurities. The natural platinum which contains osmium, copper and iron cannot be used for this purpose. (Original 1,055,119, March 4, 1913; reissue 13,691, Aug. 10, 1915.)

Electric Furnaces

Abrasive for Grinding Steel.—An electric-furnace abrasive of oxides of aluminium, magnesium, and titanium is patented by Dr. Herbert T. Kalmus of Brookline, Mass., the patent being assigned to the Exolon Co., Cambridge, Mass. Abrasives consisting essentially of alumina are said to have been found too brittle for certain classes of steels, the cutting edges of the grains failing under compression before they become dulled. Experiments showed that pure alumina tends to crystallize with a coarse structure which it is very difficult to prevent by any of the practical devices for operating electric furnaces. Magnesium and titanium oxides in the proportion of their molecular weights, when fused with alumina in the right proportion, give a resulting product of very fine-grained, crystalline alumina, the spaces between and surrounding the individual crystals being filled with magnesium aluminate, magnesium titanate, and eutetics of these with alumina. This product possesses the proper qualities to give efficient cutting action on hard steels and other hard

metals. Neither the oxide of titanium nor the oxide of magnesium alone gives the desired combination of abrasive properties.

In commercial practice emery, or aluminous material, containing the oxides of magnesium and titanium in the right proportions, is mixed with carbon in sufficient proportion to reduce all impurities, charged into an electric furnace and fused. The stationary arc-type in which the electrodes are gradually raised is preferable. The iron oxide and silica content should be gaged to have a ratio of six to one in order to produce ferrosilicon as a by-product. By the fusion, a pig of segregated metals, resulting from the furnace reduction, is formed at the bottom of the furnace and a pig of abrasive material is formed in the body of the furnace above the metal pig; these may be allowed to cool in the furnace, then separated. An abrasive was prepared from emery which contained 95.5 per cent Al_2O_3, 1.5 per cent MgO, and 3 per cent TiO_2. This product was hard, tough, fine-grained, and practically insoluble in water and acid solutions. When working with hard varieties of steels it is desirable that the abrasive should not contain more than 3 per cent or less than one-half of 1 per cent magnesium or titanium oxide. Iron oxide and silica should not be present in excess of 1 per cent. The temperature of the furnace is kept high enough to reduce the iron oxide and silica, but below the reduction temperature of alumina, so as to prevent the formation of sub-oxides or carbides. This process is said to make possible the use of domestic emery ores, which had heretofore been found objectionable owing to their magnesium content. Usually the emery ores used have been foreign, which were practically free from magnesium oxide. (1,149,064, Aug. 3, 1915.)

Calcium Carbide from Carbide Fines.—When carbide fines have been utilized for directly remelting in an electric furnace and causing the material to solidify in masses, it has been found that the product was not of good quality, giving a low yield of acetylene. This was found to be due to a loss of carbon during the remelting, and the fines are difficult to smelt owing to their irregular conductivity. In a patent of HERMAN L. HARTENSTEIN of Constantine, Mich. (assigned to Continental Investment Co., Duluth, Minn.), it is proposed to mix the carbide fines with finely divided coke, charcoal or a suitable grade of coal and treat this mixture in an electric furnace. This can be accomplished in the ordinary types of electric furnace in much the same manner as calcium carbide is ordinarily made. The amount of carbon employed in the mixture should be enough to reduce moisture that is present to hydrogen, carbon dioxide to carbon monoxide, etc. In this manner reduction of the calcium carbide by oxygen or oxides is prevented. There should also be enough carbon present to transform any other calcium compounds present, like calcium hydrate, oxide, carbonate, etc., into calcium carbide. In practice the waste carbide or carbide fines are analyzed, since the composition varies greatly with age, state of fineness, etc. The amount of unchanged carbide is determined and also the amount of oxidants capable of affecting changes in the carbide. After having determined this the necessary carbon and carbide fines are mixed and fed into an electric furnace, where the mixture is heated and reduced to a molten condition. It may then be allowed to cool in the furnace or be tapped. The carbide is claimed to be of high grade and much superior to the dust used in its production. (1,152,506, Sept. 7, 1915.)

Preventing Blue Powder in the Electric Reduction of Zinc Ores.—A patent for preventing sulphidization of zinc vapors in the electric reduction of zinc ores has been granted to Mr. WOOLSEY MCA. JOHNSON of Hartford, Conn., and is assigned to the Continuous Zinc Furnace Company, Hartford, Conn. It is of interest in connection with the puzzling problem of preventing the formation of blue powder in the condensation of zinc reduced in electric furnaces. The presence of sulphur in the free state, as carbon disulphide, sulphur dioxide or trioxide causes a partical sulphidization of the zinc vapor, forming a coating which prevents the zinc globules from coalescing into liquid zinc. In this process the ores are first calcined, the charge being so proportioned as to give a resulting product analyzing about as follows: 30 per cent Zn, 10 per cent Pb, 2 per cent Cu, 15 per cent Fe, 8 per cent SiO_2, 4 per cent CaO, 1 per cent MgO, 3 per cent S. The roasting temperature is about 950 deg. Cent., and the conditions such that sulphates other than those of barium, calcium, and lead are decomposed.

The hot calcined product from the roasting operation is mixed with 15 to 20 per cent of soft coal. The fluxes for the final electric furnace treatment may also be added at this stage. The mixture is then fed into a preheater furnace of the continuous coal or gas-fired type such as the McDougall. In this preheater the $PbSO_4$, $BaSO_4$, Fe_2O_3, CuO are reduced to PbS, CaS, BaS, Fe and iron suboxide, and Cu. No reduction of ZnO should take place.

Other reducing agents might be used in place of carbon, such as hydrogen, carbon monoxide or hydrocarbons, for instance.

The hot product from the preheater is then charged, without access to the air into a continuous electric furnace, where the following reactions take place:

$$ZnO + C = Zn + CO$$
$$ZnO + Fe = Zn + FeO$$
$$ZnS + Fe = Zn + FeS$$
$$ZnS + Cu_2 = Zn + Cu_2S$$

The iron is absorbed by the slag, the sulphides of iron and copper are absorbed by the matte. Lead sulphide is reduced to Pb by the iron or copper. The sulphur of the BaS and CaS is taken up by the Fe and Cu, and the Ba and Ca enter the slag as silicates. A large excess of metallic particles is continuously descending through the charge and slag into the matte. These metallic particles effect the desulphidization of vapor, charge and slag, and the vapor leaves the furnace in the right condition for condensing to liquid zinc. It is, of course, necessary to use the right temperature, for if the furnace were heated as high as 1350 or 1400 deg. C., carbon disulphide, SO_2 or SO_3 might form, and the matte might also be slightly decomposed. (1,150,271, Aug. 17, 1915.)

Preventing Punctures in Flame-Arc Furnaces.—A method of preventing punctures in flame-arc furnaces is patented by EINAR TROYE of Christiania, Norway. It consists in allowing an air space between the outer iron cover of the furnace and the brick lining. Air is passed through this space at a suitable pressure and may later be used in the furnace if desired. More than one air space could be used with walls of asbestos interposed between them. This method is claimed to allow of a considerable reduction in the thickness of the brick wall and to make a completely puncture-free furnace, also avoiding any current loss in the earth. (1,148,343, July 27, 1915.)

Boron Nitride.—A process for making boron nitride is patented by Dr. GEORGE WEINTRAUB of Lynn, Mass., and assigned to the General Electric Co. In this process borax and a cyanogen compound such as a cyanide or ferrocyanide are finely powdered and mixed and then heated to 2000 deg. C. in an electrical resistance furnace. All products such as carbonates, cyanates,

and the excess of borax or boric anhydride are volatilized and boron nitride remains. The process is continued until no more fumes are evolved and a white stable product is left. The yield is 30 per cent and upwards of the theoretical. (1,135,232, Apr. 13, 1915.)

Electrolytic Furnaces

Alkali and Alkaline-Earth Metals.—An electrolyte of cyanide or cyanamide for the production of metallic sodium, calcium, etc., in an electrolytic furnace is patented by Mr. CHARLES E. ACKER of New York and assigned to the Nitrogen Company. According to a process of Ashcroft (801,199, Oct. 10, 1905) fused sodium chloride is electrolyzed with a molten lead cathode, producing an alloy of lead and sodium. In the Ashcroft process this lead-sodium alloy was then used as the anode in a secondary electrolytic furnace which had sodium hydroxide or chloride as an electrolyte and an iron or nickel cathode. The metallic sodium liberated at the cathode and rose to the top of the electrolyte. The present patent proposes to use a secondary electrolyte of sodium or potassium cyanide or cyanamide, claiming high efficiency at a convenient temperature, and an improved product. (1,142,220, June 8, 1915.)

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Notes on Homestake Metallurgy.—A paper by ALLAN J. CLARK supplementing a former paper before the Inst. of Min. & Met., London (*Transactions*, Vol. XXII, page 68, 1912-13), was presented at the A. I. M. E. meeting in San Francisco. The present paper deals with changes that have been made in Homestake metallurgy since the former paper was written. A flowsheet is given in Fig. 1.

A new mortar recently adopted retains the old inside lines so effective in maintaining a rapid discharge. All the front above the screen rest has been cut away; also a considerable portion of the back. The result is greater accessibility and increased safety to men when changing iron—it permits the use of longer bossheads and simplifies the care of feeders. A small chip tray of 4-mesh screen rests above the discharge screen and collects floating particles of wood. These are collected and burned, the ashes having a value of $300 per ton.

Table I shows the tendency of the unoxidized ore to amalgamate less readily than was the case in earlier years, and the tendency toward recovery of amalgam farther from the battery.

TABLE I.—COMPARISON OF AMALGAMATION RESULTS ON ORES OF DIFFERENT PERCENTAGES OF SULPHIDES

Column I. All mills, three-month period in 1910.
Column II. One mill, crushing unoxidized ore exclusively, three months, 1915.

Of the Total Recovery by Amalgamation, there was Recovered from:	I. Per Cent	Cumulative Per Cent	II. Per Cent	Cumulative Per Cent
Batteries	49.4	49.4	35.6	35.6
First-row plates	37.5	86.9	42.9	78.5
Second-row plates	4.4	91.3	8.1	86.6
Third-row plates[a]	2.3	93.6	3.5	90.1
Fourth-row plates[a]	0.9	94.5	2.0	92.1
Skimmings[b]	4.0	98.5	6.9	99.0
Trap sands	1.5	100.0	1.0	100.0
Percentage of ore value		71.7	....	69.7

[a] Only two mills (440 stamps) equipped with a fourth row of plates.

[b] The "skimmings" of the above table are recovered from re-treatment of the foul amalgam, sulphide particles, etc., removed from the cleanup sink during the cleanup of the chuck-block and plate amalgam.

In an effort to determine what relation, if any, exists between the amount of quicksilver fed to the batteries, the amount of bullion recovered, and the grade of the ore crushed, the records of all six mills were tabulated over a period of one year. While the experiment was without decisive results, the results of four mills, including those crushing ore of the two extremes in value, coincided reasonably well with a curve represented by the equation:

$$T=\frac{8.5\,B-H}{H}$$

when

T = Value of ore (dollars per ton).
H = Troy ounces of quicksilver fed to batteries.
B = Troy ounces crude bullion ($16 per oz.) recovered.

A detailed analysis of lost time in the stamp mills shows a percentage of 1.07.

COST OF STAMP MILLING

	Stamping	Amalgamating		Total
		Normal Charges	Rebuilding Plate House	
Operating labor	$0.0895	$0.0164	.....	$0.1059
Other labor	0.0033	....	$0.0064	0.0097

Classification and aeration are two essentials for successful sand treatment. Aeration is necessary to prevent ferrous compounds removing oxygen from the solutions, and is accomplished by forcing air under slight pressure below the canvas filter. Laboratory tests indicate that on an average 75 cu. ft. of oxygen is absorbed by a ton of ore before its reducing action is corrected.

Although it had been recognized that high protective alkalinity was detrimental, it had been considered impossible to dispense with it entirely, or practically so. Eventually this was done, with improvement in extraction and decreased consumption of cyanide. These results were partly due also to another change made about the same time. Solutions of two strengths are used, that stronger in cyanide being used earliest in the treatment of a charge. When these solutions appear as

effluents, one portion is precipitated and the other brought to full working strength by adding cyanide, and returned to the extraction of another lot of sand.

"This custom is by no means unusual, yet wherever it is used the procedure seems to be to maintain the stronger solution at a fixed content of cyanide and to allow the weaker to vary in strength according as the varying losses in treatment may determine. This is wrong in principle. The critical strength is that below which the weaker solution will no longer dissolve its quota of gold, or, if dissolving it, will no longer freely yield it to precipitation. If the strength is greater than this, we may confidently expect some cyanide to be destroyed without giving compensatory service. In such circumstances, if the maximum working strength is reduced, the weaker solution will be automatically restored to the lowest economic strength; if it falls below this, a temporary increase in the maximum strength will restore it. In other words, cyanide should be added to the *strong* solution in accord with the determinations of strength made on the *weak* solutions. Thus, operating with a strong solution of variable strength and a weak solution also variable, but never far from its effective limit, it may be anticipated that little cyanide will be needlessly expended."

[a] Includes only larger items of repair work, necessitating the labor of a crew of carpenters.

Unit consumptions per ton of sand treated: Sodium cyanide, 0.257 lb.; zinc dust, 0.061 lb.; lime, 2.48 lb.; power, 1.09 kw.-hr.

Treatment of slime in the Merrill presses is identical in principle with that of sand, periods of aeration and treatment alternating. The minimum working strength is determined by the ability to precipitate the solutions. For a ten-day period the consumption of NaCN per ton of slime was: In treatment, 0.127; added for precipitation, 0.008; total, 0.135. The cyanide added for precipitation is usually added with the feed of zinc dust. An excessive amount of zinc dust is also necessary to insure clean precipitation of these solutions, entailing further expense in refining as well as in the first cost of zinc. These additional costs consume about 25 per cent of the profit of reducing cyanide consumption.

The tonnage of slime treated is measured by the "flow gravity" system, which the author elaborates as follows:

Procedure.—Valves on the two "sludge tanks" receiving the incoming stream of pulp are closed. The depth of slime in each tank and the time are noted. The stream of pulp is now diverted to tank *A*, the discharge valve from which is closed, the presses being served with pulp delivered from tank *B*. When tank *A* is filled, the time and volume are noted, the valve from *B* is closed, the pulp turned to tank *B* and the discharge valve from tank *A* is opened. These alterations continue throughout the period assigned for measuring. Changing, which is at intervals of about thirty-five minutes, is not instantaneous, but the actual measurements cover 90 per cent of the total time, sufficient to insure a correct average rate.

At half-hourly intervals the stream of pulp is cut by a mechanical sampler, a 5-gal. bucket being filled and the weight of pulp determined. These determinations

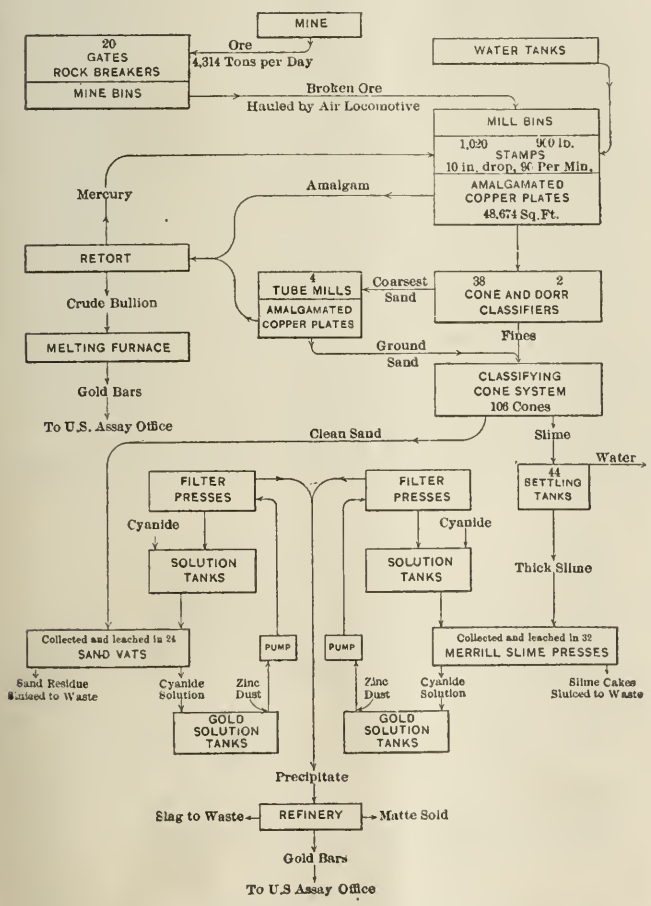

FIG. 1—FLOW SHEET SHOWING ORE TREATMENT AT HOMESTAKE MINE

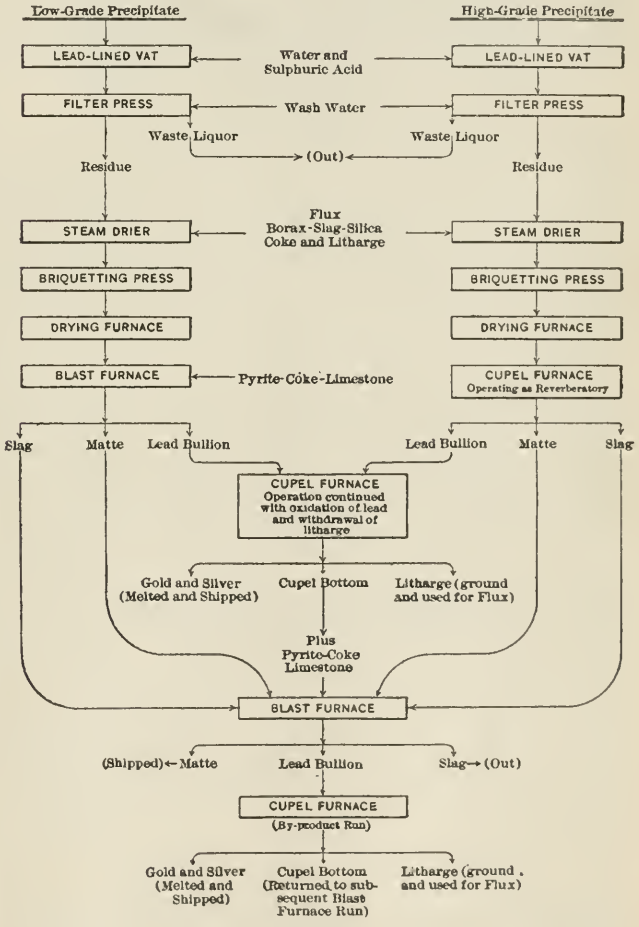

FIG. 2—REFINING OF PRECIPITATE AT HOMESTAKE

are averaged. A specific gravity determination is made on the average sample of slime.

Estimate of tonnage treated between noon of April 8, 1915, and noon on following day:

	Feet	Cubic Feet
North Sludge Tank:		
Total depth pulp to tank	132.667	
Deduct, lime water	1.078	
Balance, slime pulp	131.589	
131.589×518.85 (cu. ft. per foot of depth)		68,274.95
South Sludge Tank:		
Total depth pulp to tank	125.334	
Deduct, lime water	1.003	
Balance, slime pulp	124.331	
124.331×514.42		63,958.35
Total cubic feet for 22.05 measured hours		132,233.30
Estimated pulp for 24 hr		143,927.28
Correction for excess pulp in tanks at end of test		3,590
Cubic feet of pulp run to presses during test		140,337+

During the test, 39 determinations were made of the weight of 5 gal. of pulp. The average of these determinations gave the following data:

Percentage of solids in pulp	33.68
Weight of 1 cu. ft. of pulp	80.60 lb.
Solids in 1 cu. ft. of pulp	27.146 lb.

Total solids to presses during test = 140,337×27.146 = 3,809,600 lb. = 1,904.8 tons, which was divided among 73 presses, making the average charge of 26.09 tons.

Slime Plant Operating Costs for 1914

	Operating Labor	Other Labor	Power	Chemicals	Miscellaneous	Total
Superintendence	$0.0093	.....	.....	.....	.....	$0.0093
Assaying	0.0021	.....	.....	$0.0005	$0.0005	0.0031

Total operating	0.0670	0.0084	0.0184	0.0678	0.0222	0.1838

[a] Minor repairs are carried as Miscellanies; heavy items of repairs, necessitating the presence of carpenter's crew, are included here. Press cloths cost $0.0100 per ton of slime treated.

Unit consumptions per ton of slime treated: Sodium cyanide, 0.161 lb.; zinc dust, 0.118 lb.; lime, 3.48 lb.; hydrochloric acid, 0.393 lb., costing $0.0093 per ton treated; power, 1.15 kw.-hr.

Copper

Hydro-Electric Treatment of Copper Ores.—A research by Robert R. Goodrich on the treatment of an Arizona porphyry ore by a process including the following steps: Oxidizing roast, leaching with sulphuric acid and electrolytic precipitation of the dissolved metal is given in a paper read at the San Francisco meeting of the American Institute of Mining Engineers. The author gives the following epitome of his rather extensive paper:

1. The most suitable temperature for roasting the Arizona porphyry copper ore, containing sulphides, in order to render it amenable to acid leaching methods, is between 600 deg. C. and 725 deg. C. The more finely ground the material the shorter the time required for the roasting so as to produce the maximum amount of soluble copper: materials which will pass through a 20-mesh screen and remain on 80 mesh require about 2 hr. roasting at 600 deg. C. to 725 deg. C.; and when ground to pass through an 80-mesh screen the time required is about 1¼ hr. If the roasting is concluded at temperatures above 800 deg. C., the oxidized copper is converted into a compound which is insoluble in dilute sulphuric acid. The longer the roasting is conducted above 800 deg. C., the greater the amount of insoluble copper produced.

2. A heated solution is necessary to leach efficiently the copper from the roasted material. A 10 per cent H_2SO_4 solution at 100 deg. C. leached out, in from 3 to 6 hr., all the copper from all roasted materials (through 40 on 80 mesh, through 80 mesh, whole through 20 mesh), except material through 20 on 40 mesh, in which case the extraction was not so high.

3. The nature of the anode is an important factor in securing depolarization by sulphur dioxide gas.

4. Depolarization with consequent saving in power is accomplished when using sulphur dioxide gas with a carbon anode, while there is no depolarization with a lead anode.

5. The depolarization by sulphur dioxide gas, even with carbon anodes, does not reach the theoretical amount, being between 45 and 65 per cent.

6. The amount of depolarization effected by sulphur dioxide gas when used with carbon anodes varies with the current density, being a maximum at low current density.

7. The method of introducing the sulphur dioxide gas into the cell is unimportant. All that is necessary is that it be introduced in some way, and in such quantity that the electrolyte is saturated with the gas, so that there is some escaping by bubbling at the surface.

8. A smoother deposit of copper forms when using sulphur dioxide gas as a depolarizer than when not using it.

9. In the electrolysis of an acid solution of copper sulphate, when sulphur dioxide is not supplied to the cell and when one is endeavoring to carry electrolysis to the point of complete extraction, a soft spongy deposit begins to form on the cathode before the complete extraction of the copper is effected. There is also a considerable rise in polarization when the copper contents of the electrolyte becomes low.

10. In the electrolysis of an acid solution of copper sulphate, when sulphur dioxide is supplied to the cell, the copper contents of the electrolyte may be reduced to a very small trace with the formation of a good, firm cathode, without rise in polarization toward the end. Current density and energy efficiency remain high to the end. It is only when prolonging the operation beyond the time when but a small trace of copper remains that sulphide of copper forms as a thin coating on the cathode.

11. Lead anodes do not peroxidize or deteriorate appreciably when used with or without the introduction of sulphur dioxide into the electrolyte.

12. A novel idea—step arrangement of process—makes feasible the depositing of copper continuously, while the copper contents of said electrolyte in the respective steps remains constant. A plant composed of several steps of such cells may be operated so that a liquor strong in copper flows to the plant continuously, and the liquor which outflows from the plant is depleted of its copper.

13. The circulation of the electrolyte by the step arrangement increases the current efficiency. Such rapid circulation is not possible in plants as ordinarily arranged.

Lead

High-Lime Slags in Lead Smelting.—A discussion by S. E. Bretherton of the advantages of using more lime and less iron in the smelting of lead ores for the purpose of neutralizing silica was given in a paper before the American Institute of Mining Engineers at San Francisco. The author gives Anton Eilers credit for introducing this departure in 1878-79. The use of lime was less expensive and enabled the metallurgist to make a more silicious slag of lighter specific gravity which contributed to a better separation of metal and matte. It also prevented the formation of "sows" in the lead crucible. When smelting arsenical ores, the use of high-lime slags resulted in the production of less speiss. With the smelting of sulphide ores in Colorado and Utah, matte became a by-product and arsenic gave less trouble. It was generally supposed that the arsenic was taken up in the matte and finally lost in its treatment. The author believes that this was true to a certain extent, but gives the following personal experience to show the effect of high-lime slags in eliminating arsenic.

"The ore to be smelted contained an average of about 3½ per cent lead, 6½ per cent iron, 2½ per cent manganese, 7 per cent zinc, 21 per cent lime, 11.7 per cent magnesia, 8½ per cent silica, 1 per cent alumina, 3 per cent arsenic, and only a trace of sulphur, together with a very small amount of ore, which we called our lead ore, from another mine averaging 11½ per cent lead, 20 per cent iron, 4 per cent zinc, 3 per cent lime, no manganese, no magnesia, 30 per cent silica, and only a trace of either arsenic or sulphur. From this it can be seen that there was more than enough arsenic to make a large proportion of speiss (especially as we smelted regularly considerable speiss containing gold and silver from some old slag dumps in the neighborhood), and no sulphur to make a matte to absorb it. At the same time, the bulk of the ore being so low in iron and manganese and high in lime and magnesia, I was compelled to make a slag very rich in lime and magnesia. The result was that we produced no speiss or matte, excepting once for a few hours when we fed in some sulphide ore to see what the results would be.

"The only detail in our practice which differed from the ordinary method of smelting was to cupel our bullion for shipment until it was rich in gold and silver, so as to use the lead as litharge over again in the charge. The fact that we were able to get rid of the arsenic in the ore and speiss from old slag dumps and make a comparatively clean slag led me to believe that the high percentage of lime base in the charge and the lack of iron with which the arsenic could combine, resulted in the volatilization of the arsenic, this action no doubt being assisted by the oxidizing influence of the litharge used. While our gold and silver losses were satisfactorily low, our lead losses were very high, which was to be expected when using the lead over and over again in such an oxidized mixture and keeping the coke consumption as low as possible. Coke was the only reducing agent used."

Fuels

Oil Fuel for Heating, Melting and Heat Treatment of Metals.—A paper by W. N. BEST describing some of the applications of oil-firing in boilers for power plants and in commercial furnaces of special design for melting metals and heat treatment of metals, was presented at the San Francisco meeting of the American Institute of Mining Engineers. The paper contains a number of designs of furnaces and calls attention to the necessity for avoiding rule-of-thumb methods in applying oil combustion.

"There has been a greater development in furnace construction during the past four years than in all the world's previous history. It requires 2009 cu. ft. of air to furnish the oxygen requisite for the combustion of 1 gal. of oil. Only about 20 per cent of this air is oxygen, while the other 80 per cent is nitrogen and other gases which unfortunately must be heated up to the same temperature as the furnace, but, for economy's sake, must be expelled as quickly as possible. It is therefore necessary that the furnace construction be such that the consumed and inert gases will be expelled at once. The combustion chamber should be so located and of such form and proportions as to insure perfect reverberation of the heat, while aiding in the quick expulsion of the gases. Only one burner should be used on any billet-heating furnace, no matter whether the charging space be 12 by 18 in. or 8 by 24 ft. in size. For a regenerative melting furnace two burners are necessary; but of course only one burner is in operation at any one time. In all other melting furnaces, whether the bath be 2 ft. square or 20 by 140 ft., whether the product requires an oxidizing or a reducing flame continuously or alternately, only one burner should be used. Additional burners make the operation of the furnace too complex. While the operator may strive to run them all alike, some will be giving an oxidizing and others a reducing flame, thereby impairing the efficiency of the furnace.

"In the designing of furnaces the question is not how many burners can be used, but how few will do the work. A poorly constructed furnace will ruin the efficiency of the best oil burner ever made, while a poor burner will ruin the efficiency of the finest furnace ever designed. It is as impossible to cover a flat furnace bottom or charging space with a round flame as it is to fill a square hole with a round plug. To obtain the highest efficiency and strictest economy it is necessary to have a good furnace, scientifically designed and constructed, as well as a superior type of oil burner."

Viscosimeters

BY R. F. MACMICHAEL

Viscosimeters are instruments for measuring the viscosity of fluids. They operate on two general principles.

First.—The *time* required to produce a definite relative movement of the fluid particles under a given force.

Second.—The *force* required to produce a definite relative movement of the fluid particles in a given time.

Familiar examples of the application of the first principles are:

a.—Long capillary tube, used by scientists.

b.—Short-tube commercial instruments, as Saybolt, Engler and Redwood.

c.—Falling bodies within the fluid, as Arnold, Ladenburg and Flowers.

d.—Rising bubble.

e.—Retarded surface, as Doolittle and Stormer.

In each of these instruments the time required for a definite movement of the fluid particles to take place is noted.

The acting force in each case, except that of Doolittle, is gravity. This may be the weight of the fluid itself, or the weight of a foreign body acting within or upon the fluid, or buoyancy of an air bubble. In the case of Doolittle, energy is stored up in a steel spring, and allowed to expand itself in rotating a disk.

In well-designed instruments of this class, the control of the acting force is almost absolute. However, the time required to make a test is frequently a drawback in the use of the instrument, and the difficulties of maintaining an exact temperature during the test are often very serious.

The fluid must usually be strained before testing. On very viscous fluids, this necessitates heating. Small particles of foreign matter within the instrument may

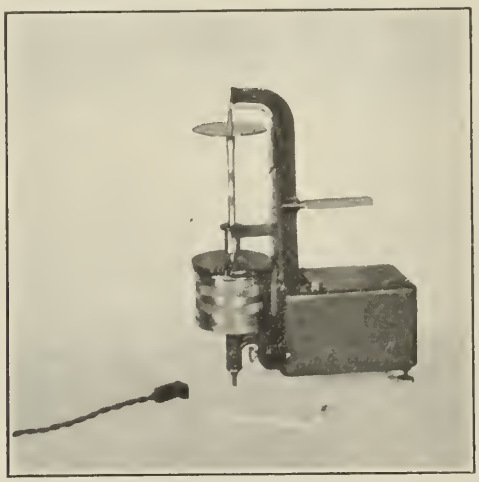

FIG. 1—VISCOSIMETER ASSEMBLED

interfere with proper action, and at times will introduce very large errors.

It is only rarely that colloidal or glue-like substances, or suspensions of finely divided solids, such as clay slips, can be handled successfully in these instruments.

Results are usually expressed in seconds of time. Even in the simplest forms of instruments, elaborate and involved calculations are required to reduce the readings to scientific units, while most of the instruments noted above are not susceptible even to such calculations. In the latter case the results are expressed in an arbitrary manner in empirical units.

The personal equation is large, and considerable care and skill are required if accurate results are to be obtained.

Viscosimeters of each of the above types have been before the public for many years. Up to the present it has not been found possible to combine in any one instrument based on the first principle all of the essential features required in a viscosimeter for general scientific and commercial use.

The most prominent examples of instruments based on the *second* principle are those of Couette, Clark and MacMichael.

In each of these instruments a cylinder or disk is suspended in a cup of fluid, and either the disk or the cup is revolved, and the torsional force noted.

Couette's experiments were conducted at an early date, and though the principles involved were sound, mechanical difficulties were encountered which proved

quite insurmountable at the time of its development.

In the more recent Clark machine, the tangential force applied to the rotating member is measured. This instrument under proper conditions gives excellent results, but the construction introduces mechanical complications which render it unsuitable for general use.

In the MacMichael viscosimeter, the force exerted by the rotation of the fluid itself on the stationary

FIG. 2—CUP AND PLUNGER REMOVED FOR CLEANING

member is measured. This force is equal and opposite to that applied to the rotating member.

The construction is simple and durable. Operation is rapid and accurate, and results are expressed directly in scientific units.

The photograph in Fig. 1 shows the machine assembled and ready for a test. A disk is suspended in the cup of fluid by a torsion wire about ten inches long, running down through the stem of the plunger, and fastened near the bottom.

The head of the torsion wire is triangular, and is held between two grooved pins at the top of the standard. The cup and plunger may be removed and replaced without manipulating any catches or fastenings.

Fig. 2 shows the cup and plunger removed for cleaning. All surfaces are smooth and rounded and may be cleaned with the greatest ease.

The cup is oil jacketed, being formed of two pieces of heavy spun brass. Within the oil jacket is immersed an electric heating coil. This coil draws current from the same line as the motor, only one connection being necessary.

The fluid to be tested is heated in place, no other heating device being required. The operation is very rapid. Stirring is effected by a slight vertical movement of the plunger.

For low-temperature work, the fluid and the adjacent parts are chilled in an ice bath or brine solution.

A bent thermometer inserted through an opening in the cover indicates the temperature, the bulb being immersed in the fluid. The temperature during test may be controlled within a small fraction of 1 deg. Fahr.

The graduated dial at the top of the plunger is secured to the stem by a friction disk, permitting the adjustment of the zero mark to its proper location. The fine adjustment is effected by means of the steel wire pointer at the head of the standard.

The same figure shows the dash pot on the stem of the plunger. This device is frictionless and automatic in action, and requires no attention from the operator. Its function is to check incipient vibrations and to permit quicker readings by damping the action.

In Fig. 3 the standard and hood are thrown back, showing the driving mechanism. The speed control is of the familiar phonograph type and gives excellent results. The motor is specially wound for this service and is furnished either for alternating current or direct current, for use on ordinary lighting circuits. Variations in voltage do not affect the accuracy of the determination.

In operation, the cup is filled to the mark on the side with the fluid to be tested. This requires about 100 c.c. The cover is put on and the thermometer inserted.

By means of the heating coils the temperature is raised to nearly the desired point. As expansion of the fluid will probably have taken place, the excess fluid is removed by means of a pipette furnished with the machine. This automatically fixes the proper level without further attention from the operator.

The temperature is brought exactly to the desired point, the thermometer removed and the motor started. Within a few seconds the dial will have come to rest, and will remain steadily at one point. The deflection noted is the viscosity of the fluid.

This entire operation is very rapid, so that the drop in temperature on ordinary work is entirely negligible.

For extreme accuracy, the temperature may be raised slightly above the desired point, and an allowance made for the drop up to the moment of reading. This will seldom be found necessary in actual practice.

The readings are in degrees of angular deflection, 300 deg. to the circle, designated as deg. M. The practical working unit is 1/1000 of the absolute unit.

FIG. 3—STANDARD AND HOOD THROWN BACK TO SHOW DRIVING MECHANISM

As water at 20 deg. C. or 68 deg. Fahr has exactly 1/100 of the absolute unit of viscosity, water at this temperature reads 10 deg. M.

Thus by shifting the decimal point practical units, absolute units, and specific viscosity may be obtained at one reading. Readings are taken directly from the dial, no intermediate calculations being required.

Gold plated torsion wires are supplied. These wires are of the very highest grade steel. They are extremely strong and their elastic properties are not affected by use. The heads are solid and will not break.

Torsion wires ordinarily give water as 10 deg. M and may be used up to 500 deg. M. This covers the range of most liquids ordinarily to be tested.

For extremely thin and extremely thick liquids, lighter and heavier wires giving readings for water of 100 deg. and 1 deg. respectively, are supplied. This covers every range of viscosity up to about 5000 deg. M, or 500 times that of water.

Calibration of the instrument is effected by testing with a standard fluid of known viscosity. Sugar syrup is used for this purpose. Water may be used for calibrating, but this is not advisable as it is too thin for the best results.

Should the reading of the dial, on test, be found to vary slightly from the correct value, the speed of rotation of the cup is altered by means of the speed control screw at the lower front of the machine.

The deflection of the dial will vary directly as the speed, other factors being constant, and the correct indication may be obtained. When calibrated accurately for one value, the readings will be correct for any other value.

The accuracy of the instrument under ordinary working conditions should be well within an error of ½ per cent above or below the true value. For extremely accurate work, extra precautions should insure results within a small fraction of this error.

As the time required for a reading is extremely short, determinations may be made on suspensions, such as clay slips, which settle rapidly.

Thus, the determination of the plasticity of clay by the MacMichael method is readily made by the use of this instrument. The instrument was originally developed for this particular purpose.

Colloidal solutions may also be handled successfully. This includes glues, gums, starch solutions, gelatine, and other similar materials. Likewise, the viscosity of complicated mixtures such as catsup, or other food materials or chemical substances, may be readily determined. Straining is unnecessary as small particles of foreign material do not in any way affect the accuracy of the determination.

The instrument, with its thermometer and pipette, is complete in itself. No stop watch is required, and no gas burners or other heating device, and no dippers, strainers, graduates, flasks or other parts except as noted.

Skilled labor is not required in its use, as any careful operator may learn to use it in a very short time. The personal equation is small.

The entire machine is built in the most substantial and durable manner, and is guaranteed by the builder.

It is believed that this instrument offers an accurate, rapid, convenient and thoroughly satisfactory means for determining the viscosity of fluids.

Seattle, Wash.

A New Vacuum Pump

Many processes, such as the various vacuum filtration systems now in general use in the mining and metallurgical field, require a vacuum. The modern powerhouse equipment invariably includes a condenser plant, the efficiency of which depends upon the degree of vacuum within the condensing apparatus.

For maintaining this vacuum and for general service in other lines where a high degree of vacuum is desired, the Ingersoll-Rand Company, 11 Broadway, New York, has recently introduced a complete line of steam and power-driven, duplex-type, "Imperial" vacuum pumps.

In general design these machines follow that of the "Imperial" air compressors, a type with which engineers and power plant operators are long familiar.

The vacuum cylinders, as will be seen from the sectional illustration, are different from those ordinarily met with. The intake valves are of the Corliss type, so placed in the cylinder head that the clearance is exceptionally low. This is a desirable feature in that the air trapped in the clearance spaces at discharge pressure will not reach such a volume, upon being expanded to intake pressure, as to greatly limit the pressure reduction which may be obtained. The action of the valve is positive and quick and, its action being independent of the cylinder and intake pressures, the pressures within and without the cylinder are as nearly equal as possible.

The intake ports are larger and direct, which together with the water jacketing of the valve tends to cool the intake gases.

The discharge valves, which are of the "direct-lift" poppet type, are placed in the bottom of the cylinder heads so that any entrained moisture or water is imme-

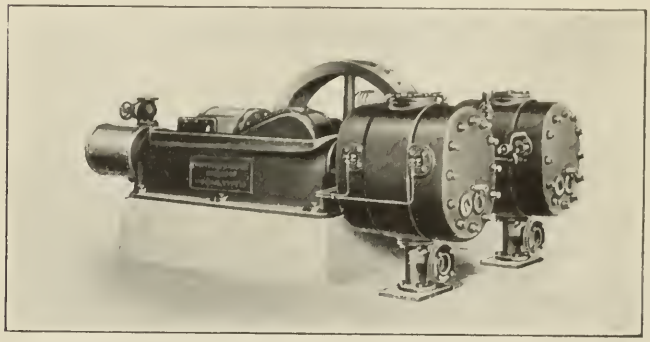

FIG. 1—STEAM-DRIVEN VACUUM PUMP

diately discharged, a feature that makes for safety in handling moist or even saturated vapor. Clearance at the point of discharge has been reduced by making the valve partially fill the port in the cylinder head. These discharge passages are also water jacketed.

The cylinders are said by the manufacturer to meet fully the requirements of satisfactory and efficient operation. The air passages are unobstructed. Tie bolts pass from head to head and hold cylinder and heads tightly assembled. Both cylinder and heads are completely water jacketed, which is said to be an essential feature in the design of vacuum pumps, as the high

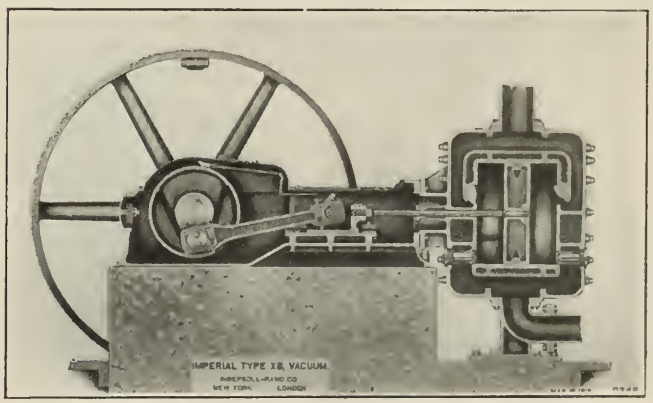

FIG. 2—SECTION OF VACUUM PUMP

ratios of compression tend to create high discharge pressures unless the heat is removed as generated.

The unusually low clearance in "Imperial" vacuum pumps has been obtained, not by dangerously close piston clearance, but by the correct design of the valves and valve ports.

Owing to the extremely low clearance, the complete water jacketing, the use of mechanically operated Corliss inlet valves and other refinements of design the manufacturer guarantees the easy maintenance of a vacuum of within ½ in. of barometer.

The running gear, that is, the main frame with its inclosed reciprocating parts, the crank shaft, connecting rod, crosshead, valve gear and wheel on both belt

and steam-driven machines are of the same design as the "Imperial" air compressor. Lubrication is by the bath system, providing automatic flood lubrication, yet retaining by the removal of covers from the casing, all the points of accessibility of the open type of machine. When operating the flywheel is practically the only visible moving part, yet the entire mechanism is readily accessible while in motion.

The Imperial vacuum pump occupies less floor space than similar capacity machines of the straight-line type, due to its duplex construction and to the fact that its speed of operation is higher.

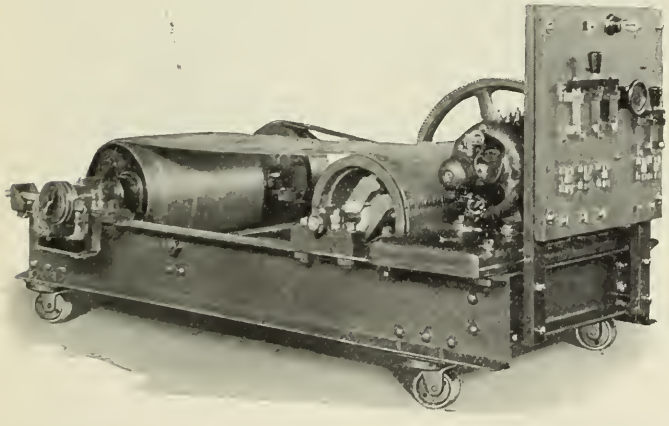
In reality a duplex machine such as this is two identical units of like capacity united by one common frame with cranks at 90 degrees. This makes it possible, should requirements fall temporarily below that for which the equipment was originally installed, to remove one connecting rod and the operation of one-half the machine discontinued, while the other half operates at its rated speed and hence its utmost efficiency, displacing, however, one-half the vapor the entire machine is capable of handling.

These machines are built in capacities from 798 to 7048 cu. ft. per minute, both for atmospheric and low-pressure (5 lb.) discharge.

The manufacturer claims for these vacuum pumps that they operate practically independent of attention and are thoroughly efficient and economical machines for maintaining a high vacuum.

New Portable Magnetic Separator Outfit

The accompanying illustration shows an interesting portable magnetic separating outfit built for the Graphite Lubrication Co., of Boundbrook, N. J., by the Cutler-Hammer Clutch Co., of Milwaukee. The separator is used for separating magnetic particles of iron, etc., from brass in various parts of the plant. The outfit is moved to the point where a separation is to be made and the mixed material of brass, iron, etc., conveyed onto the belt. The brass is projected beyond the



PORTABLE MAGNETIC SEPARATOR OUTFIT—THE MAGNETIC PULLEY IS SHOWN AT THE LEFT

pulley freed from magnetic pieces since the latter stick to the belt in passing over the magnetized pulley and are dropped below where the belt leaves the pulley.

This installation is particularly intresting, as in this plant only alternating current was available. The direct current for the magnetic pulley is furnished by a small 110-volt generator which is driven by the same alternating-current induction motor that drives the pulley. The small panel mounted at one end of the frame carries the three-pole motor knife switch and fuses, the double-pole generator knife switch and fuses, back-of-board type dynamo field regulator and pilot lamp.

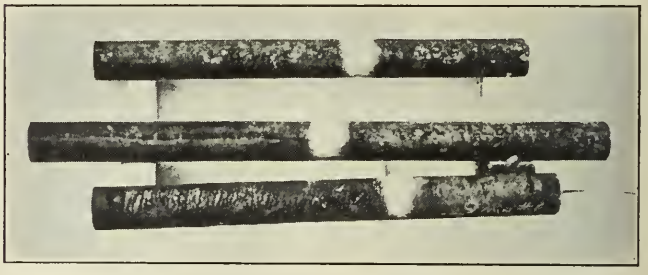
Welding Defective Cores in Paper Mill

The St. Croix Paper Company of Woodland, Me., was formerly throwing all broken and defective paper cores on the scrap pile. Much of this material was sold as junk at the best prevailing market prices. Many carloads of broken and defective cores had been disposed of in this manner before it was discovered that all of them could have been made as good as new by employing oxy-acetylene welding.

By using the Prest-O-Lite process of oxy-acetylene welding, broken cores similar to those shown in the illustration are now repaired in nine minutes. No filling material is used as a method has been found for handling the welding operation so that sufficient strength can be obtained with the material flowed into the weld from the pipe itself. Occasionally, however, a small quantity of filler rod has to be added to insure a joint that will be as strong as the rest of the core itself.

The two sections of pipe are prepared by simply cutting off in a machine with the regular cutting-off tool. The ends of the pipe are not beveled as the extra metal is needed where filling rod is not added.

The cores are steel tubes 3 in. in diameter and average about 50 in. in length. During the welding operation they are slipped over an iron arbor of the same



BROKEN CORES IN PAPER MILL WELDED BY OXY-ACETYLENE PROCESS

diameter as the shaft on which the roll is designed to run to insure perfect alignment with the longitudinal center.

As these cores accumulate very rapidly in the enormous production of the St. Croix Paper Company, it is stated that enough material, heretofore scrapped, is now on hand to furnish several years' supply of new cores without making it necessary to draw on any new material at all.

Tests of welded paper cores indicate that the reclamation process does not affect the original strength in the least—the welded portions stand the punishment incident to rough handling during continual shipping, although frequently the *original* metal in the tube is broken.

Former methods at repairing these damaged cores were very unsatisfactory. One method was to make a hammered weld in a blacksmith forge, first preparing the ends of the rolls by beveling one piece on the inside and the other on the outside so that they fit together snugly, making what was practically a lap weld. This method was exceedingly troublesome.

It is estimated that 250 lb. of coal was used daily in maintaining the fire for the blacksmith's welding operation and only a small number of cores could be repaired in a day as compared with the more economical method of welding by the oxy-acetylene process.

In view of the low cost of the oxy-acetylene welding equipment required and the greater speed with which the repair of broken cores is accomplished, the saving effected by the St. Croix Paper Company is considerable.

Personal

Mr. **Edward L. Brayton**, president of the Pelton Water Wheel Co., San Francisco, Cal., has recently spent some time in New York City.

Mr. **Russel A. Cowles** has resigned his position as a vice-president of the American Brass Company and has become associated with the Buffalo Copper & Brass Rolling Mill, Buffalo, N. Y., and has also recently been elected president of the Metals Trading Corporation.

Mr. **J. V. N. Dorr** was recently in New York, having spent the summer in San Francisco and on the Pacific Coast.

Dr. **James Douglas** of New York has donated $150,000 to McGill University, Montreal, for the erection of a students' residence. He has also been offered the position of Chancellor of Queens University, Kingston, Ont.

Mr. **L. V. Emanuel** has become associated with the River Smelting & Refining Co., Florence, Col.

Professor **W. S. Franklin** has resigned as professor of physics at Lehigh University and will make a tour of the universities of the South and West during the coming fall and winter; he offers to give, in connection with this trip, a number of theoretical and experimental lectures on some needed additions to the subject matter of theoretical mechanics; on wave motion and oscillatory motion; on electric waves; on some phenomena of fluid motion and the curved flight of a base ball, and on "Bill's School and Mine." Professor Franklin's desire is that payment be made for these lectures sufficient to cover the expenses of the trip. Among the lectures to be delivered is also that on some mechanical analogies in electricity and magnetism by which the brilliant author aroused so much enthusiasm at the Atlantic City meeting of the American Electrochemical Society last spring. Professor Franklin's address is care of Columbia University, New York City.

Mr. **Edward Hamilton**, formerly assistant general superintendent of the Duquesne Works of the Carnegie Steel Co., has been appointed general superintendent to succeed Homer D. Williams, who has been elected president.

Mr. **W. E. Hardy**, formerly connected with the Diamond Rubber Co. and the B. F. Goodrich Co., has lately been appointed sales manager of the Boston Belting Co., Boston, Mass.

Mr. **J. E. Johnson, Jr.**, has been elected chairman of the New York Section of the Mining and Metallurgical Society of America. Mr. A. H. Rogers has been re-elected vice-chairman and D. M. Liddell has been re-elected secretary-treasurer.

Mr. **Robert M. Keeney** has accepted a position with the Standard Chemical Co., Canonsburg, Pa., producers of radium.

Mr. **F. C. Newton** has resigned his position as superintendent of the American Smelting & Refining Co.'s plant at Maurer, N. J., to become vice-president and general manager of the Newton Manufacturing Co., Lowell, Mass.

Dr. **Joseph W. Richards**, on his way east from San Francisco, was the guest of the Lehigh Intermountain Alumni Association at luncheon on Sept. 27, at the University Club, Salt Lake City.

Mr. **Charles Sagert** has been made superintendent of the open-hearth steel plant of the Brier Hill Steel Co., Youngstown, Ohio, succeeding Edward Bailey, who has become connected with the Algoma Steel Co., at Sault Ste. Marie, Ontario.

Mr. **H. B. Zeller** has resigned his position as assistant superintendent of the coke plant of the Republic Iron & Steel Co., Youngstown, Ohio, to become superintendent of the new by-product plant of the Toledo Furnace Co., Toledo, Ohio.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, National Union Building, Washington, D. C.

Electroplating

AQUEOUS BATH, APPARATUS

28,590, June 5, 1860, John Matthews, Jr., of New York, N. Y.

Relates to coating the interior of lead and other tubing employed in mineral water apparatus, with silver. The tube itself is employed as the decomposition cell and cathode, a rod or wire passing longitudinally through the tube serving as anode. The tube is straightened, placed in a vertical position, and its lower end closed with a suitable rubber closure through which the anode wire passes. The anode is maintained in a central position by disks of rubber placed at suitable intervals along its length, and is arranged to be moved at will, longitudinally, in order to insure a uniform deposit on the tube. Any suitable silver-plating solution may be used.

75,258, March 10, 1868, Marshall L. Forbes, of West Meriden, Conn., assignor to the Meriden Britannia Company, of same place.

Relates to electroplating spoons and other articles, and to giving them deposits of metal of increased thickness at such places as are subjected to the greatest wear. This is accomplished by immersing different parts of the article to be plated for different periods of time. Two forms of apparatus are shown, each of which supports the spoon at its center, and permits tilting to immerse a gradually increasing surface of the spoon, giving a thick deposit at one point, gradually fading off to the part of the surface where there is little or no wear. After the spoon has received the desired partial coatings, it is removed from the holder and completely immersed, giving it a complete coating. Or the operation may be reversed, by first applying the complete coating, then the desired partial coatings.

78,497, June 2, 1868, William H. Watrous, of Hartford, Conn.

Relates to a frame for holding spoons, forks, etc., to be electroplated. The frame consists of a two-part clamp, one part pivoted to the other, and provided with a pair of jaws each having a serrated, or notched, edge, the notches in each opposite to each other, and co-operating to form a slot in which is suspended the spoon, etc., to be electroplated. The two parts of the clamp may be adjusted to each other by a screw, to admit different sized articles for plating. The complete clamp may hold a dozen or more spoons. The clamp is protected from contact with the electrolyte by a suitable non-conducting coating. The clamp and spoons are immersed in the electrolyte to a depth sufficient to entirely coat the spoons.

84,243, Nov. 17, 1868, Justin P. Woodworth, of Brooklyn, N. Y.

Relates to electrodepositing metals upon articles such as spoons, which are subjected to unequal wear, and to producing a thicker deposit upon the parts which are subjected to increased wear. A supporting rack having a number of holes or openings large enough to hold the spoon or other article to be plated is suspended within the plating tank. A narrow slot from the edge

of the rack to each hole or opening permits the insertion of the spoon. On each side of the rack, and facing the front and back of the spoons are supported deflecting plates of insulating material which shield the parts of the spoon that are not subjected to wear, but exposing to deposit the parts which are subjected to wear. These deflecting plates or shields are adjusted so that a heavy deposit is produced where desired, and a thin deposit where there is little or no wear.

108,510, Oct. 18, 1870, Dubois D. Parmelee, of New York, N. Y.

Relates to electroplating the interior of lead and other pipes. The pipe is first straightened, and then placed on a support at an angle of 20 or more degrees from the horizontal. An anode of the metal to be deposited is provided with several disks of insulating material, having serrated edges, to keep it central in the tube. Means are provided to gradually draw the anode through the pipe, so as to deposit a uniform coating throughout its length. The pipe may also be rotated, or turned slightly, if desired. The lower end of the pipe is closed by a plug, and filled with a suitable plating solution.

114,191, April 25, 1871, Dubois D. Parmelee, of New York, N. Y.

Refers to his earlier patent 108,510, upon which the present invention is an improvement. In this patent, the pipe to be coated is supported vertically, and a plurality of separate anodes are connected together and hung therein, like a chain, the entire length of the pipe. A drum above the pipe serves to support the anode, and to move it longitudinally from time to time to give a uniform deposit. The bottom of the pipe is connected to a reservoir of electrolyte which is pumped into the pipe, and returned when the deposit is completed.

128,166, June 18, 1872, Dubois D. Parmelee, of New York, N. Y.

Refers to his prior patents 108,510 and 114,191. The present patent is for the pipe coated by the apparatus described in the prior patents. It further refers to minor changes in the apparatus and method of use, for which the patent should be consulted.

148,409, March 10, 1874, William H. Bush, of New Haven, Conn.

A frame or flat box is provided with a metal top, perforated with many holes, and a screen or perforated plate within. The sides of the box are either removed, giving an open frame, or are perforated with large holes, to freely admit access to the electrolyte. Screws, tacks, rivets, etc., are inserted in the holes in the metal top, the ends or points thereof engaging the screen within. The screws are then placed in the usual cleaning solutions, then in the electroplating bath, after which the heads of the screws are suitably burnished while still in the frame.

148,409, March 10, 1874, William H. Bush, of New Haven, Conn.

Relates to a mechanism which regulates the quantity of deposit to be placed on an article. The apparatus consists of a counterbalance to one end of which is suspended the article to be plated. The balance is adjusted so that any predetermined weight of metal may be deposited, after which the lever tilts and closes a circuit which rings a bell announcing that the operation is completed, and at the same time operates a magnet which opens the plating circuit.

148,667, dated March 7, 1874, Evans Casselberry, of St. Louis, Mo., and Nathan H. Edgerton, of Philadelphia, Pa.

Consists of a receptacle through the bottom of which pass conductors to which are attached bifurcated wires or plates of platinum or other unoxidizable material. Water or other liquids in the receptacle are decomposed into their elements at the electrodes, the oxygen and hydrogen liberated is collected and may be used for fuel or other purposes.

Book Reviews

American Fertilizer Handbook. Eighth Annual Edition, 1915. Price, $1.00. Philadelphia: Ware Bros. Company.

The current edition of this useful handbook contains more complete statistics of the fertilizer industry than have previous editions. The usual directories of fertilizer manufacturers, allied fertilizer trades, cottonseed oil mills, and packers and renderers are included with special articles and complete fertilizer materials statistics. Among the special articles are the following: German and other sources of potash supply, by Charles H. MacDowell; the sulphuric acid industry, by Andrew M. Fairlie; use of concrete in fertilizer plants, by H. W. Latta; dictionary of fertilizer materials, by Thomas Coulson Pinkerton, five years of cyanamid in America, by E. J. Pranke.

* * *

Elektrochemie wasseriger Losungen.—(Electrochemistry of Aqueous Solutions), by Dr. Fritz Foerster, professor of the Institute of Technology of Dresden. Second enlarged and improved edition, 804 pages, with 186 illustrations. Price in paper cover, Marks 30; bound, Marks, 31.50 (retail price in New York, $10.50). Leipzig, 1915: Johann Ambrosius Barth.

This book is of the series of Applied Physical Chemistry Manuals edited by Prof. Dr. G. Bredig.

The first edition of Dr. Foerster's book appeared in 1905, and the decade's advance in both theoretical and applied electrochemistry has made the second edition necessary. While certain subjects are given more consideration than heretofore, the general plan is left unchanged. The author explains that it is, as before, a textbook which will point out primarily how the fundamental principles of electrochemistry are made useful by their application.

Conception of the broad field covered by the book may best be gained by listing its fifteen chapter titles, viz.: "Electrical Energy and Direct Current Electricity in General"; "The Law of Faraday and Its Practical Deductions"; "Theoretical Deductions from the Faraday Law, The Electrolytic Dissociation Theory"; "The Migration of Ions"; "Bath Voltage and Energy Efficiency"; "The Resistance of Electrolytes"; "Electrical Osmosis"; "The Production of Electrical Energy in Galvanic Elements"; General Theories of Electrolysis"; "Electrolytic Evolution of Hydrogen and Oxygen"; "Special Electrochemistry of Metals"; "Application of Electrochemistry to the Metals"; "Electrolytic Reduction"; "Special Electrochemistry of the Halogens"; "Electrolytic Oxidation." Author and subject indices are included, as well as references to all original articles.

The chapter on the application of electrochemistry to the metals is very comprehensive. It treats with all the important metals, giving greatest space to copper and its refining. The 150 pages devoted to the electrochemistry of the Halogens include both the theoretical and applied branches of this important division of the science.

Dr. Foerster is widely known by his contributions to scientific literature and his most recent edition is a reliable and useful standard reference book for all those interested in the applications of the electrochemistry of aqueous solutions.

Artificial Indigo Made in the United States

The announcement on page 776 of this issue to the effect that the Dow Chemical Company of Midland, Mich., is erecting an artificial indigo plant of a daily capacity of 5000 lb. of 20 per cent indigo paste, will be welcome news to all who, at the recent Exposition of Chemical Industries in New York City, looked at the first sample of artificial indigo made by this company. Mr. H. H. Dow has been an enterprising and courageous pioneer of industrial chemistry in America in many ways. His electrolytic work on a large scale has been of considerable originality and very successful. In transplanting the manufacture of artificial indigo—one of the greatest triumphs of German chemistry—to American soil, Mr. Dow is setting a new milestone in the development of the American dyestuff industry and deserves the heartiest good wishes for the success of his enterprise and pluck.

It still takes a very plucky man to erect a new dyestuff plant in this country. This will be evident from the report on page 779 of the meeting held last week on the dyestuff situation by the New York Section of the Society of Chemical Industry. It was a lively and enthusiastic meeting and there was unanimity of opinion that this country should and must have a dyestuff industry able to fill the needs of the country. But there was anything but unanimity of opinion as to the best way to go about it. Free expression of contrary opinions is always beneficial; and contrary opinions of all shades were expressed from the socialistic demand for a Government factory for the production of the intermediates as one extreme to the individualistic laissez-faire doctrine on the other hand that "the dumping clause is all nonsense; the textile man has a right to buy at the lowest price; everything else is theory and bunk."

This country has two prerequisite elements for the success of a large dyestuff industry—the raw materials and the market. Further a sufficient supply of chemists and chemical engineers—the intellectual raw materials of the industry—will be available in time and in time the technical skill will be acquired which comes only from long years of practice. But it would be foolish to overlook that this will take years of hard work, especially as the dyestuff industry does not lend itself to mass production. During this period of evolution the growing American dyestuff industry will need protection by the government. On this everybody in the meeting last week agreed. But while the whole chemical industry is unanimous in its conviction of the absolute necessity of a protective *tariff*, besides an anti-dumping clause, the representatives of the government shirked *tariff* discussion. Dr. E. E. Pratt, in his other-

wise excellent and very able address, thought that the tariff question is of less importance and can be left out of the discussion, as "we are not likely to reach any final conclusion in such a discussion." This may have been politically expedient, but to us it was the most disappointing note in the whole evening's discussion. Will even those government officials who are most intimately connected with the chemical industry, overlook the obvious fact to which we emphatically called attention at this place last week, namely, that the American chemical industries face a condition, not a theory, and that the abstract question of the desirability or undesirability of protective tariffs has nothing to do with the special concrete situation with which the chemical industry of this country and all who depend on it are now confronted?

Electrolytic Zinc

The production of electrolytic zinc is engaging the serious attention of an increasing number of leading metallurgical concerns, with a fair prospect of developing methods that will practically solve some unusual problems in ore treatment. This impetus to zinc hydrometallurgy with electrolytic recovery arises mainly from the necessity of devising wholly new or improved methods of treating silver-bearing zinc ores and certain complex zinc sulphide ores which are not amenable to ore dressing. Further, the prospect of high prices for spelter makes the present a peculiarly favorable time to embark in new enterprises of this sort.

At Trail, B. C., the Consolidated company is investigating the production of electrolytic zinc from a zinc-lead ore which contains the sulphides of those metals intimately associated in finely crystalline form. Mechanical methods of separation and enrichment are not applicable, and chemical means must be employed. At Anaconda an experimental plant for electrolytic zinc is in operation on certain silver-bearing Montana zinc ores. Near Salt Lake City and San Francisco further work is under way with electrolytic zinc as the goal, and encouraging experimental results are reported.

If the outcome at any one of these places gives the solution of a special problem in zinc metallurgy, a useful and economic purpose will have been served, and the way may be paved to an extension of the process. As has frequently been observed, it is unlikely that the present art of zinc smelting will be revolutionized by these special processes, but there is always the prospect that changing economic conditions will make it possible to widen a field which at first appeared narrow. Prophecy is always hazardous, but particularly so when it attempts to forecast what cannot and never will be accomplished. Electrolytic zinc may still become a case in point.

Bessemer Steel

The place that Bessemer steel now occupies in the steel-consuming industries is one that has been made by fortuitous circumstances rather than by design, and the place is not as important as it might be. This is unfortunate now, for a famine is threatened in steel, and the famine would be reduced in intensity if Bessemer steel were more generally used. The metallurgist has confined himself almost exclusively to open-hearth steel, his effort being to improve open-hearth steel rather than Bessemer. He might have done differently if he had not been restricted in the matter of phosphorus. There is, and has been for many years in the United States, practically but one phosphorus content, and that is a content that will just pass muster as being not over 0.10 per cent. It is curious in the retrospect to reflect that the influence that caused the rapid erection of basic open-hearth furnaces in recent years was the same influence that caused the phosphorus to be fixed at as close to 0.10 per cent as possible, that influence being fear of a shortage of Bessemer ores. The metallurgists have not been allowed to consider what might be done with a Bessemer steel of 0.06 or 0.08 phosphorus content. There are ores that will make such steel, but established custom is to mix them with ores of higher phosphorus content, so as to produce a steel just within the established limit. The custom has been established for years, but it is justifiable at this time to raise a question whether it has not outlived its usefulness.

The distinctively bad feature of commercial Bessemer steel is its low shock ductility in proportion to its static ductility, a characteristic usually attributed to its phosphorus content. This difference between static and shock ductility, established by the engineers, has become generally recognized in the commercial use of steel, whether or not the users themselves know the meaning of the terms static and shock ductility, for one finds the widest use of Bessemer steel to-day in the manufacture of wire, tin plate and steel pipe, all commodities which are relatively little subject to shock in actual use.

Apart from modifications that might be made in the composition of Bessemer steel by a less rigid conservation of the relatively low phosphorus ores, a more widespread use of Bessemer steel might perhaps be cultivated by a judicious educational campaign. For instance, phosphorus tends to produce coarse crystallization, and the temperature to which the steel should be heated in rolling is correspondingly limited. Black plate for tinning is rolled in packs, and to prevent scaling of the tin plate bar and sticking in the pack, which would result in surface imperfections, the rolling is conducted at a lower temperature than any other hot rolling operation. It is a fortuitous circumstance that the practice conduces to bringing out the best physical qualities of Bessemer steel, yet it will hardly be denied that it does do so, and more attention paid to rolling temperatures in other classes of mills might result in a distinct gain.

There has been little disposition in the steel-making trade to encourage the use of Bessemer steel because commercial conditions have not favored the effort. When the demand for steel is small, the producers who can furnish either open-hearth or Bessemer gladly furnish the former, for as a rule they can make it somewhat more cheaply, and every cent per ton counts in such times. When the demand for steel is excessive the buyer is expected simply to take what he can get, to select rela-

tively prompt delivery of Bessemer steel in preference to later delivery of open-hearth steel, if the earlier delivery will suit his purpose better. Thus the position of Bessemer steel, while apparently open to criticism from the technical standpoint, is regarded as defensible from the commercial standpoint.

Riffling Concentration Tables

The present method of riffling concentration tables has not varied greatly from that which was early adopted and found practicable. Such changes as have been made have been conservative, and until recently practice seemed to have become standardized, with little thought of departure from existing custom. We may draw two inferences—either we have reached the ultimate in riffling, or else standardization has acted as a bar to progress by creating the impression that there is nothing to be gained by leaving the beaten trail.

Generally speaking, it seems probable that standardization has been more complete and has been accepted with less question in the case of riffling than in other factors in ore treatment. The same type of riffling has been used with a great variety of ores and under widely different conditions. In this respect we have acted at variance with an accepted principle; viz., that each ore presents an individual problem requiring special study to provide the most efficient method of treatment. Have we given sufficient study to the development of special forms of riffling for different ores, to the end that the best results in concentration may be secured? We think not. As a rule the standard forms of riffling have been adopted without question and often without experiment, while considerable study has been given to other features of the process to be employed.

Considering the diverse conditions existing in concentratable ores, a study of the effect of variations in riffling seems to offer a fruitful field for investigation. One who has engaged in this line of research has obtained results that are surprising, leading to the broad conclusion that, for a given ore, experiment may reveal a method of riffling that will prove more effective than the standard forms. In a number of cases wherein ordinary types of riffling have been ineffective, the results have been remarkably improved by varying the depth, spacing or arrangement of the cleats on the deck. The point seems worthy of more attention than it has received in ore testing.

A "Steel Famine" Possible

The pressure upon the steel mills for steel has reached a tense stage. Buyers are clamoring to place orders and contracts, while the mills are unprecedently reserved in the making of commitments. In October, 1912, when the buying movement of that year reached its height, the increase in the United States Steel Corporation's unfilled obligations was more than a million tons. No such monthly increases are permitted now.

The insistence of the demand for steel is proved quite conclusively by a comparison of the course of prices in this movement and the course in the last movement. In the past decade there have been three major movements in the steel market, that of 1905-6-7, that of 1909 and that of 1912. Steel prices have advanced steadily from the beginning of the year to the present time. The low point of last December was a shade below the low point that preceded the 1912 rise. Present prices for finished steel products are now at an average level with the top prices reached in the 1912 movement, and they are now advancing at a more rapid rate than at any previous time in this movement, a conclusive evidence that the movement is a much stronger one than its predecessor.

To what extent the production of steel can be increased is problematical. The pressure is distinctly upon the steel-producing units, not upon the blast furnaces nor upon steel-rolling departments. To increase the production of steel it would not be necessary to build from the ore mine to the finished product. The relation between steel-producing capacity and blast furnace and steel-rolling capacity, however, is an abnormal one, because an important proportion of the present steel output is of shell steel, involving a heavy discard from the ingot, and thus the proportion of steel rolled to steel poured is abnormally low, and this low proportion is to be simply concurrent with the duration of the war. A not unimportant fact is that the production of steel in the next three months may be less than in the past three months, on account of unfavorable weather conditions.

The United States has about 45 per cent of the pig iron making capacity of the world, and approximately the same proportion of the steel-making capacity. Six months ago the proportion would probably have been estimated at nearer 40 per cent, but the performance of American blast furnaces in the past few months, many of them, if not the majority, breaking all their previous records, though with no change in the physical equipment, indicates that the total capacity of the United States is two or three million tons a year greater than was estimated before this recent test.

All the other iron-producing countries of the least importance are engaged in the war. As a group their exports of iron and steel to non-producing countries are very greatly reduced, and the non-producing countries, recovered in some part at least from the financial shock produced at the outbreak of the war, and with the stocks of material they were carrying greatly reduced if not entirely exhausted, are calling for much more material from the United States. The entente allies, although as a group large producers of iron and steel, are calling upon the United States for enormous tonnages of material in various stages of manufacture.

Business in the United States has been rapidly reviving, with further expansion promised. Productive capacity in the iron and steel industry has grown much less rapidly since 1909, when the great construction program the industry had assumed in 1906 and 1907 was finished, than it did in earlier years, and altogether it is not surprising that a famine in steel should now be threatened.

American Indigo Industry

The Dow Chemical Company of Midland, Mich., is erecting an artificial indigo plant with a capacity of producing 5000 lbs of ordinary indigo paste daily.

As mentioned in our report of the First National Exposition of Chemical Industries, held in New York City in September, a sample of artificial indigo was then exhibited. It may now be stated that this had been produced by the Dow Chemical Company which had a miniature factory for the production of indigo in successful operation for several months.

It is interesting to note in this connection that there are 39 research chemists on the staff of the Dow Chemical Company. They are working in nine different laboratories.

Niagara Falls Section American Electrochemical Society

Transformers for Electric Furnace Work

(*From Our Special Correspondent*)

An air of unnatural solemnity overhung the meeting of the Niagara Falls Section of the A. E. S. at the Niagara Falls Power Co. on Oct. 12. Whether this was due to the fact that some of the liveliest members were engaged elsewhere in electioneering; whether to the whispered tones employed by most of the speakers, apparently awed by the solemnity of a "first meeting"; whether to the fact that the president had secured more material than he could comfortably work off in a reasonable time and consequently was unable to employ his favorite tactics of stirring things up, the fact remains that there were no casualties.

L. E. Imlay opened the proceedings by directing the attention of the audience to the useful subject of reactance in transformers, external and internal, and described, with diagrams, its effect in protection and its effect on regulation. W. S. Horry, who followed, refused to be bound by any narrow regard for the subject of the evening; he preferred to warn the section of the importance of starting its life with a proper conception of its duties and its limits; "from the Niagara River to the secondary we meet on common ground," he stated, and broadly hinted that beyond the secondary were mysteries into which it would be, to say the least, tactless to inquire. After defining a transformer as something which was bound to be frightfully overloaded in the course of its life, he stated that he did not see that anything more could be asked than that shop tests should show that specifications had been complied with, though, he added, as an afterthought, that provision against breakdowns was, of course, paramount. That this paramount condition is not always fulfilled was the burden of the next three speakers, who told harrowing stories of their experiences in recent years. These pictures were, however, not without lighter relief, as when F. J. Tone celebrated Columbus Day by describing how Paul Lincoln and F. A. J. FitzGerald discovered power factor in the early days of the Carborundum company. A. M. Williamson gave a psychological study of the effect on an operating superintendent of the information that "number one unit is on the bum and due for a ride on the flat car," but paid a tribute to the increased efficiency of the repair department of the transformer company by contrasting the 175 days necessary for the repair of the first unit with the most recent record of forty-five on the fourth; the curve was apparently logarithmic, and indicated an approach to 100 per cent efficiency in 1926. F. A. Lidbury sighed for the old days of 2200-volt primary operation, and described some highly unconventional surgery performed on an old transformer built in 1897, for which he evidently had a great affection. F. A. J. FitzGerald described some experiments made by simultaneously observing the temperature of oil in transformers and the temperature of the coils themselves by the "thermoscope," and drew the conclusion "that transformers which are apt to be overheated should be supplied with devices that will let the operators know when the coils are at a dangerous temperature instead of the thermometer in the oil, for this is worse than useless, giving as it does a false sense of security."

Mr. McConahey of Pittsburgh followed with an interesting description of problems in transformer design and manufacture, and showed a large number of lantern slides chiefly illustrating methods of bracing. He prefaced this exhibition by the remark that he was going to let us into a few transformer secrets, that "we electrical engineers are not like you electrochemical men—we don't keep everything we know under our hats." After this wild horses could not drag from us what he said.

John J. Frank of Pittsfield followed, and he really tried to start something. "When you are in trouble, call upon someone who may know more about it than you do," he began, and left little doubt in the minds of his audience whom he meant; after this, however, we were scarcely prepared for his admission that "twenty years ago we didn't know as much about transformers as we do to-day." Acting upon the Billy Sunday principle, that the easiest way to become popular with your audience is to abuse them, he proceeded to draw up a frightful indictment of electric furnace men. According to the speaker, they habitually overloaded transformers 500 per cent; and "when a piece of apparatus is rated 1000 kw. and you take 5000 out of it for years something must happen." Worse still, short-circuiting transformers was one of their favorite amusements, and they were further guilty of hiding from the innocent transformer manufacturer all manner of frightful conditions, high frequencies, rectification phenomena, and so on. Of course, this roused the president's ire at once, as it was intended to do, and there might have developed a certain liveliness had not Mr. Greene, also of Pittsfield, who followed, thrown oil on the troubled waters by admitting that transformer designers owed much of what they to-day know to the co-operation of users of transformers, and particularly to electric furnace men. According to Mr. Greene, the manufacturer now knows how to build to withstand short-circuit and voltage stresses, and on this assumption the most important question is now that of voltage regulation. The induction regulator, while most satisfactory, is too costly, therefore control by taps and dial switches, with intermediate arrangements where necessary, is now being resorted to. He outlined the tendencies in construction along these lines at the present day.

After some discussion as to the respective merits of internal and external reactance, and the amount of reactance for various conditions, in which F. J. Marshall, A. J. Jones, R. H. White and C. A. Winder participated, the meeting adjourned.

The Iron and Steel Market

Steel buyers have become much more insistent in the past fortnight, while steel producers have become still more reserved in the matter of making contracts for forward delivery, resulting in a tense situation, with prices tending to advance more rapidly than at any previous time in this upward movement, now ten months old. Effective Oct. 25, the Carnegie Steel Company advanced bars, plates and shapes $1 a ton, to 1.50c.,

this price at once becoming the minimum of the market. The company's previous advance was dated only ten days earlier, while the preceding advance had been about a fortnight earlier, making a total advance in these products of $3 a ton in less than thirty days. With their related products of skelp, hoops, bands, etc., these products comprise fully one-half the total rolled-steel product of the industry, excluding standard rails, which may properly be excluded in such a comparison as they have not changed definitely in price in more than fourteen years.

The average price of all finished steel products is now equal to the average in the winter of 1912-13, when the great advance of 1912 had culminated and the market was preparing for a period of decline. Prices are still about $2 a ton below the highest level reached in the 1909 rise, and about $6 a ton below the level of 1907. It would be quite unsafe to venture a prediction that the records of 1909 and 1907 would not be broken even in a very few months, so strong is the present price advancing tendency.

The physical influences in the steel market are very strong. Mills have been falling farther and farther behind in deliveries, although in the past three months they have not only produced steel at a much greater rate than ever before, but have doubtless attained the maximum output of which they are capable. Consumptive demand by domestic industries generally is increasing, while the railroads are facing a car shortage not merely during the crop-moving season but thereafter, while their net earnings are at a new high record. The demand from certain belligerent countries is extremely heavy, with no signs of abatement, and the demand from neutral countries is constantly increasing.

The mental influences in the steel market are equally strong, in the matter of tending to advance prices. Buyers of steel are familiar with the fact that war tends to raise prices and recognize that the demand for steel is unprecedented, so that they are much less disposed to resist advances than is usually the case. Sellers are distinctly governed by a different policy than formerly. The theory that steady prices for steel mean steady demand has not worked out satisfactorily. Having passed through a long and severe depression, steel producers are committed to a policy of securing returns when returns can be secured, and the demand with which they are confronted is in the main not such as would be curtailed by price advances to the extent that might be expected under normal conditions. It is a patent fact that conditions in the world are very far from normal.

Thus both physical and mental influences combine to give a strongly advancing trend to steel prices. The end is by no means in sight, and it is easy to imagine prices advancing much more in the next ten months, possibly in the next six months, than they have advanced in the past ten.

Connellsville Coke

An outstanding feature of the general course of prices in the iron and steel industry during the first nine months of the year was that Connellsville coke failed to score any material advance, whereas in previous price movement in the industry coke advanced much more in percentage than did pig iron or steel. The reason was that the rapid erection of by-product coke ovens in recent years produced a total coke-making capacity much in excess of the possible requirements of blast furnaces. Late in September, however, the strength in the general situation became so great that furnaces began to inquire for coke for 1916 delivery, against the expiration of contracts at the close of this year, and in succeeding weeks, up to the middle of October, the major portion of the contract business was done at prices averaging about $2.25 per net ton at ovens, an advance of perhaps 50 cents a ton over contract prices for the present half-year. Furnace coke for prompt shipment remained at a relatively low price. The middle of October found prompt furnace coke at $1.75 to $1.85, and then prices jumped suddenly until within a few days as high as $2.75 was paid for coke for spot shipment. The production of the Connellsville region expanded until a point was reached at which labor scarcity intervened. It remains a question whether the scarcity of coke for prompt shipment will be relieved, or the contract price for next year will advance to the level of the prompt market.

Pig Iron

After the fairly sharp advances that characterized the pig-iron market in July, August and September, a distinct lull occurred in buying, and prices were stationary for practically the first three weeks in October, when a fresh advancing movement began, based not so much upon an increase in buying as upon sentiment, as steel prices were rising rapidly and a broader market for pig iron seemed in prospect. In the past fortnight Southern iron has advanced 50 cents a ton, while the Chicago furnaces marked up prices by no less than $1.50 and foundry iron in the valleys advanced 50 cents, to a level with the previously established market for basic iron, a level to which it was entitled by reference to cost of production. The steel mills do not buy merchant pig iron to the extent usually expected when they are crowding for production, but predictions are made that consumption by iron foundries is destined to increase materially. The market is quotable as follows: No. 2 foundry, delivered Philadelphia, $16.25 to $16.75; f.o.b. furnace, Buffalo, $15.50 to $16; delivered Cleveland, $15.25; f.o.b. furnace, Chicago, $15.50 to $16; f.o.b. Birmingham, $12 for prompt and $13 for first half delivery; at valley furnaces, 95 cents higher delivered Pittsburgh: Bessemer, $16; basic, malleable and foundry, $15; gray forge, $14.50.

The Jones & Laughlin Steel Company has leased Rebecca, a merchant stack at Kittanning, Pa., and will manufacture its ferromanganese at that furnace, thus releasing one of the stacks at its Aliquippa works for the production of standard basic. Rebecca was idle, but plans had been completed by the owners for blowing it in on basic iron for the market.

Steel

Soft steel billets have not been really a market commodity of late. The mills were oversold for early deliveries and did not care to make commitments for late delivery. Nominally the market has been called $25 for Bessemer and $26 for open-hearth billets, with $1 extra for sheet bars, but practically there have been no sellers. Transactions for 1916 delivery are just beginning. A sale of 4500 tons of open-hearth sheet bars for delivery January to June has been made at slightly over $30 delivered, equivalent to about $28 at maker's mill, Pittsburgh, and Bessemer sheet bars are reported to have been sold for first quarters at about $27, Pittsburgh. Makers of large rounds for shells, possibly caught short, have paid all the way from $50 to $70 for billets made to shell steel specifications, discards 25 or 30 per cent, ingots chipped, and analysis fairly stringent though by no means difficult. Rods are $32 to $33, Pittsburgh.

Finished Steel

Effective Oct. 21 wire products were advanced $2 a ton. Bars, plates and shapes advanced $1 a ton about Oct. 25. Black and blue annealed sheets have advanced rather steadily. Tubular goods are unchanged.

Current quotations, f.o.b. Pittsburgh, unless otherwise noted, and in general for delivery at mill convenience, with premiums sometimes paid for prompt shipment, and with forward contracts difficult to place:

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.50c.

Shapes, 1.50c.

Steel bars and bands, 1.50c., base; steel hoops, 1.70c. to 1.75c.

Iron bars, 1.559c. to 1.609c., Philadelphia; 1.35c., Chicago; 1.45c. to 1.50c., Pittsburgh.

Plain wire, 1.70c.; wire nails, $1.85 per keg, base; painted barb wire, 2.00c.; galvanized barb wire, 2.70c.; fabricated wire fence, 69½ per cent off list, in carload lots.

Sheets, blue annealed, 10-gage, 1.70c.; black, 28-gage, 2.10c. to 2.20c.; galvanized, 28-gage, 3.50c. to 3.60c.; painted corrugated, 28-gage, 2.30c.; galvanized corrugated, 28-gage, 3.55c. to 3.65c.

Tin plate, $3.10 to $3.20 for 100-lb. cokes.

Steel pipe, ¾ to 3-in., black, 79 per cent off list; galvanized, 63½ per cent off list.

Boiler tubes (less than carloads), 3½ to 4½-in., 71 per cent off list.

Structural rivets, 1.90c.; boiler rivets, 2.00c.

Notes on Chemistry and Metallurgy in Great Britain

(From our London Correspondent)

The Organization of Scientific and Industrial Research

We are a strange race. A national research scheme has been established. It was needed badly enough. But the net result is a ruling authority of successful politicians advised by ultra-scientific figure-heads.

There is first of all the establishment of a Committee of the Privy Council responsible for the expenditure of any new money provided by Parliament. This comprises the Lord President, the Chancellor of the Exchequer, the Secretary of State for Scotland, the President of the Board of Education, the Chief Secretary for Ireland, "together with such other Ministers and individual members of the Privy Council as it may be thought desirable to add." Under this category Lord Haldane, Mr. Arthur Acland, and Mr. J. A. Pease have been added to the Committee.

The second link in the chain is the advisory council which has to advise the Committee on:

(1) Proposals for instituting scientific research.

(2) Proposals for establishing or developing special institutions or departments of existing institutions for the scientific study of problems affecting particular industries and trades.

(3) The establishment and award of Research Studentships and Fellowships.

The first members of the advisory council are Lord Rayleigh, Dr. G. T. Beilby, Mr. W. Duddell, Prof. B. Hopkinson, Professor McLelland, Professor Meldola, Professor Threlfall, and Sir William M'Cormick. Of course Mr. Duddell, and to a certain extent Mr. Beilby, are open to suspicion as having some practical experience of applied science, but so far as the advisory council is concerned there is no direct representative of manufacturing interests. As for the Committee of the Privy Council and hope of representation of manufacturing interests by men who know depends on the fortuitous chances and mischances of who may be the members of H. M. Government at any given moment. There is in fact no prospect that the men who know will under the present scheme ever sit on the ultimate court of administration.

Yet despite these defects which your correspondent voices and which are very widely recognized, the scheme is by no means doomed. Salvation will be with the practical scientists on the Institutional Research Committees and in the sub-committees they appoint to deal with specific subjects. In spite of all the very learned or politically very successful figure-heads, in spite of all this top hamper one can still hope for good results. It is another question whether the over-all efficiency will not be capable of great improvement. In England figure-heads are necessary, and one supposes that it is only as a sop to the modern democratic unrest that they are not at once more numerous and more picturesque, and more uselessly arundite. According to all precedent there should at least have been added a spiritual peer, an eminent Assyriologist, a titled philatelist, the Astronomer Royal, and the President of the divorce court.

The Lighting of Factories and Workshops

The first report of the Home Office Departmental Committee on lighting in factories and workshops has just been issued, the Committee feeling that although the investigation is incomplete, and cannot be completed under the conditions prevailing at present, it is desirable to make available to the public the work already done, and to formulate certain recommendations regarding suitable standards of illumination. The report contains an immense amount of detailed information, and the subject is discussed at considerable length. The conclusions of the Committee in brief are that statutory standards of "adequate and suitable illumination" should be set up, and the standards suggested are minimum illumination on a horizontal plane at the floor level of 0.25 foot-candle in workrooms, 0.4 foot-candle in foundries, 0.1 foot-candle in passages, and 0.05 foot-candle in open spaces out of doors. These recommendations are subject to certain qualifications and exemptions, and are, of course, only provisional; they will serve, however, to indicate approximately the standards that will eventually be adopted, and will thus be of assistance to works managers, who will also find the mass of data contained in the voluminous appendices of the greatest value.

Market Prices

AUGUST, 1915.

Copper opened (3d) £72.10 and was £74 on the 4th, then fell away to £66.17.6 on the 13th. It subsequently improved a little to £67.17.6 on the 16th, but afterward continued to fall to £64.7.6 on the 23d. On the 25th a sharp rise of £3 occurred, and on the 26th £72.15 was reached, and £72.17.6 on the 27th. It closes lower at £68.17.6.

Tin opened £156.15 and dropped away to £150 by the 9th, and, after touching £152.6 on the 11th, to £149.10 on the 13th. It then hardened slightly but was again falling on the 18th and reached £148.5 on the 20th. On the 24th it was £150.5. This metal also participated in the rise on the 25th, and was £153 on the 27th, closing at £151.5.

Cleveland opened 65/10½ and touched 66/3 on the 5th and 66/4½ on the 9th and 11th, but afterward went lower, declining to 64/1½ by the 20th. On the 23d it was 64/7 and closed 65/6.

Hematite remained at 95/- throughout the month.

Scotch Pig opened 71/10½ and was 72/4½ by the 9th and on the 11th, but 71/10½ on the 13th and 70/31½ on the 20th. On the 24th it had recovered to 71/1½ but closed 70/9.

English Lead opened £24.15 and fell steadily to £21.10 on the 12th, recovering then to £22 and on the 24th to £22.10, closing same price.

The Dyestuff Situation—Papers and Discussion

Before the New York Section of Society of Chemical Industry

With the largest attendance which has ever occupied Rumford Hall, in the Chemists Club, the New York Section of the Society of Chemical Industry held a meeting on the evening of Oct. 22 for the presentation of papers and discussion on the dyestuff situation in this country. It is estimated that between 400 and 500 were present. Every available space was taken and many were forced to stand throughout the meeting, showing the live interest which is taken in this question. The chairman of the section, Dr. **William M. Grosvenor,** in opening the meeting said that regular business would be dispensed with and then gave over the conduction of the meeting to Dr. **Charles F. Chandler.**

Dr. Chandler gave a very interesting talk, showing the tremendous advantage which Germany has over America in making dyes in view of her many years of valuable experience and wonderful commercial development. In reviewing the discovery of dyes he said that Wolf in 1771 was the first to make an artificial organic dye. He treated natural indigo with nitric acid, forming picric acid. However, the epoch-making invention was Perkin's mauve (1856) and the present dyestuff industry really dates from that time. Dr. Chandler, who had visited many of the largest German factories, spoke of the wonderful and intricate development which has taken place in their dye industry. Friedrich Bayer & Company of Elberfeld, had in 1875 eleven chemists. In 1905 they had 300 doctors of philosophy—university graduates—and 8000 workmen. Is it any wonder that they can make dyes with this co-operation between university and factory? This company exhibited 161 colors at the Centennial Exposition in 1876. Not long ago they bought a square mile of land for additions to their factory. One of the newspapers recently gave an account of a plant under contemplation which was to make dyes in Long Island City. This plant was to be 40 ft. by 75 ft. A splendid account of the development of the coal tar industry is that by Friedlaender comprising thirteen volumes and describing the industry from 1877 to 1912. We ought to prevail upon our own Government that the Bureau of Census bring up to date and re-issue the catalog of U. S. chemical patents published in 1902. This would be a very valuable reference work.

DR. CHANDLER: *Hall's process for cracking gas oil—three plants in Europe of a total daily capacity of 21,000 gal. gasoline.*

In concluding Dr. Chandler eulogized the splendid work of the American WM. A. HALL in the cracking of petroleum (U. S. Pat. 24,491, 1913), and gave out some facts of history so far not published. In 1913 Hall put up a small plant at Greenpoint and Dr. Chandler was asked to pass expert opinion on the process and product. Hall started out from gas oil, which at that time was 3½ to 4 cents per gallon. Upon cracking this, 10 per cent gaseous and 90 per cent liquid products were obtained; of the latter 55.76 per cent consisted of "motor spirits," or gasoline. Later improvements, such as a second treatment, brought the yield of motor spirits well over 70 gal. per 100 gal. of gas oil. By actual tests it was found that an automobile required less Hall gasoline than that of the standard. For example, at 1600 r.p.m. 18 per cent more of the standard gasoline was consumed, and at 1200 r.p.m. 31 per cent more.

However, Hall found great difficulty in interesting capital in this country in 1913, and accordingly took his process to England. There he succeeded in obtaining funds and set up a plant with an output of 6000 gal. of motor spirits per day, besides valuable by-products, such as benzol (about 6 gal. per 100 of gas oil) and toluol (about 10 gal.).

During the last year the English Government assisted in the erection of a second 6000-gal. plant, and both plants are now working night and day. A third plant of 9000 gal. has been erected in Continental Europe.

Dr. Chandler then introduced the first speaker on the program, Dr. **E. E. Pratt,** chief of the Bureau of Foreign and Domestic Commerce, Washington, D. C.

Dr. **Pratt** presented a very able paper on "Do We Want a Coal-Tar Industry?" He first reviewed the German industry, giving statistics of capitalization and production. Of the world's production, valued at $92,150,000, Germany produced $68,300,000, or 74 per cent of the world's supply. Three factors are to be taken into consideration in discussing the American dyestuff industry, viz., raw materials, markets and technical skill. The United States has five times the coal supply of Europe, consequently this raw material is well taken care of. The market is about $15,000,000 annually. In technical skill we are not so well equipped, but this has been because of the lack of demand. Our schools can turn out all the chemists needed.

DR. PRATT: *Do we want a dyestuff industry? If so, it must be protected. What protection is necessary?*

Dr. Pratt reviewed the attempts of American manufacturers to make dyes since the first factory was started in Buffalo in 1879. He showed how the foreign interests had undersold American manufacturers at rates below market prices in order to drive them out of business. He quoted from a letter of the Benzol Products Company to the Commissioner of Corporations under date of Jan. 2, 1915, showing the relentless endeavors of the European interests to drive this concern out of business. At one time they lowered the price of aniline oil to such an extent that a price of 8.5 cents failed to secure the order for the American company when the regular market price was 10.9 cents per pound. In 1912 a British member of the European convention tried to induce the Benzol Products Company to go out of business, offering to sell them aniline oil so they could still make a profit on their contracts. "Such unfair methods as these must in some way be prevented. The total loss, direct and indirect, now being borne by American users of dyestuffs and dye wares amounts to not less than $1,000,000 per day. Our users of colors have reverted to dyestuffs and methods long since obsolete and almost forgotten.

"Since the outbreak of the war the five domestic concerns manufacturing dyestuffs have doubled their outputs. One new plant is now in existence and is producing 1000 lb. daily. Another plant will be ready for operation about Nov. 1, and still another capitalized at $15,000,000 has started plans for extensive works. We are making progress but there is a long way to go."

A report is now being prepared by Dr. Thos. H. Norton showing exactly the amount of each of the artificial dyestuffs now in current use in this country consumed by our various textile and other industries during the fiscal year 1914. Such a census of the dyestuffs has never been attempted before and should be a great help in establishing our industry.

"The most powerful weapon, however, in the hands of the foreign manufacturer is the power to throw out of gear our enormous textile industries and all dependent interests during the period inevitably necessary to create an American coal-tar industry. Recommendation will be made by the Department of Commerce that Congress, in whose hands this matter ultimately rests, shall pass such legislation as will, beyond the peradventure of a doubt, furnish the necessary protection. The experience of Canada, South Africa and Australia in this matter should be of great assistance. These countries have passed laws protecting their home industries. Dr. Pratt did not think the tariff question was of such importance as to warrant its discussion, as no final conclusion in that matter would likely be reached, and other means are at present of more importance.

The next paper was presented by Mr. **J. F. Schoellkopf** of Schoellkopf, Hartford & Hanna Co., Buffalo, N. Y., who have been manufacturing since 1879. He spoke on "The Aniline Industry from a Manufacturer's Viewpoint." He emphasized the fact that to be made economically, a great variety and a flexibility of machinery and equipment was necessary. The annual consumption of dyes is estimated at 40 million pounds. Probably close to 1000 different colors are used and no two are made exactly the same. About one dozen colors constitute 75 per cent of the production. The European factories have a larger producton than ours and can consequently run cheaper. The Farbwerke-Hoechst has 300 chemists, 100 of which are analytical and the other 200 have charge of the manufacture of about 500 colors, so that one chemist has only two or three colors under his direct supervision. Here in America people expect one or two chemists to control the manufacture of a thousand dyes and insist upon automatic processes of manufacture. It is absolutely necessary for our American factory heads to realize that, for example, sulphur black and direct black are as different as soap and wood pulp.

MR. SCHOELLKOPF: *Dyestuff manufacture does not lend itself to mass production. A very important problem is the manufacture of the intermediates.*

The most serious difficulty in introducing the dyestuff industry in this country is the fact that it does not lend itself to mass production. There are too many different kinds and shades of dyes necessitating frequent changes in apparatus and methods during the course of the year. This is a distinct disadvantage from an American point of view. The United States has always been most successful in mass manufacture of products of universal use. For instance, the manufacture of automobiles in this country is by far greater than anywhere else. American high cost of labor and natural inclination toward mechanical work favor such products as the automobile.

A very important phase of the dyestuff problem is the manufacture of the intermediates, such as Michler's ketone. We need a large ready stock of these. Some years ago Schoellkopf was influential in getting our government to place these on the free list, since they could be made much cheaper in Germany than in this country. We are now making intermediates in this country, but by no means enough. Mr. Schoellkopf thought that the suggestion made by Mr. I. F. Stone in his address at the Exposition of Chemical Industries (page 663 of our issue of Oct. 1, 1915) in regard to the Government manufacture of intermediates was timely.

In order to show that the manufacture of dyes was not an easy matter and required considerable experience, a list of some of the necessary apparatus was given. This included nearly every variety of apparatus known to the chemical industry. Since the dyestuff industry is subject to change of style a constant shifting of manufacture and, therefore, a great flexibility of apparatus is necessary.

Quite a few German colors are patented in this country for which there can be no competition. But fortunately most of the colors that now control the market are made according to patents which have expired. Mr. Schoellkopf said his own factory had been able to lower the prices from year to year by applying improved methods to old products. This they had done rather than try to make a great variety of new colors. They are making but 136 different dyes out of a possible 1000 now demanded by the textile and other manufacturers. Viewed from a manufacturer's standpoint he said the situation was also difficult owing to the shortage of supplies, including sulphuric and other acids.

Mr. Schoellkopf cited a number of stories from the daily press which greatly amused the audience. One newspaper account contained the recommendation of devoting a "room in each textile mill" for the manufacture of the hundred or more dyes required for that mill.

In concluding Mr. Schoellkopf summarized the immediate requirements of the American color industry as follows: (1) Cheap heavy chemicals; (2) cheap benzol, toluol, etc., (3) large supply of intermediates; (4) co-operation of the United States Government.

A paper on "The Dyestuff Situation in the United States" was then presented by Dr. **Thomas H. Norton** of the Bureau of Foreign and Domestic Commerce, who reviewed the situation and discussed the part of the Government in alleviating the situation. The country is now manufacturing enough aniline oil to satisfy the normal demand. The future depends on what the legislature will do next December. In 1913 about 3000 short tons of colors were made here. The imports were 25,000 tons, of which 22,000 tons came from Germany. In 1916 over 9000 tons will be made and by 1917 our production ought to be 16,000 tons.

DR. NORTON: *A plea for unity in the dye industry, a Government factory for intermediates, a Bureau of Standards for Dyestuffs.*

The largest hosiery mill in the United States and in the world employs 2500 operators. Ordinarily it requires 500 pounds of dyestuffs daily to cover the needs of its dyehouse. Four weeks ago its stock of colors had dwindled to half a barrel. About 160,000 dozen pairs of hose were stacked up awaiting dyes, and more than 1000 operatives were laid off.

Dr. Norton said that despite the efforts of the Government to secure the free passage of European dyestuffs to this country it has not succeeded in releasing more than 50 tons of dyestuffs of German origin since the middle of March, 1915. The powerful association of hosiery manufacturers has agreed to bear the burden of increased tariff duties on dyes of foreign origin, if that is necessary to secure the establishment of an independent American industry.

Dr. Norton made a strong plea for *unity* in the American dye industry. Financial, technical and commercial unity is absolutely necessary for success. He made the following recommendations:

(1) A Government factory for the production of the intermediates as proposed by Mr. Stone.

(2) A Bureau of Standards of Dyestuffs which would set a standard in the purity of dyes, would recommend best methods of dyeing wool, silk, etc., with the various dyes, would protect and help along the young industry and would serve in general as a bureau of information.

(3) A corporation made up of members of the various dyestuff *consumers*—all dyestuffs to be purchased through a central agency, which agency would be assisted by the national bureau. All consumers who would purchase imported dyes at "dumping" prices would be penalized or ruled out altogether.

Mr. **W. H. Childs** of the Barrett Mfg. Co. then presented a paper outlining the policy of the American Coal Products Co. and its subsidiary, the Barrett Manufacturing Co. He said that the manufacture of aniline oil was started by the Barrett Mfg. Co. in 1899, but was not a success, mainly on account of the competition from the foreign "Kartels."

MR. CHILDS: *History of Benzol Products Company. We need a protective tariff and a Scientific Tariff Commission.*

Later the Semet-Solvay Company and the General Chemical Company, together with the Barrett Company formed the Benzol Products Company. By 1913 this company produced 20 per cent of the aniline oil consumed in this country. The foreign concerns tried every means in their power to drive them out, but they continued manufacturing even though they lost money every year. Then came the war. On Jan. 1, 1915, they started manufacturing at their new plant at Marcus Hook, N. J., and are now producing a quantity in excess of the total consumption prior to the war.

Mr. Childs discussed at length the matter of protective legislation. We must realize that the peace perils of Germany and Japan are far more serious than their war perils. Tariff revision is a necessity.

Mr. Childs advocated the formation of a *scientific tariff commission,* this commission to be altogether non-partisan and to be composed of men and women such as Perkins, Edison, Logan, Byllesby, Mitchell, Jane Addams, etc. This commission would study the economic problems of the present and make well-founded recommendations to the Government.

A paper on "Common Sense on the Dyestuff Question" was read by Dr. **J. Merritt Matthews,** consulting engineer of New York City. He said that a great many textile manufacturers have the idea that dyes can be made in a small room by quick and simple means; they have not the faintest conception of the complexity of the aniline dyestuff manufacture. He deplored the propaganda which has been carried on by the newspapers, without doubt in good faith on their part, for numerous wildcat schemes for making dyes; they did not realize the harm they were doing by causing the public to believe the problem was solved and no further difficulties would be encountered.

DR. MATTHEWS: *Tariff protection for the intermediates is most important. Our country never prepared in the military sense without an "intermediate" industry.*

One of the most amusing of Dr. Matthews' stories was that of the owner of a large cranberry bog who wanted to make "cranberry red" from his cranberries, extracting the red dye without in any way impairing the food value. Dr. Matthews pointed out that the crux of the situation lies in the economic production of the *intermediates,* as well as ready supply of sulphuric acid and other necessary chemicals. What this country requires more than anything else to relieve the dyestuff situation is the firm and permanent establishment of the manufacture of the intermediates. We need tariff protection not merely for the dyestuffs, but chiefly for the intermediates, such as Michler's ketone.

It is to the Government's best interests to protect and foster factories for the production of the intermediates, not only for the sake of the dye and textile industries but also on account of the *military* importance of these factories in time of war.

Mr. **John P. Wood,** president of the National Association of Woolen Manufacturers, gave a short talk on the consumer's interest in dyestuffs, in which he stated that there was already sufficient power vested in the Government authorities to prevent dumping, provided it was rightly exercised, and he thought it was going to be a difficult matter to adjust conditions from the standpoint of tariff. The chemists must realize that the tariff is a political question, and they must not ignore present political conditions. The situation is, of course, grave, and the consumers are anxious to do all in their power to foster an American industry so that a repetition of the present conditions cannot occur. He explained the difficulty of obtaining Government action, and the long time needed for proper study of the tariff question. In a certain case a study of only one schedule occupied a period of two years, and then the commission which had made the study reported to the Government that its results were only partial and that it had not adequately finished the work.

MR. WOOD: *We need a tariff not only on dyes in bulk but on dyes that enter the country on cloth, leather, etc.*

He said the dyestuff industry was created out of a protective policy and the same policy ought to be followed now. But we must not only have a duty on the dyes in bulk, but also on the dyes that enter the country on cloth, leather, etc. Proposals made must take into account the fact that consumers need dyes now, immediately, and whereas ten years may ensue before a complete industry is established here, in the meantime the consumer needs the dyes and should be able to get them from somewhere.

Mr. **John Alden** of the Pacific Mills, Lawrence, Mass., commented further on the consumer's interest in dyestuffs. He said that our present supply of dyestuffs consisted of the following: (1) Old stock; (2) small amounts from Switzerland and England; (3) indigo shipped here from China; (4) colors from mills who have more than they need; (5) colors made in this country. To-day the mills are dependent on the last three items with the indigo from China being more or less uncertain. It costs 1 cent per yard more to produce fabric using the Chinese indigo. Many mills would be shut down if it were not for the colors made in this country from our own intermediates. Prices of dyes are very high and it costs more to produce the colors on cloth. For example, with the American navy blue the cost per yard of a number of goods has increased by more than 5 cents as compared with the German dye used before the outbreak of the war. In the same way the cost has increased for aniline black by 1 cent per yard, for wine by ¾ cent per yard, and for para red ⅞ cent per yard.

MR. ALDEN: *The shortage of dyes has quite materially increased the cost of dyed fabrics. This is serious.*

He said that the public had been led to believe through news from various sources that the dyestuff problem was practically solved and consequently the textile manufacturers had been prevented from raising the prices on their cloth very much.

Dr. **Wm. H. Nichols,** chairman of the board of the General Chemical Company, emphasized the great difficulties in carrying on the work of making dyes, and urged that great care be taken in starting new enterprises. He said that colors and intermediates cannot be created merely from the wish to do so, and that a great injury had been done by giving people the view that it is easy to make them. He attributed the success of the industry in Germany not

DR. NICHOLS: *Opening of general discussion. It is very difficult to make dyes efficiently on a large scale.*

merely to government protection, but to the intense application and devotion of the German to the science of chemistry.

Dr. **Chas. L. Reese**, chemical director of the du Pont Powder Company, said that his company is not manufacturing dyes and is not in a position to do so. It is making some intermediates for its own use, but does not intend to go into dyestuff manufacture.

Dr. **Wm. Beckers** of the W. Beckers Aniline & Chemical Works of Brooklyn, N. Y., considered protective tariff legislation as the most vital point in the whole dyestuff situation. The alizarine and indigo derivatives are still on the free list because formerly these dyes were agricultural products which could not be "raised" in this country on account of unsuitable climatic conditions. In consequence of these alizarine and indigo dyes being on the free list, our textile mills have favored these and slighted the aniline dyes. If this is continued the former products are apt to take the place of aniline colors, sulphur colors, etc. The carbazol products are the latest of this class, and the steady growth of these colors could result in their being developed to such an extent as to hurt the aniline dye industry. "The American dyestuff industry is a baby giant still asleep in his cradle, and it is our duty to see that his body and all of his limbs are properly developed and not one of his legs cut off."

DR. BECKERS:

Alizarine and indigo derivatives are still on the free list. This is a discouragement for the manufacture of aniline dyes.

Mr. **Herman A. Metz**, formerly Comptroller of New York City and president of H. A. Metz & Co., said that he represented all sides of the industry, being manufacturer, importer and consumer, and had also had a great deal to do with the tariff question. He said he had always advocated duty on all dyes or none, but that consumers here had backed up the free importation of alizarine dyes, as it of course meant a cheaper product to them and there did not seem to be any likelihood of their being made here. He said the situation demands immediate action as the consumers need the foreign dyes and are going to need them all during the time that the American industry is being developed.

MR. METZ:

The textile industry is much more important than the dyestuff industry. Textile men have a right to buy as cheaply as possible.

The American textile industry Mr. H. A. Metz considered much more important than the American dye industry and we must not impair or destroy the one for the sake of the other. "The dumping clause is all nonsense. The textile man has a right to buy at the lowest price obtainable. Everything else is theory and bunk."

Dr. **Marston T. Bogert** of Columbia University pointed out that the dyestuff industry is primarily dependent upon properly trained chemists. "The industry of producing the chemist is the fundamental industry of all." We ought to establish in this country an institute such as the Kaiser Wilhelm Institute in Berlin. The American university cannot very well meet the situation of supplying the proper material as regards efficiently trained chemists unless the country assists the university in its endeavors.

DR. BOGERT:

The industry of producing the chemist is the fundamental one. We need a Kaiser Wilhelm Institute in this country.

Professor Bogert was the last speaker. After a unanimous vote of thanks to the several speakers on the program the meeting adjourned at a quarter to twelve—one of the longest and most interesting meetings ever held at the Chemists' Club.

Coming Society Meetings

The New York Section of the **American Electrochemical Society** will hold its second regular meeting of the season jointly with the Illuminating Engineering Society on Thursday, Nov. 11, at 8 p. m., at the United Engineering Societies Building, 33 West Thirty-ninth Street, New York. The subject of the evening will be "Electrical Phenomena in Vapors and Gases," and the following interesting program is announced:

"Unstable States in Arc and Glow," by Mr. Walter G. Cady, Wesleyan University, A. E. S.

"Gaseous Conductor Light," by Mr. D. McFarlan Moore, Edison Lamp Works, I. E. S.

"Electric Arc in Complex Vapors at Reduced Pressures," by W. A. Darrah, Mansfield, Ohio, A. E. S.

The speeches will be illustrated by experiments and lantern slides.

Other meetings and lectures during November are:

American Chemical Society (New York Section) at Rumford Hall, Chemists Club, Friday, Nov. 12.

Society of Chemical Industry (New York Section) at Rumford Hall, Chemists Club, Friday, Nov. 19.

Franklin Institute Lectures, Philadelphia, Pa.:

C. H. Herty, University of North Carolina, "Turpentine Industry Development in the Southern States," Thursday, Nov. 4.

J. C. McLennan, University of Toronto, "Spectra, Their Origin and Some of Their Characteristics," Thursday, Nov. 11.

A. A. Michelson, University of Chicago, "On the Ruling of Diffraction Gratings," Wednesday, Nov. 17.

The School of Chemistry of the University of Pittsburgh

The new professional School of Chemistry of the University of Pittsburgh began its work on Sept. 27, 1915, under the deanship of Dr. Raymond Foss Bacon, director of the Mellon Institute of Industrial Research. A prescribed four-year undergraduate curriculum leads to the degree of Bachelor of Chemistry, and the staff of instruction includes the regular faculty of the university and fellows from the Mellon Institute of Industrial Research who are especially qualified in various theoretical and technical branches. This combination gives the new school the opportunity to offer not only the usual undergraduate and graduate courses in chemistry and technology, but also specialized work under men who are experts in specific American industries. In addition, thirty special lectures by prominent chemists and technologists in the Pittsburgh district, have been arranged for the academic year 1915-16. Attendance at these lectures is required of the student body, but they are also open to the public.

The professorate of the new school is constituted as follows: Alexander Silverman, M.S., professor of chemistry and head of the department of inorganic, analytical and physical chemistry; David S. Pratt, Ph.D., professor of chemistry and head of the department of organic, sanitary, and micro-chemistry; Samuel R. Scholes, Ph.D., E. Ward Tillotson, Jr., Ph.D., and Edmund O. Rhodes, M.S., professors of applied chemistry; Benjamin T. Brooks, Ph.D., professor of chemical engineering; William A. Hamor, M.A., professor of chemistry; Henry A. Kohman, Ph.D., and Harold Hibbert, Sc.D., professors of applied organic chemistry; Leonard M. Liddle, Ph.D., and R. Phillips Rose, M.S., professors of organic chemistry; Lester A. Pratt, Ph.D., professor of inorganic chemistry; and C. C. Vogt, Ph.D., professor of physical chemistry. Thirteen assistant professors and ten instructors complete the teaching staff of the school.

Zinc Oxide from Lead Blast Furnace Slag, as in Operation at South Chicago

BY H. B. PULSIFER

When the "National" plant of the American Smelting & Refining Co., located at South Chicago, Ill., was dismantled[1] early in 1915 some of the buildings were spared

FIG. 1—GENERAL VIEW OF PLANT—DUMPS, CRANE, FURNACE BUILDING AND STACK

FIG. 2—CRANE ON DUMP (LOOKING TOWARD LAKE)

and the place was leased to Messrs. Hedges and Divine for the recovery of zinc oxide from the slag dumps.

B. F. Hedges had been superintendent of the refinery[2] for over seven years and R. D. Divine had been metallurgist at the same place for some years. These men had previously made several laboratory tests and short experiments, even, with the large blast furnace to study the expulsion of the zinc from slag on heating with limestone and coke. They had the courage and confidence to make alterations, install the additional equipment necessary and start operations at their own expense. Cheerful to relate, the experiment is successful; their hopes are largely fulfilled, and each day's operation adds to their profits.

The process consists of smelting the refinery slags in the lead blast furnace with additional lime and considerable coke on the charge; the furnace is run with hot top and the heavy zinc fume is collected in bags as the finished product of the operation.

The principle of the process is not essentially different from similar work as carried out at the Oker plant in the Harz[3] mountains or in California plants[4], which have smelted copper ores high in zinc with volatilization of more or less of the zinc. The condition of best operation as at present worked out is worth attention, while the successful prosecution of the experiment will doubtless be copied with renewed vigor wherever circumstances shall allow.

THE SLAG DUMP

The slag dump as left by the lead refining operations covering a quarter century covers a space of some 4 acres and contains a maximum of possibly 150,000 tons of slag running over 10 per cent metallic zinc. Fig. 1 shows the plant and the dumps as seen from the side next Lake Michigan; Fig. 2 is another view of the ground, this time looking east, toward the lake. Certain spots in the dump will probably contain as high as 15 per cent zinc; it will mostly average 12 per cent, but some piles of coal ashes will have to be moved to get at the slag under them. The slag is, of course, practically all that runs from the lead blast furnaces previously charged with the refinery residues. The zinc came from the skimmings off the refining furnaces after the

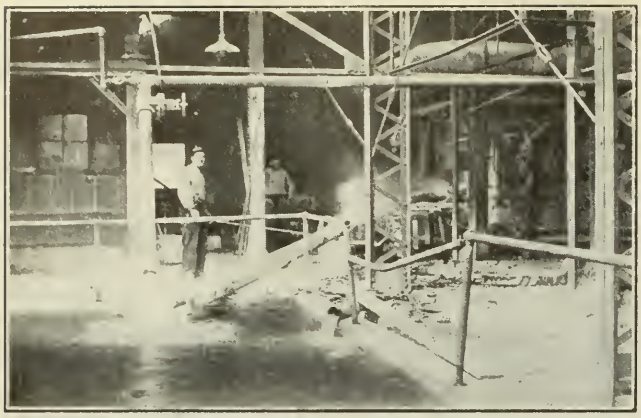

FIG. 4—SLAG FROM BLAST FURNACE RUNNING INTO GRANULATING TANK

desilverization by the Parkes process, this skim, along with many other residues and materials, constituting an important part of the blast furnace charges.

HANDLING THE MATERIALS

This is accomplished by the Browning locomotive crane, as seen in Figs. 1, 2 and 3. The crane digs out the slag and carries it to the hopper above and close to the feed floor of the furnace. The granulated slag is lifted out of the granulating tank by the same crane and deposited in cars or taken back to the dump on the water front, as desired. The limestone, coke, and any other materials can be brought to the furnace by the tracks, bins and elevator formerly used for the same purpose. The locomotive crane was new equipment supplied by Hedges & Divine.

THE BLAST FURNACE

The former bullion blast furnace, which had long been used in a shortened condition, was lengthened out from five to nine jackets on a side, making the furnace now

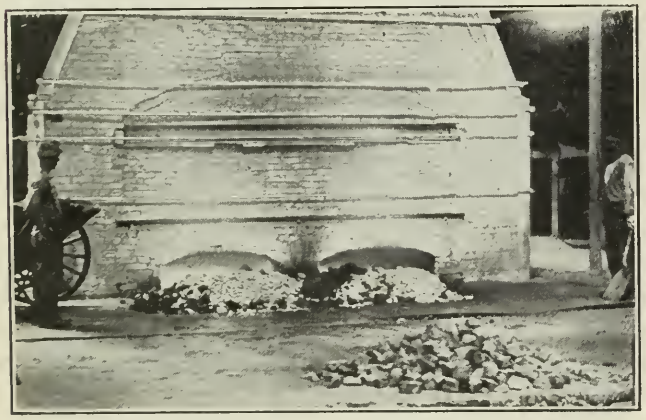

FIG. 5—FEED FLOOR OF BLAST FURNACE

about 46 in. x 156 in. at the tuyeres. The crucible and curb were built up another foot to get more fall to the granulating tank, while the inside capacity of the crucible was largely filled in, and has since become entirely so, slag and lead now flowing out together into the small pot forehearth. Raising the jackets shortened the curtain of brickwork above them up into the shaft but presented no difficulty. From the settling pot the slag flows out through a trough into the granulating tank well shown in Fig. 4.

Considerable experimentation as how best to feed the furnace finally resulted in low hand feeding from one side only. A charge ready to be pushed in is seen in

FIG. 6—FAN AND FLUES IN FAN ROOM

Fig. 5. A charge buggy is seen at the left of the print; only a few feet further to the left are the feed-spouts, which draw into the buggies from the overhead hopper as seen in Fig. 3. The top of the charge is kept nearly at the level of the feed floor; the top is usually red hot; a dense white fume subdues the flickers of the red (calcium) and green (zinc) flames which play up into the big brick flue head.

The furnace is now running smoothly on 12-oz. blast and taking around 65 tons per twenty-four hours. The charge consists of the dump slag, limestone and coke (partly coke breeze). Recovery of zinc is probably not

FIG. 7—BAG ROOM—DISCHARGE ENDS OF PRINZ & RAU MACHINES

over 50 per cent, for the granulated slag still goes some 5 per cent zinc. Besides the oxide driven off there is a noteworthy recovery in lead bullion and speiss—a ton or so each day. This bullion and speiss is, of course, silver-bearing. No change was made in the tuyeres for the new work; there are nine on each side, one to each of the cast-iron jackets; they are approximately 3.5 in. inside diameter. No crusts or hangs have yet appeared inside jackets or shaft after more than two months' steady running.

COLLECTING THE OXIDE

The white oxide which is evolved from the charge in billowy puffs is drawn through about 700 ft. of steel flue by a fan at the bag house. This fan is a No. 80 exhauster made by the Clarage Foundry & Machine Co. of Kalamazoo, Mich. An Allis-Chalmers direct-current

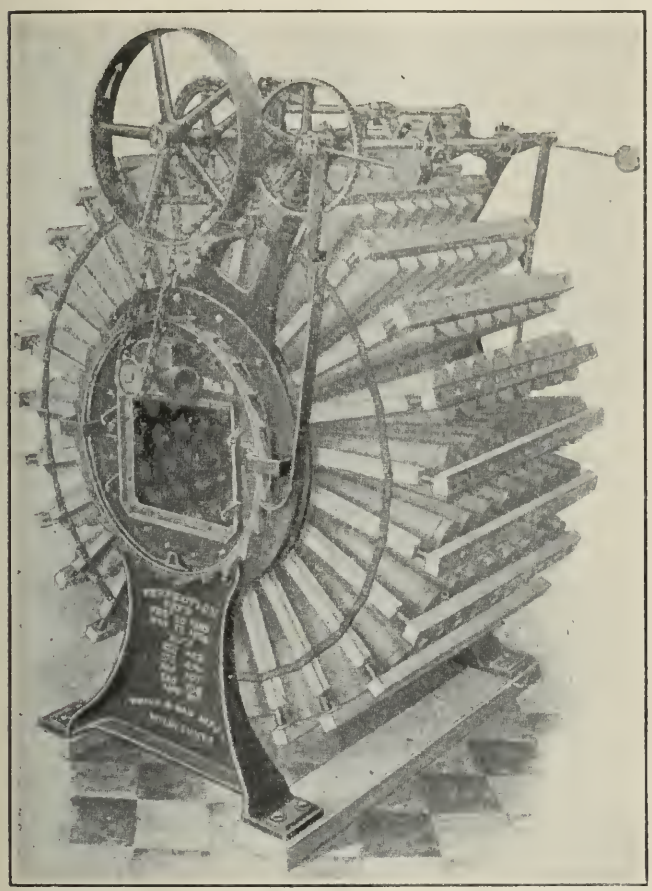

FIG. 8—THE PRINZ & RAU DUST COLLECTOR

motor, 25 hp., taking 220 volts and 96 amp. at full load, pulls the fan.

Fig. 6 shows the intake flue on the left; cooling air enters at the square orifice between that and the pipe to the bags, which comes out at the right. The temperature of the gas is held just under 200 deg. Fahr. A rather heavy fume settles out and builds up in the flue nearer the furnace; this is removed mostly through hoppers, but to get it all out the furnace must be temporarily banked so that men can enter.

Fig. 7 shows the last stage of the recovery. Here the oxide is collected in six Prinz & Rau dust collectors and the bags are filled. This bag room immediately adjoins the fan room. The flue from the fan is divided to supply each of the six machines; from the machines the collecting flue for the gases leads through another fan to the stack so conspicuous in Fig. 1. Unless a bag is damaged and leaks there is no visible exhaust from the bags. The Prinz & Rau machines have many small bags in lines under one supporting base for each line. As each line of bags comes vertical on the cycle the motion halts, the pressure has already died out in that line of bags and a sharp knocking dislodges the collected oxide; then the machine starts another notch to bring perpendicular the next line of bags, the cleaned bag is again inflated and passes downward around the axis. The dislodged oxide falls into a trough; a screw conveyor works it forward to the inclined trough, falling sharply into the paper bag. A full bag has averaged 55 lb. weight, the product containing about 74 per cent zinc and 6 per cent lead.

With the present fancy prices for spelter and oxide the recovery of some 3 tons of oxide a day represents a very respectable profit on the venture. Recovery is, however, far from what might be wished, while the cost of fuel is somewhat large. Further work ought certainly to remedy these defects. There is here a splendid example for further efforts on other dumps and at other plants. Not so very much of improvement would make the process workable on many a zincy dump; not much imagination pictures slag running from blast furnaces into converters (such as the Fink furnace) for the recovery of zinc after smelting for lead without intermediate cooling of the slag.

Removing Iron Scale by Pickling; Theory vs. Practice

BY CARL HERING

When iron is worked into sheets, wires, tubes, etc., the well-known bluish-black scale is produced each time that it is heated to the annealing temperature, or in the case of tubes, to the welding temperature. This hard scale must be removed before the metal can be again rolled or drawn, or before it can be tinned or galvanized. This is usually done by immersing the oxidized metal in sulphuric acid, which is termed "pickling."

Many persons are contented with the knowledge of this fact that iron thus coated with scale can be cleaned by immersing it long enough in sulphuric acid; the method has been known and used for generations. Those manufacturers whose motto is to "let well enough alone," that is, those for whom the methods of their fathers and grandfathers are good enough, are satisfied with this process.

The progressive manufacturer, however, who believes in looking after leaks, will do well to study this process more carefully. This black oxide of iron is Fe_3O_4 and it will be found that this is not soluble in sulphuric acid, at least only with difficulty at objectionably high temperatures. In a test recently made by the writer, a piece of the scale alone, without any metallic iron, was immersed for a prolonged time in rather strong sulphuric acid (sp. gr. 1.2); no gases were evolved and it was found to have lost no weight. It may be that some varieties of Fe_3O_4 are soluble, but this hard, bluish-black kind produced in the annealing furnaces, does not seem to be. At rather high temperatures solution is claimed to take place, but such temperatures cause acid fumes to be generated which are very objectionable.

A possible reason for its not being soluble is the equation $Fe_3O_4 + 3H_2SO_4 = 3FeSO_4 + 3H_2O + O$ which shows that free oxygen would have to be evolved if it were soluble. As this oxygen was combined with the iron it presumably requires a supply of energy to free it. Moreover as this oxygen must be changed from its solid form in the oxide, to the gaseous form, still more energy is required to supply the latent "heat," or more correctly, the energy of volatilization.

As the oxide is already in a low state, from the energy standpoint, little if any energy can be expected to be set

free by its solution. Hence it seems to be necessary to supply some energy from external sources. In the usual pickling process this is supplied by the dissolving of some of the metal itself, whereby good metal and acid must be consumed.

The action in the usual pickling process is therefore not a direct solution of the oxide. The scale is removed partly by dissolving the iron underneath it, and partly by forcing it off by generating hydrogen gas between the scale and the surface of the clean metal by the dissolving of the metal by the acid. It is possible that some of the hydrogen evolved by the dissolving of the iron, combines with the oxygen which must be set free, and that an actual solution of the scale then takes place in part at least; if so, less external energy would have to be supplied.

But in any case, the action in the usual pickling process is dependent fundamentally on the dissolving of some of the good metal, and not on the dissolving of the scale alone. The dissolving of good metal is not an incident in the process, but is a necessary part of it.

The process is therefore intrinsically incorrect in principle, as it is not a true dissolving of the scale, but must consume good iron and a corresponding amount of acid. The scale is not dissolved (or only partly) but the good metal is.

In the electrolytic process, however, the action is reversed; the scale is rendered readily soluble and the metal insoluble, hence it is correct in principle, the scale alone being dissolved. In this process, first brought out by C. J. Reed, and patented by him, the iron is made the cathode, not the anode as was suggested before. In an experiment recently made by the writer, a sheet of this scale alone without any metal attached, was made the cathode in sulphuric acid, and it was found to go into solution very readily when a current was passed, thus showing that when made the cathode, this oxide dissolves readily. It is not reduced to metallic iron, but goes into solution as oxide.

The reason, apparently, is that the tendency to develop hydrogen at the cathode reduces this higher oxide to a lower one, which then is soluble chemically; or perhaps the higher oxide or the partially reduced oxide is dissolved electrochemically, as we know it is in the case of the peroxide of lead on the cathode in a nitrate of lead bath.

Another factor is that the energy which it seems must be supplied when this oxide is to be dissolved in sulphuric acid is now supplied by the current, and it is certainly much cheaper to generate this energy in a dynamo than by dissolving good metallic iron in sulphuric acid, as in the ordinary pickling process of our forefathers.

But whatever be the explanation, the facts are that this oxide is readily dissolved in sulphuric acid when made the cathode. It is also a fact that when the current density is high enough to keep the clean metal covered with hydrogen, no good metal will be dissolved. Hence it is correct in principle; it will dissolve the scale only, will not dissolve any good metal, and will require the consumption of only as much acid as is necessary to dissolve the scale.

Although the amount of good metal and acid consumed in the ordinary pickling process, and saved by the electrolytic process, may be small relatively to the weight of the article pickled, yet when many tons of steel are cleaned per day, as in some large works, the value of these unnecessary wastes amounts to considerable. Mr. Reed (see Trans. American Electrochemical Society, Vol. XI, p. 182) estimates that this saving would be about 50 to 75 cents per ton, amounting in a single works to from $2,000 to $3,000 per day.

Another advantage lies in the fact that the oxide is sometimes formed in rather deep pits. To remove this by the ordinary pickling process would require a prolonged immersion, which would dissolve much good metal and probably make new pits, besides appreciably changing the thickness of the wires, sheets and tubes. The cost increases greatly when the oxide is in deep pits or adheres so tightly that it is difficult to dissolve the metal beneath it. While in the electrolytic process the oxide in such pits merely requires a longer treatment, but does not dissolve any metal, nor does it consume any acid uselessly.

In the case of tubes, the removal of the scale by the ordinary pickling process, sometimes involves the consumption of so much of the good metal that the tubes become seriously roughened and reduced in size and strength.

The anode in this process is most conveniently made of lead. The ordinary scale is removed in about a minute's treatment, less when thinner and more when thicker. The cost of the electric energy is very small, amounting to only a few cents per ton of wires and sheets. The iron comes out of the bath almost white, resembling silver, in marked contrast to the dirty gray appearance in the ordinary pickling process. It is then probably also in much better form for galvanizing and tinning.

In a recent test made by the writer under the ordinary conditions of pickling, that is, with dilute acid and at high temperatures (near the boiling point), the consumption of steel from sheets from which the oxide had been removed, was found to be about 1¾ lb. per thousand square feet per minute of immersion. It is, therefore, quite great, amounting to many tons per day in large works. Roughly, the acid required to dissolve this metal has about the same money value as the steel, or a little more, assuming the latter to be of good quality and to have had considerable work done on it. Both are unnecessarily wasted, as the above does not involve the acid usefully used to dissolve the scale.

Moreover, the surface of the steel which had been thus treated for about 50 per cent longer time than required for the pickling, was found under the magnifying glass to be full of fine pin holes and to be porous, hence would require far more tin or zinc to coat it, if, indeed, it could be well coated at all. A corresponding test made under electrolytic pickling conditions, while current was flowing, showed that no steel was dissolved.

In another test made by the writer, one electrode was made of a slab of scale alone (without iron), the other of cleaned iron, the solution being the hot, dilute one used for ordinary pickling. This was found to act as a battery of about 0.12 volt, the current in the liquid flowing from the iron to the scale, hence dissolving the iron. This shows that in the ordinary pickling operation, a local electrochemical action exists which dissolves the iron at the exposed parts.

A statement often made, especially by those who have little respect for scientific investigations, is that in specific cases practice has shown theory to be wrong. The present case is one in which it may be said that theory has shown the practice of many years to have been wrong.

The present war, so disastrous to Europe, has given a marked impetus to exports from this country, and if by reducing the cost of manufacture by such saving of waste and by other economies, the selling prices can be reduced, this country might be able to enjoy the markets of the world after the war. It is the well-known lack of attention to the saving of waste and to the smaller economies, which is an important factor in depriving us of the markets of the world in competition with other nations which give more attention to such details.

A Rapid Precise Standardization of Acid Solutions

By MERLE RANDALL AND CHARLES C. SCALIONE

A choice of a reliable method for the standardization of acid solutions has been the subject of extensive researches. We shall not attempt to devise a new method. We wish, however, to bring to the attention of analytical chemists, and to adapt to the technical laboratory, the sodium carbonate method used by Richards and Hoover,[1] in the determination of the atomic weights of carbon and sulphur.

This method has the advantage of extreme simplicity, accuracy and rapidity.

Aside from the personal factor of the analyst, the accuracy of a standardization depends on the accuracy with which the acid is measured and upon the definiteness of composition and amenability to weighing of the standardizing substance. Barium sulphate is of indefinite composition, very difficult to filter and weigh, and can be used only for standardizing sulphuric acid. Silver chloride has a definite composition, but its application is limited to hydrochloric acid. The method is tedious, and without extreme precaution and large expenditure of time, its use is less accurate than the sodium carbonate method described below. Because of varying atmospheric conditions substances containing water of crystallization are of indefinite composition. Powdered substances, like Iceland spar, are not definite in composition due to the varying content of absorbed water. Sodium carbonate of sufficient purity, except in respect to water, is available in most laboratories. If not available it can be easily purified by recrystallization in glass or porcelain, or in an ordinary platinum dish if extreme precision is desired. Richards has repeatedly shown that the only reliable method of completely removing absorbed water and other gases is to fuse the substance. Sodium carbonate can be easily fused.

Procedure.—Weigh out roughly into a previously ignited and tared platinum crucible half a gram of pure sodium carbonate. Provide the crucible with a rose crucible cover and pipe stem delivery tube. (A hard glass delivery tube is satisfactory.) Heat slowly to fusion, on a pipe stem triangle, in a slow stream of carbon dioxide from a commercial carbon dioxide cylinder,[2] connected to the pipe stem delivery tube of the crucible by means of a rubber tube. Keep fused three minutes. Remove the flame and allow the salt to cool in the stream of carbon dioxide. While the salt is in a fused condition and cooling, the stream of carbon dioxide is increased. This serves to prevent the decomposition of any of the carbonate as well as to cool the crucible quickly. Run out from a tared weight burette[3] into a beaker flask a quantity of acid roughly estimated to be a little less than that required to neutralize the sodium carbonate employed. Carefully weigh the cool crucible containing the fused salt, then introduce it into the acid solution, covering the beaker with a watch glass. When violent action has ceased boil the solution a few minutes. Allow to cool and when fairly cold introduce a few drops of methyl red indicator[4] Complete the titration drop by drop, with acid drawn from the weight burette previously used. The process may, of course, be conducted with even less trouble by adding at first a slight excess of acid and titrating back with a very dilute hydroxide.

Experimental.—The researches of Richards and Hoover have shown that the accuracy approaches that of the atomic weights. The accuracy in less experienced hands is high. The following new data are presented:

Sodium carbonate containing 5.97 per cent of water was re-fused five times in a current of carbon dioxide. The successive weighings were, 8.43539, 8.43543, 8.43540, 8.43538, 8.43542. No change within experimental error took place.

Dilute hydrochloric acid was standardized by the above method. The results are given in the following table:

No.	Weight of Acid Solution	Weight of Fused Na_2CO_3	Na_2CO_3 per Gm. of Solution	Per Cent HCl
1	261.01	0.5247	0.002010	0.1507
2	151.24	0.3043	0.002012	0.1509
3	113.69	0.2286	0.002011	0.1508

A student using this method for the first time with a strong sulfuric acid solution obtained 26.32 per cent, 26.34 per cent and 26.33 per cent H_2SO_4. A complete standardization can be made in forty-five minutes. The method is applicable to any strong acid and with choice of a suitable indicator to any weak non-volatile acid.

We believe that this method of fusing sodium carbonate in a current of carbon dioxide is more rapid than any other method of bringing a standardizing substance to constant weight. The other manipulations require no more time than those of other standard methods.

Chemical Laboratory, University of California,
Berkeley, Cal.

[1]Richards and Hoover, J. Am. Chem. Soc. 27, 95, 108 (1915).

[2]Carbon dioxide from commercial cylinders is the most convenient. If it is not available carbon dioxide produced in a Kipp generator with acid and marble and passed through cotton to take up the acid spray and then over calcium chloride, will be found satisfactory.

[3]For ordinary work a volumetric burette may be used; but for accurate standardization the weight burette is recommended. A weight burette can be made from a thin-walled glass-stoppered separatory funnel of suitable size by drawing off a tip close to the stopcock. A small test tube provided with a perforated cork is a satisfactory covering for this tip during weighing. The pipette can be suspended from the balance beam while weighing by means of a fine wire loop. Ordinarily the time for weighing the burette is less than that required for the proper drainage of the volumetric burette.

[4]Methyl red is recommended but if not available methyl orange will be satisfactory. Methyl red will be found very advantageous as there is only a two-color change from alkali to acid while methyl orange shows three. For a full discussion see Richards and Hoover. *loc. cit.*

Thermal Principles of the Blast Furnace

BY J. E. JOHNSON, JR.

(*Continued from page* 720)

I had for several years past investigated the subject of the amount of the moisture in the atmosphere as measured by local determinations of the dew point, and as taken from the records of the Weather Bureau, with a view of determining the effect of a given weight of water-vapor on the economy of the furnaces, the ultimate object being to find the relation between the cost of removing the moisture and the value of the saving so made.

Curves of fuel consumption for the year, taken from the furnace books for the corresponding weeks in several years and averaged, were of exactly the same general shape as the curve of annual humidity, but, calculating the effect of the humidity on the basis given by Bell, failed to account for more than a small part of the effect produced.

No adequate explanation was forthcoming until an analysis of the top gases was made, which should have showed a very considerable quantity of hydrogen based on the moisture contents of the blast, but which actually showed very little. This proved very clearly that the hydrogen formed at the tuyeres by the dissociation of the moisture took oxygen from the ore at a higher level in the furnace, where the temperature was sufficiently low to permit the simultaneous existence of water-vapor and carbon, and that in this operation the hydrogen restored as much heat as the original water-vapor had absorbed for its dissociation, so that the explanation

of the loss caused by the presence of water, mentioned above, was not the true one at all.

It then became clear that the heat was absorbed at the tuyeres or in the bosh during the process of combustion (it being entirely impossible for water-vapor to exist in the presence of incandescent carbon) and, being a first charge on the assets of the combustion, was deducted from the already scanty supply of available heat, so that its effects were of the same order and degree, but of opposite kind from those produced by hot blast.

The calculations of available heat with moisture present have to be modified from those of dry blast, because part of the oxygen required for the combustion of the carbon is furnished by the moisture, and the air required per pound of fuel is accordingly diminished.

To illustrate, let us take the case of air containing 0.75 lb. of moisture per 1000 cu. ft., or (on the basis previously explained) per 75 lb. of air, corresponding to spring and fall conditions, with blast and critical temperatures as before, 1000 deg. Fahr. and 2750 deg. Fahr. respectively.

The oxygen in 75 lb. of air is 17.25 lb. and in 0.75 lb. of water is $\frac{8}{9} \times 0.75 = 0.667$ lb.; that is, $17.25 \div 17.917 = 96.28$ per cent of the total oxygen comes from the air.

The air per pound of coke is therefore $0.9628 \times 5.22 = 5.022$ lb. and the heat brought in by it is 1192.7 B.t.u.

The total heat of water-vapor per pound at 1000 deg. is 1552 B.t.u., and the water-vapor being just 1 per cent of the air by weight, the quantity brought in is 0.0502 lb., so the total heat brought in by it is 78 B.t.u. The heat of combustion and that brought in by the coke remain the same, so the total assets of the combustion become 6152.6 B.t.u.

The heat taken out by the nitrogen is 2594.6 B.t.u., that by the hydrogen is 52.4, and that by the dissociation of 0.0502 lb. of water is $\frac{0.0502}{9} \times 61{,}560 = 342.5$ B.t.u. The heat removed by the CO is, as before, 1431.6, or a total thermal expenditure of 4421.1 B.t.u., leaving as the heat available 1431.6 B.t.u. against 1697.5 B.t.u. with dry blast; all other conditions remaining the same. This is a reduction of 15.6 per cent, just about the difference in fuel consumption that is found in practice under the given conditions. If the same loss were referred to the 6000 B.t.u., which represent the approximate total heat development from 1 lb. of fuel, the loss would be 4.4 per cent, which is an insignificant fraction of the actual results in practice.

The results given in Fig. 1 were obtained by a series of calculations similar to the above.

It is hoped that these diagrams will have more than an academic interest to furnacemen, as they furnish an easy means of determining the probable results in fuel economy of any change in the temperature or humidity of the air. They also furnish the means of determining the increase in blast temperature necessary to counteract the effects of a given variation in moisture. While it does not now seem likely that we shall ever obtain stovemen who will determine the moisture from hour to hour, and proportion the blast temperature to meet it, the thing is not impossible; and if some genius would kindly invent a recording and direct-reading instrument for measuring the humidity of the atmosphere, this result might be achieved in fact.

These results, being based on what is supposed to be a new theory of the action of heat and moisture in the blast, will naturally be viewed with some skepticism, so that proofs of their substantial accuracy are in order.

Fortunately the data supplied by Mr. Gayley furnish an admirable opportunity. The critical temperature alone is lacking, but from the kind of iron made may be assumed to have been 2750 deg. Fahr. The humidity, before the dry blast was used, averaged about 5.25 grains per cubic foot, or 0.75 lb. per 1000 cu. ft., and the blast temperature was 720 deg. Fahr. After the application of the dry blast the humidity was about 2 grains, or, say, 0.3 lb. per cubic foot, and the blast temperature was 870 deg. Fahr. By interpolation on the diagram we find the available heat in the two cases to be 1090 and 1420 B.t.u. per pound of fuel respectively. The coke-consumption before the change was about 2140 lb. and, to be in inverse proportion to the available heats, should have been 1640 lb. after the change. Actually it was 1700 lb., a difference which is certainly no larger than might reasonably be expected, considering the many other factor varied. Notable among these is the increased ratio of CO_2 to CO in the top gases, with the correspondingly increased tendency of these gases to dissolve carbon from the fuel in the upper part of the furnace, and prevent its reaching the hearth.

This feature, of which, obviously, the diagrams can take no cognizance, is of the first importance in an exact determination of results.

At many works the effects of the higher humidity of the summer are masked by the fact that the furnaceman carries a higher heat in summer than in winter, either deliberately and for purpose of neutralizing the effect of the humidity, or simply because he finds that the furnace will stand more heat without sticking or other objectionable results. But at the furnaces with which the writer is connected, a constant temperature of 850 deg. is carried the year round, and under these conditions the variation in fuel is clearly apparent, the fuel per ton of iron being about 20 per cent more in the most humid weather than in the dryest. The critical temperature at these furnaces is known to be about 2750 deg. Fahr, the average low humidity is about 0.25 lb. water-vapor per 1000 cu. ft., and the average high humidity is about 0.95 lb. For these conditions we find from the diagram that the available heats are 1400 and 1160 B.t.u., which are in the ratio of 1.20 to 1, or precisely the same as the fuel consumption in the two cases.

In order to obtain a wider range of comparison, I have taken the work of a two weeks' period in two successive years (at precisely the same season in each) done by a small charcoal blast furnace, working with cold blast one year and hot the next.

The comparison is not very satisfactory, because the critical temperature could only be obtained approximately in one case and estimated in the other, the percentage of lime used being twice as great for hot blast as for cold, with a correspondingly great influence on the critical temperature (as will be explained presently). Moreover, in the cold-blast campaign a considerable quantity of cold slag was charged, to overcome the tendency to work "dry," which was not done in the hot-blast campaign.

The recorded fuel-consumption in the two cases was in the ratio of 1.7:1, while the available heats based on the probable critical temperatures in the two cases and without allowance for the remelting of the additional slag in the cold-blast campaign are as 1:2—a reasonable correspondence, considering the circumstances.

I recently found what appeared to be an authoritative statement, that at the Clyde Iron Works (England) the fuel consumption in January-August of 1829, 1830 and 1833, with cold, warm (300 deg.), and hot (600 deg.) blast respectively, was 8 t., 1 cwt., 1 qr.; 5 t., 3 cwt., 1 qr.; and 2 t., 5 cwt., 1 qr., or fuel consumption in the ratio of 3.42:1.56:1, while the available heats, with a

critical temperature of 2750 deg. and average moisture, are as 1 : 1.73 : 2.63, a correspondence which is not by any means accurate, but considering the magnitude of the saving and the probable effects of secondary results is not at all to be despised.

Other considerations of the same general kind in which the data are not available for quantitative comparisons will be given later, but will best be preceded by some remarks on the determination of the critical temperature.

Determination of Critical Temperature.—The paucity of published data of definite character on this subject led me to attempt direct experimental determinations.

This seemed a field in which a radiation pyrometer might be employed more conveniently than any other, and with the advantage of absolutely self-luminous bodies to observe. Accordingly, a Mesuré & Nouel "lunette" pyrometer was obtained. This instrument is not exact, and, for wide ranges of temperature, particularly at the upper or lower extremities of the scale, could not be trusted very far; but for a limited range near its center results obtained by any reasonably careful observer are closely comparable.

Many thousand observations were made with this instrument upon the iron and the cinder, where they flowed over their respective dams, at every stage of many hundred casts.

At first no connection whatever could be observed between the condition of the furnace, the kind of iron being made, and the reading of the pyrometer. Sometimes, it would show much higher temperatures with white iron than with gray, and, again, it would give the opposite result, until I almost gave up hope of getting any information as to the action of the furnace from it. But finally, I observed that the readings were influenced almost solely by the relative calcareousness or siliceousness of the slag, and the difficulty of interpretation then disappeared.

FIG. 1—HEARTH HEAT AVAILABLE PER POUND OF COKE, COUNTING 0.85 LB. OF FIXED CARBON ACTUALLY BURNED IN HEARTH, WITH DIFFERENT CRITICAL TEMPERATURES ALSO DIFFERENT BLAST TEMPERATURES AND DIFFERENT MOISTURE CONTENTS IN THE BLAST

One or two things were eventually brought out with great clearness which are not recorded elsewhere, so far as I know, and are therefore given here, since, though they may be known to others, their publication may still serve to bring out valuable discussion.

The first point noticed was the absolute collapse of the old notion that gray iron was always made in a hot furnace, and white iron in a cold one. (The furnaces were working on basic iron, and the silicon was therefore limited to 1 per cent, so that gray iron in this case means iron with only about this percentage of silicon.)

The next observation was that, in spite of the common statement that black cinder is made because the furnace gets too cold, the black cinder, in reality, was very frequently much hotter than the light.

On the other hand, the old founders' saying that "lime gives heat to the furnace" was confirmed completely, the cinder being without exception hotter in proportion, as it was more limy, as long as the furnace continued to make good iron. Even when the iron became hard, the cinder might still be at its very hottest if very limy.

It was also noticed that the cinder always controlled the temperature of the iron, and that as long as no cinder came through the tap-hole the temperature of the running iron remained practically constant, but as soon as the cinder came the temperature of the iron went up considerably and became the same as that of the cin-

der, which was always decidedly higher than the previous temperature of the running iron.

These observations, confirmed so many times that their accuracy for the given conditions could not be questioned, made it plain that, since the cinder became less fusible as it became more calcareous, it remained longer in the bosh, exposed to the heating action of the ascending gases, before acquiring the high fusion-temperture at which it could flow down into the hearth, while less calcareous slags melted sooner and ran down out of the range of action of the products of combustion.

The cinder, moreover, exercises a deterrent action on the iron as it drips down through the bosh, and by delaying its passage longer, as well as by direct contact, heats the iron nearly to its own temperature, a process which is completed as the metal passes through the layer of slag on top of the iron in the hearth.

The cinder requires not only to be heated up to its temperature of fusion, but far enough beyond this point to give it sufficient fluidity and consequent activity to remove the sulphur coming from the coke, and permit the dissolved oxide of iron to separate out.

So long as sufficient heat is produced in the hearth to impart to the cinder the temperature necessary to give this fluidity, the iron oxide is reduced and separates out; the cinder remains bright; and silicon can be reduced and can stay in the iron, making it gray. But when the temperature required is so high that sufficient heat for this purpose is not furnished in the hearth, the cinder becomes too thick and viscous to permit the operations mentioned; the oxide of iron remaining in it makes it black and, acting as a powerful oxidizer, prevents silicon from going into the iron.

This condition may arise in any one of three ways: (1) By an increase in the lime-content of the slag, raising its fusion-temperature; (2) by a reduction in the quantity of available heat, due to decreased temperature of the blast or increase of moisture; or (3) by a slip, bringing down into the hearth a quantity of improperly digested material.

It thus becomes evident that the temperature necessary, not only to melt the cinder, but to make it sufficiently fluid to perform its functions properly, is the "critical temperature," since the slag and iron must be brought to this temperature, and the final reduction of the ore must be performed above it (and, most probably, other reactions). What may for convenience be called the free-running temperature of the cinder is therefore taken in this paper as the critical temperature.

FACTS OF PRACTICE EXPLAINED BY THE CRITICAL TEMPERATURE

One of these is the fact that furnaces working on rich ores do not commonly show the low fuel-consumption as compared with those working on siliceous ores, which might be expected in view of the large quantity of heat required to melt the slag. The explanation seems to be that in smelting the richer ores the much smaller slag-volume available for carrying off sulphur, requires a much more calcareous slag, and therefore a higher critical temperature, which reduces the available heat per pound of fuel enough to offset largely the advantage of having less slag to melt.

The extremely low fuel-consumption of charcoal furnaces furnishes an illustration of the opposite kind. Having practically no sulphur in the fuel to contend with they can run on a very siliceous and fusible cinder, so that their critical temperature is several hundred degrees lower than that of coke furnaces smelting the same ore—which largely increases the amount of available heat.

The fuel-consumption of furnaces making ferromanganese is, on the other hand, out of all proportion to that of iron furnaces in view of the fact that the heat required for the reduction of MnO_2 is only 25 per cent more than for that of F_2O_3; but this again becomes explicable when we consider the temperature necessary in the two cases, which, though not definitely known, is known to be much higher for manganese than for iron. In the case of iron, nearly all the reduction is effected before the charge reaches the critical temperature; but with manganese this is far from being the case. The quantity of "available heat" required is therefore much higher, as well as the temperature of its application, and the fuel consumption per pound of manganese is therefore much greater.

Similarly the fuel-consumption in the production of iron with 3.5 per cent silicon is probably at least 20 per cent greater than that required for 1.5 per cent silicon iron, though the difference in the heat actually required for its reduction is only 7 per cent. But the silicon cannot be reduced at all except at high temperatures and the critical temperature is therefore raised, as well as the quantity of heat required above it, so that the fuel-consumption is augmented in correspondingly higher ratio.

It is interesting in this connection to consider why in order to make high-silicon iron with a reasonable fuel-expenditure a small hearth is necessary. The reason probably is that since the necessary high temperature cannot be secured by the use of calcareous slag (because such a slag does not allow the silica to leave it and be reduced to silicon) it can only be secured by a longer exposure of the charge to the products of combustion, and for this purpose the currents of both gas and dripping iron must be of smaller cross section, thereby virtually lengthening them and increasing the number and duration of the contacts of the dripping iron with the incandescent fuel—the condition most favorable to the reduction of silicon and its absorption by the iron.

If the claim here made for the existence and position of a "critical" temperature be admitted, it follows that the attainable economy of fuel is subject to a double limitation: (1) By the total development of heat produced in the furnace per pound of fuel, and (2) by the proportion of this heat available above the critical temperature.

A legitimate corollary to this proposition is, that the work done in the process may be divided into two parts, that done below the critical temperature and that done above it, corresponding approximately to the work done above the zone of fusion and that done below it, or, roughly, to that done in the shaft of the furnace and that done in the bosh and hearth. We may for convenience call these respectively the preliminary and the final work. The total heat introduced into and developed in the furnace being H_t and the part expended in the bosh and hearth in the final work being H_a (the "available" heat), the heat necessary for the performance of the preliminary work is $H_t - H_a$.

From the investigations of Bell and others we know with considerable accuracy the total quantity of heat required for the production of a unit weight of pig iron, and from the diagrams herewith given we can determine approximately the proportion of this which must be applied above the critical temperature. In view of the preceding discussion it is apparent that there must be a reasonably definite ratio between these two quantities or between the latter and their difference—in other words, between H_a and $(H_t - H_a)$.

This can be put in the form of an equation which will help to make the matter clear.

If we call the total heat required to produce a unit of

iron R_t, and the fuel required per unit of iron (calculated on this basis) n_1 (H_t being, as before stated, the total heat developed in the furnace by the unit of fuel), we have

$$\frac{R_t}{H_t} = n_1 \qquad (A)$$

or $R_t = n_1 H_t$, the equation, of which both sides were so magnificently and completely analyzed by Bell.

If, however, we denote by R_a the heat required, above the critical temperature, per unit of iron produced, H_a being the available heat and n_2 the fuel-consumption determined on this basis, we have

$$\frac{R_a}{H_a} = n_2 \text{ or } R_a = n_2 H_a \qquad (B)$$

Both A and B must be satisfied if the reduction is to be complete.

If we should increase the degree of oxidation of the fuel, and thus increase H_t without affecting H_a we would effect no fuel economy since we should do the preliminary work upon a larger quantity of ore than the available heat could take care of in the bosh. The furnace would consequently become cold and an increased qnantity of fuel would have to be used to make good the deficiency in available heat.

If, on the other hand, we increased the available heat H_a without increasing the total heat H_t we should either change the grade of the iron enough to absorb the heat-excess or drive the heat up to the higher zones of the furnace, with those disastrous results which furnacemen know under the caption "too hot and sticking." But no fuel would be saved because no more heat being produced for the preliminary work no increase in the quantity of ore prepared for final reduction could take place, hence no increase of output for the same fuel.

It is thus seen that it is necessary to increase the two quantities of heat in the same ratio if any economy is to be achieved. Here the quotation from my former paper ends. It should be particularly noted that, as mentioned above, the mere conception of a critical temperature without determining what this temperature is and what controls it, is of little use and the determination that it depends upon the free-running temperature of the slag is almost as important and as useful in understanding the action of the furnace as the conception of the critical temperature itself.

In fact, the French metallurgist, M. A. Lodin, published in *Comptes Rendus*, Nov. 28, 1904, a brief note suggesting the critical temperature theory to account for the results of the dry blast, but used the fusion temperature of the slag instead of the free-running temperature as the critical temperature. He did not connect it up with the hot blast or the broad facts of practice nor give any quantitative results, and the suggestion did not receive any attention, as far as known to me. My own "disclosure" of the idea was made in patent applications filed April 9, 1903 (see U. S. patent 783,-044), and my original chart of "available heats" was dated and witnessed 1902. Since that time it has become evident that the term "available heat" is too loose, since heat not "available" in the hearth and bosh passes up into the shaft of the furnace and does useful work there so becoming available. I have therefore substituted the terms "hearth heat" for this and use the corresponding term "shaft heat" for that developed or carried into the shaft.

The first requisite to making and understanding such calculations is a table of thermochemical data and specific heats and I give below tables I, II and III of these quantities taken from Prof. J. W. Richards' "Metallurgical Calculations" and where necessary converted to Fahrenheit temperatures and British thermal units instead of calories.

This excellent work had not been published at the time the calculations in the article above quoted were made and the data available to me were not as accurate as those given by Professor Richards.

I have recently recalculated the hearth heats under different conditions in accordance with these more accurate data for the chart, Fig. 1. This is substituted for the original Fig. 1, as the results it gives are the same in principle but somewhat more accurate and the range of conditions covered is wider.

It will be noticed that the chart is based on 85 per cent fixed carbon burned in the hearth which may seem strange as all good coke is much higher than this in fixed carbon. The reason is that the iron made takes up about 4 per cent of its own weight of carbon so that on the basis of a pound of coke of 89 per cent fixed carbon per pound of iron, 0.85 lb. carbon represents approximately the actual amount burned in the hearth with no solution loss, but when much of the coke is lost by solution, it is necessary to determine the actual weight

of fixed carbon burned in the hearth. The results taken from the chart can be applied to this actual weight (in pounds) by dividing by 0.85.

We shall presently revert to this matter of solution loss and its consequences at greater length.

Need often arises to figure quickly the total heat imparted to the furnace by the coke under different conditions allowance being made for the CO_2 from different proportions of limestone, for different top temperatures, and different ratios of CO to CO_2 in the top gas; for this purpose; a chart, also from "Notes on the Physical Action of the Blast Furnace," is reproduced as Fig. 2, from which this quantity may be directly taken. $L = 0$ means the condition when no limestone is charged and $L = 1$ means one pound per pound of coke, intermediate quantities can easily be interpolated by eye with sufficient accuracy. This diagram is based on a pound of fuel of 99 per cent carbon. A supplementary diagram at the top gives the heat brought by the blast for a pound of coke at different temperatures which should be added to the other for the total. This diagram saves much tedious figuring, but must be used with discretion because it takes no account of the presence of any hydrogen which is often produced by the decomposition of moisture from the charge and the oxygen from this moisture oxidizes CO to CO_2 and gives a very distorted impression of the time conditions, unless its source be taken into consideration, because the decomposition of the water absorbs almost as much heat as the corresponding oxidation of CO to CO_2 gives out.

This diagram is based on 0.9 lb. carbon while Fig. 1 is based on 0.85 lb. The discrepancy arose when Fig. 1 was recalculated, both having been based on 0.9 lb. originally; 0.85 is undoubtedly more correct, but Fig. 2 can only be used for rough approximations, and it is hardly worth while to recalculate it merely for the sake of uniformity.

(To be concluded)

The **mica** produced in the United States in 1914 was valued at $328,746.

The Stark Rolling Mill Co. of Canton, Ohio, maker of "Toncan" metal has sent us a booklet on "Corrosion, the Cause, the Effect, the Remedy," and also a small booklet entitled "The Sheet Metal Primer."

Testing of Rubber Goods.—Circular No. 38 of the Bureau of Standards, recently issued contains much valuable information on rubber, including the manufacture and physical testing of rubber and the chemistry of rubber.

The **International Oxygen Company** is erecting an oxygen and hydrogen generating plant at Verona, Pa., in the Pittsburgh district, for the accommodation of its customers in that vicinity. This new factory will also serve as a demonstrating installation of the I. O. C. system for inspection by the rapidly increasing number of heads of industries who are deciding to secure the economies resulting from the production, in their own shops, of their required oxygen and hydrogen. Mr. Phillip J. Kroll will be manager of this branch.

Awards for Heat Insulating Material.—The Superior Jury of Awards at the Panama-Pacific International Exposition, San Francisco, has awarded a Grand Prize to the nonpareil heat-insulating materials for general excellence. These materials are manufactured by the Armstrong Cork & Insulation Company, Pittsburgh, Pa., and include nonpareil insulating brick for industrial furnaces, ovens, boiler settings, kilns, etc., nonpareil high-pressure steam covering for high pressure and superheated steam lines, feed-water heaters,, etc., nonpareil cork covering for drinking water systems, brine and ammonia lines and all cold pipes, and nonpareil corkboard for cold storage rooms.

A New Electrolytic Method of Sewage Disposal*

BY J. C. OLSEN

(*Concluded from page* 739)

EXPERIMENTS USING LIME AND CURRENT

The first series of experiments were carried out for the purpose of ascertaining the effect of the operation of the machine with the addition of lime on the character of the sludge and the effluent. The machine was operated under what may be termed normal conditions. Lime was introduced into the sewage before passing through the machine in quantities equal to 1000 to 1300 lb. per 1,000,000 gal. which is equivalent to 7½ to 9½ grains per gallon. The quantity of lime used was ascertained by the tank being filled with milk of lime of known strength. Titrations were also made of the effluent to ascertain the amount of calcium oxide present in excess over that required to react with the dissolved carbonic acid and the alkalinity of the sewage. The current varied in different tests and ranged from 19.5 to 40.9 amp. This amount of current represented a range of 22.5 to 44.7 coulombs per liter treated (85 to 169 coulombs per gallon). This quantity of electricity will liberate theoretically from 0.00174 to 0.00332 gram per liter or 1.21 to 2.31 c.c.

Samples were taken of the raw sewage designated as "A," of the inflow to the sedimentation tanks designated as "B," and also of the effluent from the sedimentation tank designated as "C." Several samples designated as "D" were also taken of the outfall into the stream at a point several hundred feet distant from the buildings of the plant. These samples were used for the determination of physical appearance, chemical composition, count of bacteria, dissolved oxygen and putrescibility. Samples of sludge were also taken from time to time for examination with reference to putrescibility.

Table I gives the average of a considerable number of analyses of the samples taken at the four points indicated.

TABLE I.—AVERAGE OF THE ANALYSIS OF RAW AND PURIFIED SEWAGE BY ELECTROLYTIC PROCESS

Calcium carbonate		294.8	95.3	
Bacteria count by agar	288,000	46,256.5	471	169

The amount of oxygen liberated by the electric current was relatively small. It ranged from 1.74 to 3.32 mg. per liter of sewage treated which is equal to 1.21 to 2.31 c.c. per liter.

It will be noted that the percentage of nitrates increase from 0.02 in the raw sewage to 2.22 in sample B and to 3.8 in sample C, which indicates oxidation of the nitrogen of the sewage.

The percentage of ammonia decreased from 26.5 to 20 and 13.6 respectively in samples B and C. Undoubtedly, ammonia is lost both by oxidation and volatilization.

The percentage of organic nitrogen decreased from 13.8 in the sewage to 9.2 in sample B. This disappearance of organic nitrogen is, no doubt, partly due to oxidation brought about by the anodic oxygen and partly to precipitation by the lime in the sludge as it was found to contain a considerable amount of nitrogen. The decrease in organic nitrogen continues between B and C which is probably due partly to further precipitation in the sludge and partly to further oxidation. In this manner 60 per cent of the organic nitrogen is removed from the sewage. This large reduction of the organic nitrogen is an important factor in this method of sewage purification.

The oxygen consumed decreases from 42.6 to 26.4 to 20.7 which indicates removal of a large proportion of the dissolved and suspended organic matter.

The per cent of saturation of dissolved oxygen increases from 13.89 to 26.59 and 38.38 which is a total increase of 34.49 per cent.

The bacteria count decreased 84 per cent between A and B, and 99.83 per cent between A and C, which indicates a high degree of purity in the effluent.

A considerable amount of the organic matter is no doubt precipitated with the lime in the sludge and this accounts for some of the changes noted. A considerable number of the bacteria are no doubt removed in this manner. The flocculation and precipitation of the sludge is very rapid after electrolysis and is much more rapid and complete than when lime only is used. This is probably due to the fact that the organic matter in the sewage is present as a colloidal solution which the electrolysis precipitates.

A comparison of the composition of sample C (which was taken after sedimentation, which, in this plant, occupied about 4 hr.) with samples B and A shows that the differences noted between A and B have become more pronounced, that is, nitrates, dissolved oxygen and free lime continue to increase; an exception is found in nitrites which decrease. The remaining constituents decrease in quantity, namely: Ammonia, organic nitrogen, turbidity, color, alkalinity and bacteria. Carbon dioxide naturally remains absent in the presence of free lime. The increase in free lime and decrease in alkalinity is due to the fact that the reaction between the lime and the calcium bicarbonate and other alkaline salts in the sewage requires several hours for its completion and that it is for a time supersaturated with respect to some of the salts formed. The ammonia, no doubt, slowly volatilizes and considerable amounts of atmospheric oxygen are absorbed during sedimentation. The reduction in turbidity and color is, no doubt, due to precipitation.

A number of tests were made on the overflow from the sedimentation tank (sample C) after it had passed through a pipe several hundred feet long and was discharged into a stream flowing from the plant. The time required for this flow was estimated to be about 15 min. The dissolved oxygen rose from about 40 per cent to about 80 per cent while the bacteria count fell from 471 to 169. These results indicate the great purity of the effluent. There could not be any readily oxidizable organic matter in a water which will absorb oxygen so quickly and hold 80 per cent of its saturation value. The drop in bacteria content points to the same conclusion. This was confirmed by allowing samples of this effluent to stand in the laboratory and making bacteria tests on succeeding days. The bacteria count steadily decreased for as long as 9 days.

Table II.—Stability of Effluent from Electrolytic Process

		37	
	At time of taking sample		
550,000			103
	After standing 4 days		
620,000			24

The quantity of lime added varied considerably during the course of the investigation, the average being about 1300 lb. of hydrated lime (72 per cent CaO) per million gallons. This is equal to about 113 parts calcium oxide per million or 6.6 grains per gallon.

A considerable proportion of this lime reacted with the free carbon dioxide in the sewage and then with the calcium bicarbonate, forming calcium carbonate, which constituted a large part of the flocks which settled and formed the sludge. The excess remained as free calcium hydroxide in the effluent. Considerable time was required for the completion of these reactions as was shown by adding lime to a sample of the sewage and titrating with standard acid using phenolphthalein and methyl orange as indicators.

Not only does the reaction seem to be slow but the liquid seems for a time to be supersaturated with calcium carbonate.

Tests were made with no lime at all and a considerable number of proportions up to an excess of nearly 200 parts per million of calcium oxide. When no lime was used and electrolysis only, very little purification of the sewage resulted as shown by bacteria count and clarification and flocculation. Table III gives the result of electrolysis of the sewage with a very small amount of lime as indicated by the alkalinity and absence of calcium oxide. The small amount of nitrates and oxygen consumed and large amount of organic nitrogen and oxygen consumed indicate only slight purification which is also shown by the high bacteria count.

A still higher degree of purity was obtained by using an excess of lime equal to 236 parts per million as shown by Table V.

This high purity was obtained in spite of the fact that the amount of current used was equivalent to only 1.448 c.c. of anodic oxygen per liter.

The effect of the electric current in increasing flocculation and purification of the sewage is strikingly shown in the following experiment.

At the time of starting the experiment the machine was running normally and had been so for several days, current, lime and agitation being employed. The effluent was clear and excellent in every respect. The lime was added at the far or outlet end of the machine.

Sewage flow, 755,000 gals. per day.

Current, 40 amp., 120 volts.

About 1000 lb. of hydrated lime (72.87 per cent calcium oxide) being used per day. This is equivalent to 965 lb. of lime per million gallons, or 9 grains of lime per gallon.

Under these normal conditions the appearance of the liquid in the flume was good, with large flocks, which

settled rapidly in the Imhoff tube, leaving a clear liquid above. The Imhoff reading was 20 c.c. (All Imhoff tube readings were made after ten minutes' sedimentation.) The final effluent was nearly water-like in appearance, odorless and there was no odor in the tankhouse or plant generally.

1.50 p. m.—The current was cut off, and the agitation by means of the paddles stopped. The flow of milk of lime into the sewage at the outlet end of the machine was continued.

1.55 p. m.—The liquid in the flume had become very noticeably darker, with much smaller flocks.

2 p. m.—The liquid in the flume was decidedly dark, the flocks small. Imhoff tube reading, 3 c.c.

2.02 p. m.—The current was turned on again, other conditions remaining the same.

2.07 p. m.—The liquid in the flume was lighter and the flock better.

2.12 p. m.—The liquid in the flume same as at 2.07 p. m. A half gallon was lighter in color than a similar sample at 2. Imhoff tube reading, 10 c.c.

2.17 p. m.—The point of lime feed was changed, so as to allow the lime to be admitted at the suction end of the pump, thereby being mixed with the sewage which then passed through the machine. The current was turned off, and there was no agitation by means of the paddles.

2.22 p. m.—The liquid in the flume was darker, and the flocks smaller.

2.31 p. m.—The liquid in the flume still dark, the flocks small and poor. In the Imhoff tube, the flocks appeared small and poor. Imhoff tube reading 0.75 c.c.

2.32 p. m.—The electrolyzing current was again turned on and agitation by means of the paddles started. The lime continued to be added through the pump.

2.42 p. m.—Color dark in the flume, but flocculation better.

2.46 p. m.—Imhoff tube reading, 16 c.c., but the sediment was dark in color.

2.47 p. m.—The electrolyzing paddles and current continued in operation but the lime was introduced at the outlet end of the machine. This reproduced the conditions found at 1.30 p. m.

2.52 p.m.—The liquid in the flume became lighter, with a heavy flock, quickly settling. The deposit in the Imhoff tube was heavy, and settled rapidly.

This experiment, together with the one previously made, showed that electrolyzation of the sewage serves to produce a lighter colored effluent, and materially increases the amount of flocculation and precipitation of the suspended matter in the sewage, probably because the current tends to agglutinate the colloidal particles.

The chemical analyses of the effluent show that when the current and lime are both used the effluent is more free from nitrogenous organic matter, 60 per cent of the total organic nitrogen being removed; whereas when the current is not used only 11 per cent of the nitrogenous organic matter is removed and the bacteria multiply in the effluent, probably because of the greater abundance of food.

In order to secure information as to the effect of lime only on the Elmhurst sewage, a number of experiments were carried out in which conditions were identical with the electrolytic treatment except the electrolyzation. Table VI gives the average of these results.

It will be noted on reference to the results given in Table VI that the percentage of nitrates in sample B is very small and differs in this respect from the corresponding average in the electrolytic treatment (Table I). In sample C (Table VI), however, the percentage

TABLE VI.—AVERAGE OF THE ANALYSES OF RAW AND PURIFIED SEWAGE WITH LIME ONLY, WITHOUT ELECTROLYZATION

	Sample *A*	Sample *B*	Sample *C*
Nitrogen as			
Nitrites		0	0.32

Total solids			131
Bacteria per c.c.			
Agar	187,000	54,120	5430

of nitrates is 3.6 which is very nearly equal to the corresponding average in Table I.

The organic nitrogen decreases from 3.6 to 3.4, which is a reduction of only 6 per cent compared with 40 per cent in the table of electrolytic treatment (Table I). Between B and C there is a further decrease of only 6 per cent compared with 20 per cent in the table of electrolytic treatment. This indicates an important difference between these methods of treatment and shows that the removal of organic nitrogen is comparatively slight in the case of treatment with lime alone.

The total increase in percentage of dissolved oxygen between samples A and C is 18.32 per cent as compared with 24.49 in the case of the electrolytic treatment. The decrease in bacteria count between A and C is 9.7 per cent as compared with decreases of 84 and 99.83 per cent respectively in the case of the electrolytic treatment.

The most striking evidence of the very marked purifying effect of the treatment with lime and electrolyzation is obtained by noting the change in bacteria content on allowing samples to stand for one or more days. These results are given in Table II.

TABLE VII.—STABILITY OF SEWAGE AND EFFLUENT WHEN USING LIME ONLY
Represented by the Number of Bacteria per C.C. Incubated on Agar

A	*B*	*C*	*D*
	At time of taking sample

	After standing 3 days		
820,000	338,000	105,000	

It will be noticed that the bacteria increase very rapidly after treatment with lime only. In this respect there is a very striking difference when samples which have been subjected to electrolysis and lime are allowed to stand. In this case there is a very marked decrease in the already low bacteria count. An exception to this condition is sometimes found in sample B which has not passed through the sedimentation tank.

The difference between the two processes is also very noticeable on an inspection of sewage disposal plants operated by the two methods. At plants using lime only the effluent is dark colored, quite high in bacteria and far from pure. Both effluent and sludge produce considerable odor so that the disposal works are a nuisance to nearby neighbors while the effluent pollutes streams into which it is discharged.

On the other hand the Elmhurst plant during the time it has been operating on 750,000 gal. of sewage has been entirely free from unpleasant odor, the effluent being clear and free from color and could be discharged

into any stream without causing any pollution whatever.

It is common, when discussing electrolytic processes for sewage treatment, to speak of the liberation of chlorine, or the formation of a hypochlorite by the action of the electric current upon the common salt present in the sewage, and then to credit such substances with much of the beneficial action claimed for the process. Careful chemical examination made at various times of the effluent of the electrolytic machine at Elmhurst failed to give any reaction whatever for free chlorine or hypochlorites. The conclusion seems warranted that neither of these substances is present in the sewage electrolyzed by the process.

In order to confirm this conclusion, a study was made of the effect of adding bleaching powder to sewage. A visit was first made to Providence, R. I., where lime and bleaching powder have been used for a great many years in the treatment of the municipal sewage. At the Providence plant 144 lb. of bleaching powder and 400 lb. of lime are used per million gallons of sewage treated. The amount of bleaching powder added is 17.3 parts per million, the available chlorine being 5.7 parts per million. This is equivalent to 1.3 mg. of oxygen per liter which is about the amount of anodic oxygen produced by the electric current in the Landreth machine. At Providence the treated sewage is allowed to settle in sedimentation tanks.

The effluent as discharged into the river contains from 20 to 50 per cent of dissolved oxygen. The dissolved oxygen in the river is generally zero. Sixty-five per cent of the total bacteria were removed, as counted on litmus agar, incubated at 37½ deg. The B. Coli removed amounted to 97 per cent. The effluent is putrescent and quite impure, but the use of the process is justified by the polluted condition of the river, so that the requirements for purity are very low. The statement was made that if it should become necessary to secure a higher state of purity, a more efficient process of sewage disposal than the one now in use must be installed.

Laboratory tests were made with Elmhurst sewage. Bleaching powder and lime were added in the proportions used at Providence, namely, 144 lb. of the former and 400 lb. of the latter. The odor of hypochlorites was very noticeable and persisted for about 24 hr. No odor of this kind had ever been detected on the effluent at Elmhurst. The sewage also remained turbid and did not settle clear even after several days' standing.

The bacteria count was reduced about 97 per cent, but on standing 21 hr. the bacteria count had risen and was higher than that of the raw sewage. The odor of chlorine had also disappeared, showing that the bleaching powder prevented the growth of bacteria but did not remove the organic matter and produce a stable effluent. The results are given in Table VIII.

Another test was made in which twice as much lime and bleaching powder was added as used at Providence. This would give chlorine equivalent to about 2.6 mg. of anodic oxygen per liter, which, with the amount of lime used, would give a very clear and stable effluent by the Elmhurst electrolytic process. In this experiment the chlorine odor persisted for 24 hr., the bacteria count was very low on the second day but after standing for three days, the bacteria count on agar was 5,550,000 and the liquid had a putrid odor. The results are given in Table IX.

In another test the untreated sewage as well as the treated sewage was allowed to stand and was plated. After five days the bacteria count was 4,460,000 in the sewage treated with bleaching powder. The results are given in Table X.

Table VIII—Bacteria Per C.C. in Raw Sewage and Sewage Treated with Lime, and Bleaching Powder

Bleaching Powder Added, 144 Lb. Per Million Gal. Lime Added, 400 Lb. Per Million Gal.

B. Coli	.....	0

It is apparent from these results that bleaching powder has a very marked destructive action on bacteria but that there is very little action on the dissolved organic matter. It is, no doubt, very effective in purifying a contaminated water but is not a suitable reagent for the oxidation of the large amount of organic matter present in a sewage so as to produce a stable effluent.

The sludge produced at Elmhurst amounted to about 1500 lb. of the dried material. The moist press-cake contained about 69 per cent of water. It contained about 0.59 per cent ammonia equal to 3.7 per cent proteid and 0.54 per cent calcium phosphate, the remainder being mostly calcium carbonate. While moist the press-cake has a slight odor of ammonia which becomes more

intense if the sludge is kept in a closed vessel. Putrescibility tests showed it to be stable for more than four days. When allowed to dry, it becomes entirely odorless. A number of methods of disposal of this sludge seem to be feasible. It can be used as a filler on low ground as it will not produce a nuisance. If used in this manner, filter pressing would be unnecessary if vacant ground near the plant is available as the liquid sludge could be pumped out. The sludge would also find some use as a fertilizer. It could also be burned so as to recover the lime.

COST OF OPERATION

A careful study was made of the cost of operation of this process of sewage disposal. The actual cost of operation of the Elmhurst plant cannot be taken as the normal operating cost of a plant of this kind because the plant was designed and built for an entirely different process and because during the period of the test it was not continuously operated on a normal basis. The operating cost will include the following items: electric current and power, lime, labor, maintenance supplies, etc., and sludge.

ELECTRIC CURRENT AND POWER

From the study made of the process a fairly accurate estimate may be made of the minimum amount of electric energy required for the electrolyzation of a million gallons of sewage and this was found to be 85 kw.-hr. The cost of electric current varies greatly in different localities. At 2 cents this item would be $1.70 per million gallons.

Electric energy was also used to rotate the paddles and produce agitation in the machine. This required 60 kw.-hr. per million gallons, and at 2 cents would be $1.20.

A small electric motor was used to operate the agitator in the lime vat and consumed 16 kw.-hr. which at 2 cents would be $0.32.

LIME

It was possible to make a very close estimate of the amount of lime required which was about 950 lb. of calcium oxide or approximately ½ ton of commercial lime. Under favorable conditions lime can be obtained in carload lots at about $6 per ton, making this item of cost $3 per million gallons.

LABOR AND SUPERVISION

It has been very difficult to estimate the cost of labor and supervision for a plant of this kind from the experience at the Elmhurst plant. This element of cost will decrease very rapidly with the size of the plant and will also vary with the method of sludge removal employed. For a 10,000,000-gal. plant $3 per million gallons would seem reasonable.

MAINTENANCE AND SUPPLIES

The principal item of expense under this heading will be the renewal of the iron electrode plates. This and other items would be covered by an allowance of $1 per million gallons.

SLUDGE DISPOSAL

The cost of sludge disposal would vary with local conditions and especially with the methods of disposal which may be utilized. The simplest and cheapest method of disposal consists in pumping the liquid sludge on the land adjoining the plant which must be filled in. The cost of pumping the sludge obtained from a million gallons of sewage is very small. If the sludge is used for fertilizer it must be filter-pressed. This will cost about $2.50 per million gallons of sewage. In a farming section the filter-pressed sludge will be removed by the farmers. Where this is not feasible the sludge must be disposed of by removal and dumping on waste land or at sea. Where this is necessary the cost may be considered $2.50 per million gallons of sewage.

TABLE XI.—ESTIMATED COST OF SEWAGE DISPOSAL BY ELECTROLYTIC PROCESS FOR A TEN-MILLION-GALLON PLANT

Lime, 5 tons at $6.00 per ton	$30.00
Electricity for electrolyzation at 2c	17.00
Electricity for agitation at 2c	14.20
Labor and supervision	30.00
Maintenance and supplies	10.00
Sludge disposal	25.00
	$126.20
Cost per million gallons	$12.62

ADVANTAGES OF THE METHOD

The advantages of the method may be briefly stated as follows:

(a) The effluent is of a very high degree of purity and may be discharged into any water course without creating any nuisance whatever or injury to fish or oysters.

(b) No odor or other nuisance is produced by the plant so that it may be located at any sewer outlet or other convenient point.

(c) The amount of space required for the plant is very small. This very much reduces the cost of the necessary site and gives a much more general choice of location.

(d) On account of the freedom from nuisance and small space required, plants may be located at convenient points and the construction of costly trunk sewers obviated.

(e) The initial cost of installation is low as compared with other processes.

The Chemical Engineering of the Hardwood Distillation Industry*

BY JAMES R. WITHROW

It would require more time than we have at our disposal to go into the details of the chemical engineering of the hardwood distillation industry. General features will be pointed out, just sufficient to give a broad survey of the problems involved in plant operation.

The industrial demand which the hardwood distillation industry meets is sufficiently indicated by the mere mention of acetic acid, methyl alcohol, acetone, chloroform and formaldehyde, without burdening you with statistics of their production, consumption, exportation and importation. The number of industries and objectives in the arts which benefit by the availibility of these substances is surprisingly great, though not all of these substances are exclusively the products of this industry.

Development

The development of the industry appears to have been very simple. From the earliest times charcoal appears to have been used in the arts and especially in metallurgy.

That liquid products could be formed during the charcoal production was very early observed. Uses were gradually found for these products, and in course of time a demand was created for them, with the result that wood carbonization was largely changed in method so as to improve the yield of the desired by-products.

The historical development of this industry is one of the most interesting in the annals of industrial chemistry, because it illustrates so well the battledore and

*A paper presented in the symposium on wood distillation at the Seattle meeting of the American Chemical Society.

shuttlecock fortune of so many of these industries. So often the by-product of to-day becomes the main product of to-morrow, and the new industry, which appears the worst competitive enemy of one industry, becomes the greatest blessing of the old industry in the next decade.

The liquid products accompanying charcoal production are said to have been recovered by the ancient Egyptians and utilized by them in embalming the dead. Pliny mentions their recovery in Syria and Theophrastus in Macedonia. As chemical knowledge in those days appears to have been very limited, and engineering skill as much so. the recovery of liquid products must have been trifling, and it was many centuries before chemical knowledge made possible and the arts demanded intelligent development.

Notwithstanding the later development of the engineering as well as chemical side of the industry the essential features of primitive wood carbonization have come down practically unaltered to the present day. This primitive charcoal burning is still practised wherever wood is plentiful—in Russia, Scandinavia, Austria-Hungary, Germany (Westphalia and the Harz), New Jersey, Maryland, etc.

In spite of various uses to which they were put in early times no real appreciation of the value of the liquid substances known to be formed during carbonization of wood came until the dawn of modern chemical investigation. Lack of sufficient fundamental chemical knowledge was largely responsible for this. For instance, as early as 1658 Glauber identified the so-called "burnt-wood acid" with acetic acid, yet not until 1802 was it identified with the acetic acid of fermentation by Thenard. In 1661 Robert Boyle discovered wood-spirit in wood distillate, yet not until 1812 did Taylor notice its analogy to grain alcohol.

The true character of this "spirit" was only established after a series of investigations by Colin, Dobereiner, Gmelin, Liebig, Sweitzer, and especially Dumas and Pèligot, ending about 1835. As a result of these investigations, together with those on the composition of the wood tar and wood gas, there came an increased effort to recover such of these by-products as were suitable for use in the arts in general, as well as in the organic chemical industries that were at this time struggling for a footing upon the investigations of the great masters of our science. The first step in this revolution was the use of by-product kilns and retorts in place of the old sod-covered pits or heaps, for carbonization. It would seem that from this point, at least, the development of the industry should have been consistent and perhaps rapid, but this was not the case.

Apparently the first product to have been systematically recovered was the wood gas. This was first used in England for illuminating purposes somewhat prior to the chemical developments just mentioned. The honor, however, for the exhaustive investigation of the illuminating, heating and power value of this gas belong to the Frenchman Phillip Lebon.

The weakly illuminating wood gas was soon outclassed, however, by the development of coal gas production, and the whole hardwood distillation industry had a precarious existence during a large part of the last century, even in spite of the fact that a satisfactory method of purifying the crude acetic acid had been devised as early as 1824 by Mollerat and Jasmeyer.

The products of the destructive distillation of coal, such as coke, illuminating gas, tar and tar distillates, were sharp competitors of the wood products. Yet when the wood industry seemed about to be relegated to the primitive woods, the sudden development of the coal-tar color industry started a demand for acetic acid, methyl alcohol and acetone which has since been augmented by the demand for the same products in the production of celluloid and smokeless powder, as well as many synthetic organic substances used in pharmacy and the arts.

The demand for methyl alcohol within a few years after Perkins' discovery of aniline dyes became so great that the price was enormous. It is not surprising, therefore, that at that time in England wood was distilled with the sole object of getting wood alcohol. A like situation is said to have arisen at one time in benzol manufacture, coal having been for a while distilled with the sole object of obtaining benzol for aniline production.

These general statements regarding the development of the industry bring us to the present situation where we recover mainly the primary products—wood gas, raw liquor (pyroligneous acid), tars and oils, and charcoal. It should be noticed in passing that while most engineering skill is a matter of quite recent development, and chemical engineering is perhaps the most recently developed phase of engineering, yet it has been able reasonably to keep pace with chemical development in this industry at least, and this may be due largely to the fact that the development of engineering methods, and the understanding and fabrication of engineering materials of construction developed along with the science of chemistry and are somewhat dependent upon it.

The Problem of the Industry

Broadly speaking, the problem of the hardwood distillation industry is the complete utilization of the weight of the original wood as far as this is possible by economical chemical engineering manipulation for the production of the products which it will yield of main industrial use or value, i.e., charcoal, acetic acid and methyl alcohol.

Economical chemical engineering involves the use and sequence of such operations as will give the maximum financial return, per unit of raw material consumed, consistent with a proper balance between low cost of operation, low initial cost of plant and highest speed of turnover (processing raw material).

When wood is heated sufficiently in the atmosphere it tends to burn, of course, to residual ash, steam and carbon dioxide, for the most part. If the air is partially excluded we obtain residual charcoal and volatile products varying widely in composition, depending upon the extent of air exclusion, from the condition of almost complete combustion of volatile products to practically entire elimination of combustion or atmospheric oxidation when air is excluded as completely as possible. The problem of the industry may be met therefore by heating the wood sufficiently to carbonize it, and in such a way as to eliminate as far as possible any atmospheric oxidation of the volatile products and, at the same time handle the distillates in such a way as to minimize refining or purification difficulties.

Modern chemical engineering skill has met the conditions of reasonably efficient solution of the problem with fair success, as is shown by the extent of the industry, and without doubt will advance still further.

Every problem, however large, is merely a series of smaller sub-problems, and each of these in turn is often resolvable into still other problems. In studying the problem of any chemical industry it is natural to divide it as far as possible into

1. The nature of the demand or market for the products or objectives of the industry.
2. The chemistry involved.
3. The operations or engineering involved.

The chemistry of the hardwood distillation industry

finds its basis in the phenomena attending destructive distillation. Much more should be known about destructive distillation than *is* known. Our concern at this time, however, is with the engineering problems involved in the utilization of this chemistry. Suffice it to say in the matter of the chemistry involved, that the products of heating the wood, as is usually the case in destructive distillation, are gaseous, liquid (condensate) and solid (residual charcoal). The gas as a whole is combustible. The liquid is acid, and in two (or three) nearly non-miscible phases—tar (and oil) and dilute alcoholic acetic acid, with dissolved tar and other substances.

Chemical Engineering Operations

The engineering operations of the industry may be divided in general into four divisions.

1. Those concerned with the preliminary handling of the raw material.
2. Those concerned in the destructive distillation proper or so-called primary distillation.
3. Those concerned with the treatment of the liquid distillate or secondary distillation.
4. Those concerned with refining operations, and derived product production. The latter is not generally connected with what is known as the crude hardwood industry, and will therefore be indicated in great brevity.

The engineering operations which group themselves in these four divisions, and which are necessary for the accomplishing of the objects of the industry, are:

I.—*Preliminary Handling of Wood.*

1. Harvesting the timber—cutting, splitting.
2. Seasoning, transportation and storage.

II.—*Preliminary Distillation.*

1. Loading oven cars.
2. Charging and sealing ovens.
3. Firing ovens (distillation).
4. Condensation and fuel gas recovery.
5. Pulling ovens (discharging hot charcoal cars).
6. Cooling charcoal.
7. Pulling charcoal coolers.
8. Aging charcoal.
9. Screening charcoal—*charcoal for the market.*

III.—*Secondary Distillation (of Condensate Obtained in II,* 4).

1. Settling "raw liquor" (condensate II, 4).
2. Separation of tar (and oil) from "raw liquor" (continuous decantation).
3. Redistillation of settled tar (for further recovery of "raw liquor"). Copper or wooden stills.
4. Condensation of acid distillate (oil added to "boiled tar," water added to original "raw liquor"—condensate II, 4).
5. Redistillation of settled "raw liquor" (for further tarry-bodies elimination). Continuous copper stills.
6. Condensation of "boiled liquor."
7. "Mixing boiled liquor" with lime (neutralization).
8. Distillation of neutralized "boiled liquor" in lime-lee still (iron).
9. Condensation of weak alcohol-acetone.
10. Settling or filtering lime-lee still residue (aqueous calcium acetate).
11. Evaporation and crystallization of lime-lee residues.
12. Drying crystallized acetate of lime (sacking, weighing, analysis). *Gray acetate of lime* (80 *per cent*) *for the market.*
13. Redistillation of weak alcohol-acetone for oil separation and concentration (Burcey pans, fractionation).
14. Condensation of alcohol-acetone in fractions. *Crude* 82 *per cent alcohol-acetone for market or refinery.*

IV.—*Refining and Derived Product Manufacture.*

Alcohol.—1. Chemical treatment of crude alcohol ($NaOH$ or H_2SO_4).
2. Distillation and condensation for elimination of chemicals, etc.
3. Fractional distillation (column still).
4. Condensation with "heads and tails" elimination. *Refined methyl alcohol and acetone-alcohol for market.*

Gray Acetate.—1. Distillation with sulphuric acid or (HCl).
2. Dust elimination from vapors.
3. Condensation of acetic acid (commercial).
4. Refining by redistillation and fractionation after chemical or electrical treatment. *Refined and concentrated acetic acid for market.*

Gray Acetate.—1. Destructive distillation.
2. Dust elimination from vapors.
3. Condensation of crude acetone and oils.
4. Separation of oils from acetone.
5. Chemical treatment (alkali) for acid elimination.
6. Redistillation for "white oil" elimination.
7. Fractional distillation of acetone.
8. Condensation. *Acetone for the market.*

Each and every one of these operations calls for its own special form of apparatus or construction, and modifies to a varying extent the design and operation of the plant. They are the essential operations or chemical engineering proper which must be carried out to secure the results obtained in first class practice. There has been indicated also, in a limited way, how some of these operations must be carried out. Sufficient preliminary discussion of the development of the industry has been given to illustrate the connection which appears to have existed between the development of both chemical knowledge and engineering skill and the growth and development of this industry.

In concluding I must express my indebtedness to Mr. Edward H. French, to whom I owe my first opportunity, a number of years ago, of working upon the problems of this industry upon which he was himself engaged.

More Engineering English

From the October *Bulletin of The Engineering Society* of Buffalo:

"Mr. H——, having made a vocation of this practical art of manufacture, will undoubtedly be able to learn us a way to stronger build our organization . . ."

Evidently there is room for another hyphenated profession—that of Literary-Engineer.

Magnetic Separator Pulleys.—As illustrative of the varied applications of their magnetic separator pulleys the Cutler-Hammer Clutch Co., Milwaukee, Wis., has issued Bulletin 25 describing its many uses, method of installation and principles of operation.

Molybdenite.—At the molybdenite mine at Dacre, Ontario, Canada, which has been worked for the past year and a half and which is controlled by Willam J. Spain, 417 Fifth Avenue, New York, a concentrating plant is now being installed and is expected to be in running order by January, 1916. The ore is a very high-grade molybdenum sulphide. The great interest which is being taken at present in molybdenum is due to the fact that molybdenum has properties very similar to tungsten and can be used as a substitute for tungsten in various applications, especially in special steel manufacture. This is of considerable importance in view of the present high price of tungsten.

The Relation of Chemistry and Mechanical Manipulation to the Evolution of the Glass Industry*

BY ROBERT L. FRINK

To do more than touch upon the generalities of the subject, would evolve a great amount of data, and lengthy explanations. It would necessitate to present for criticism or ridicule many of the mooted questions which many now consider as fixed and well determined from a practical standpoint, while from a chemical standpoint they must be considered irrational. Therefore I must and will endeavor to deal with those generalities only which show the progress of the glass industry from a mechanical and chemical standpoint, and I will touch only upon those specific conditions and materials that go to make up success or failure in handling, forming and making of glass articles by the processes of to-day.

If one has access to the information which is upon record in the Patent Office or in memoirs or can be obtained from personal conversation with some of the older men in the industry, it is astounding to learn that many of our advanced mechanical appliances and means for manipulating glass, were conceived, and in some instances exploited, fifty, sixty or more years ago There is perhaps no instance in the annals of the Patent Office wherein the understanding of the true properties and requirements of glass are set forth in any more definite manner than in the old French patent of Loup, of 1854, wherein Loup has conceived and designed a mechanical device for the producing of cylinders of glass by means of what is at present known as a "bait member." This is lowered into a body of molten glass, withdrawn therefrom, air pressure is supplied within the cylinder thus formed, and then a cylinder is progressively drawn from the molten body. However, Loup recites that the temperature, the specific heat, the expansion and contraction of the glass, and the air within the cylinder are all factors in producing a uniform cylinder of glass, and that composition affects all these factors.

Later Opperman attempted to produce the same result by a considerably different process, using purely mechanical devices throughout to obtain the drawing of the cylinder, the introduction of the air thereto, and the control of the pressure of the air therein. He, however, makes no specific reference to any of the physical properties of the glass, or their effect upon the success or failure of his apparatus to produce the required result.

Later Sievert, Lubbers, George and Shortle, and others, besides myself, attempted the production of glass in this manner, and at a still later date the American Window Glass Company in 1904 took up Lubbers' conception, a somewhat crude but nevertheless demonstrative device, and exploited same, introducing at Alexandria, Indiana, a full equipment for the production of window glass. This process comprised the lowering into a bath of glass a pipe similar to the ordinary glassblower's pipe, although larger and heavier, withdrawing this pipe from the bath of glass, introducing the air through the pipe member, and controlling the air pressure in a manner as to blow out and form a cylinder of glass.

The preliminary results obtained in this operation appeared to be perfect, so far as the forming of the cylinder was concerned, and the officers of this company had so much confidence in the results that they installed these machines in a number of their plants. Certain modifications and improvements were added whereby it was deemed that the cost of manufacture, maintenance and upkeep would be reduced below that of the original plant. It was found, however, that under practical operating conditions there were other fatcors, hidden ones, which greatly affected the amount of glass which could be delivered to the warehouse, and that it was quite a different proposition to make cylinders of glass in quantities, sizes and thickness, and cut them into lengths, flatten them, and again cut them into sheets the quality and perfectness of which would permit of their being placed upon the market. A cylinder might be made that was perfect and drawn perhaps to a length of 20 ft. or more, but when it was attempted to lower this cylinder, cut it up into lengths or flatten it into flat panes of glass, breakage would occur, and this breakage sometimes would be in excess of 80 per cent of the total production. At times it amounted to as much as 90 per cent of the possible production.

The cause of this breakage seemed entirely obscure to the most practical and successful glassworkers and glassmakers, and for a time it seemed as though the prediction of old glassworkers was about to prove true, namely that "the devil resides in glass and man can not take him out." However, as is usually the case when the practical "rule-of-thumb" man meets unknown difficulties, he turns to science for assistance, and by the combination of logical theory with methodical practice the problem is solved.

It was found that these breakages occurred as a result of the differences which existed in the composition of the glass comprising an individual cylinder, and that the operators were seriously hampered by the lack of information concerning the correct temperatures to be used, concerning the difference of expansion and contraction between the metal forming the bait and the glass, concerning the effect of the chemical composition of the glass and the chemical reactions caused by the conditions of operation of the furnaces, namely, temperature, fire conditions, quantity of material melted or moved through the furnace, and the action of combustion gases.

After lengthy investigations had been conducted and these conditions had been determined, and the chemical and physical properties of glass had also been investigated, many of the early difficulties were overcome, and the process of mechanically forming glass cylinders became clear and much simplified, and to-day stands as one of the foremost successful inventions of the age, although this very same process and the principles involved therein were conceived and attempted by Loup in 1854. Loup might have been successful in accomplishing what is accomplished to-day had he been in a position to command the results of research and the benefit of the progress which has been attained in our present-day chemical industries, and had he been able to get the financial assistance, whereby he could have worked out the conceptions set forth in the preamble of his patent application. For therein he hinted at or directly stated the primary factors which govern the sequence and method of producing glass cylinders. All attempts prior to 1904 unquestionably failed because of the lack of knowledge of the material that the experimenters were working with, its mechanical constitution and means of controlling such constitution.

In 1882 Clark, and subsequently Schulze-Berge, Sievert, Dolan, George and Shortle, Fourcault, Colburn and I attempted making glass in sheet form by withdrawing a sheet of glass from a bath of molten glass, or by flowing a stream of metal in sheet form over a weir or dam-like aperture, or by forcing it through an aperture. Even Mr. Edison has attempted the production of sheet glass in this form, and to this day it is

*An address made before the First National Exposition of Chemical Industries in New York City on Sept. 25, 1915.

still being attempted. Vast sums of money have been expended in an endeavor to produce a sheet of glass uniform in thickness and having plane surfaces, but all attempts so far have been commercial failures, and I firmly believe for no other cause than our lack of knowledge concerning chemical and physical control of those factors which co-operate to produce a homogeneous glass.

In 1903 I produced sheets of glass from 0.003 in. to ⅜ in. in thickness, which appeared to be perfect when entering the annealing oven and coming from the forming device, or before they had cooled to a temperature of less than 250 deg. C. But below this temperature they would begin to warp and get distorted in a manner which made them entirely unfit for commercial use. It has been said that there is one sheet machine on which there has been over a million dollars expended in an endeavor to produce a sheet of glass directly from the bath of molten glass, but failure has as yet been the only result, due entirely to "warping" as it is called, and to lack of homogeneity.

Other factors which have been a great bane to the sheet glass manufacturers are the mottled appearance of the glass and the difficulty in producing glass which can be placed into windows and retain its surface lustre or be free from "fading" as it is termed. This fading is in fact a disintegration or delinquence of the surface due to adsorption or the chemical effects of gases or moisture coming in contact with the surface of the glass and combining with the constituents thereof.

In the making of pressed ware, i. e., tumblers, jelly dishes, cake dishes, punch bowls, etc., much difficulty is experienced in obtaining a glass which can be manipulated in sufficient quantities in an iron mold and pressed out in the desired form, so as to obtain the tone configuration of the mold without showing imperfections. In recent years, since the advent of the pressing and blowing machines for the making of bottles, milk jars, table ware, fruit jars, etc., many of the difficulties before mentioned have presented themselves. That is to say, the machine may be of good design and produce ware of commercially perfect shape from the molds, but in subsequent operations to which this ware is subjected, many sources of loss occur. In the making of goblets, shades, etc., after the article has been formed from the molten mass, and either cooled to atmospheric temperature or reduced in temperature to 100 or more degrees below the solidifying point, it must be again subjected to the impinging heat of a flame to round the edges or permit a reshaping of the piece, and this treatment will often cause the ware to fly to pieces. Or perhaps the ware may be subjected to a grinding operation, and the abrasive effect of the wheel or stone or perhaps the rise of temperature occasioned by the grinding will produce breakage. In the case of milk jars, fruit jars, or bottles subjected to sterilizing or pasteurizing operations, the sudden heating or cooling of the same would cause them to break and possibly incur the loss of the liquid placed in them, and all of these conditions are due to heterogeneity.

Perhaps one of the greatest banes of the electric lamp manufacturer is the breakage of his stems, or the joints between the stem and the bulb, or possibly the imperfect sealing of the leading-in wires. Again another defect which he has to contend with and which is due to lack of chemical control, is the smutting of the bulbs, this being again a chemical effect upon the surface of the glass caused by the contact of gases which attack the glass and reduce the lead therein.

I have gone to some length in enumerating some of the principal causes of loss in production and lack of satisfaction as to quality in the different cruder and grosser branches of the glass industry, in which it has been thought inadvisable, or at least unprofitable, to employ a scientist or chemist for the purpose of investigating and determining the causes of these losses. This is due, to a great extent, to the fact that the glass manufacturers and the men in control of the glass factories are, in the majority of cases, men who have grown up in the business and have been compelled to devote their time to the practical problems as they saw them and had no time to investigate the possibilities of scientific research.

As a matter of fact, there are a great many so-called first-class glassmakers, and men who are responsible for large productions and finest quality of ware, whose knowledge of the constitution of glass begins and ends the moment when the material enters the furnace, and as a matter of fact many of them still believe that glass is composed of sand which has been reduced to a molten state by being placed in a mixture with such ingredients as lime, soda, potash, feldspar, fluorspar, cryolite, antimony, zinc oxide, borax, or whatever else their batch formula may call for, and that after it has been subjected to fire all of the ingredients with the exception of sand go up the stack. It is only the more progressive individuals who have studied this matter, who have benefited by research, and who have any true conception of the actual composition of the glasses that they are making. However, even they, in many instances, have no true knowledge as to the properties given to the glass by the materials they use, and in fact there is but little actual specific knowledge available.

It is true that in Europe, and in recent years also in this country, there has been considerable progress in the making of certain glasses for special purposes, and we owe much to Guignand, Bontemps, Schott, Hovestadt, Harcourt, and others, who having contributed greatly to our knowledge of the composition and making of optical glasses manufactured in closed pots, or under conditions whereby perfect control could be had of the atmospheric, melting and temperature conditions. But there has been little or nothing done, in a practical way at least, to give us specific information as to the effects of the chemical constituents of glass when the same is made in tank furnaces, in open pots, or under varying fire conditions or how they affect our various processes of manufacture. As I have found by extensive experiments and research, the tensile, crushing and electrical strength, also the fluidity or viscosity of glass can be varied through a wide range by variation of these conditions.

Further, it seems to be pretty well established that in the making of glasses in tank furnaces, the homogeneity of the glass is governed to a considerable extent by the uniformity of fire conditions. However, I make bold to state that the chemical constitution of a glass is the more important factor which makes possible the production of a homogeneous glass in a tank furnace. I mean that the relative proportions of the constituents are more important than the actual constituents; that is to say, a glass may be composed of soda, lime and silica only, and unless the proper chemical proportions are maintained we will not get a uniform and homogeneous product under variable fire conditions, while on the other hand other combinations can be used and if the proportions are right, and the fire conditions are properly maintained for such proportions, homogeneity will result. In this, I believe, we have before us one of the most salient problems that affects the greatest number of glass manufacturers.

It is true that for the production of certain classes of articles, like thermometers, measuring vessels, etc., it is necessary to observe uniform and definite composition, in order that the required expansions, heat re-

sisting properties, electrical properties, etc., may be obtained. But for the glass manufacturers who are producing the greatest tonnage, and the greatest amount of ware in dollars and cents throughout the country to-day, the vital problem consists of:

What can I do to obtain the greatest amount of melted material for the minimum cost? How can I produce it in finished product for the minimum cost? What will assist me in putting my ware into packages, ready for the market, with minimum breakage or loss?

Right here is where the chemical industry can be of incalculable assistance to the glass industry, for if the manufacturers and operators of our chemical works, who mine, manufacture or sell the raw materials to the glass manufacturers will but put their shoulders to the wheel they will assist in turning the glass manufacturer's prejudiced mind from his pagan thought that —"an ounce of practice is worth a ton of theory," and they will, in a short time, sell to the glass manufacturers much of their by-products, waste material, or perhaps raw material, at a larger profit to themselves and at the same time enhance the profit of the glass manufacturer.

I regret that I am not in a position to elucidate more clearly this subject; I can, however, point out a few instances to show the possibilities.

In the average glass factory when trouble occurs and the glass contains various imperfections, or when breakage begins to become excessive, the first thing that will be investigated will be the sand pile. The sand will be immediately condemned should it be a little dark in color or a little too fine or a little too coarse, or not exactly of the same shade of color as the sample (which, in many factories, can be found preserved for the purpose of comparison, and which perhaps was selected at a time when some abnormally good runs were made). The next step will probably be to change the sand and get a carload or so from some other source of supply, when in reality sands do not differ by more than 1 or 2 per cent in the amount of silica which they contain.

Now if instead the manufacturer had gone to his lime bin, and had taken a sample of the lime when his trouble started and had it analyzed it is probable that he would have found that the actual calcium oxide content had increased or diminished by 10 or 15 per cent above or below normal. It is possible that he had been using before a lime which carried 80 to 82 per cent of CaO, but on the next order the manufacturers may have been short of his particular kind and may have shipped him a car from some other source or from another one of their mines where the material had been taken from a greater or lesser depth in a stratum of rock, and which may have contained, say, 50 to 60 per cent of CaO and from 20 to 30 per cent of magnesium oxide. Now his melting conditions had been adjusted originally for lime which contained approximately 80 per cent of CaO with only 2 per cent, or at the most 3 per cent of MgO, so that they were not adjusted to the use of the new lime, with the result that the product was "cordy," "stringy" or hard glass.

In another instance the glass worked may have been using an oxide of manganese for decolorizing purposes which contained, say, approximately 80 per cent of MnO_2, but for some reason he may have purchased manganese from another source and the material may vary 5 to 15 per cent in MnO_2. The result is that the color of his glass goes from white to pink or green, and his glassmaker begins to use various "dopes" for the correction of such troubles, without any knowledge whatsoever of the effect produced by what he uses other than that it is "blue" or smalts, arsenic, antimony, borax, cryolite, fluorspar or nitre. Now if the manufacturers of these products would join with the glass manufacturer in investigating these troubles or would furnish material of known composition, the glassmaker would soon learn to appreciate the value of such knowledge.

There are innumerable instances of this kind. If some of our manufacturers would take steps to furnish to the glass manufacturer raw materials of exact composition which would give him a more uniform product with less melting cost and less loss, or if they would, as outlined above, lend some encouragement to the founding of establishments for investigating problems of glassmaking a great deal could be accomplished.

Lancaster, Ohio.

Inflammability of Mixtures of Gasoline Vapor and Air

The Inflammability of Mixtures of Gasoline Vapor and Air is discussed by G. A. Burrell and H. T. Boyd in Technical Paper 115, of the Bureau of Mines.

The authors in their conclusions say in part: "Two methods for determining the content of gasoline vapor in air are discussed. One has to do with the introduction of the mixture into an exhausted glass vessel, cooling it at the temperature of liquid air, removal of the air, and finally the measurement of the partial pressure of the gasoline vapor by means of a manometer attached to the liquefaction bulb.

"Another method consists in burning the gasoline vapor in oxygen and, from the contraction and carbon dioxide produced, calculating the percentage of gasoline vapor.

"When a 100-c.c. Hempel explosion pipette was used and the mixtures were ignited from the top, there was obtained as the lower limit of complete inflammation a value lying between 1.9 and 2.0 per cent of gasoline vapor. The upper limit under these conditions was found to be between 5.2 and 5.3 per cent of gasoline vapor. The gasoline used had a specific gravity of 73 deg. B. Under the same conditions, except that the mixtures were ignited from the bottom, there was obtained a value lying between 1.5 and 1.6 per cent of gasoline vapor as the low limit. With the same grade of gasoline, with a 2800-c.c. vessel, and with ignition from the bottom by means of an electric flash produced by pulling apart two wires through which a current of 7 amp. at 220 volts was flowing, there was obtained a value lying between 1.4 and 1.5 per cent of gasoline vapor. The high limit under these conditions lay between 6.0 and 6.4 per cent of gasoline vapor.

"When the initial temperature is increased before igniton of the mixtures the low limit is gradually decreased until with an initial temperature of 400 deg. C. the low limit lies between 1.02 and 1.22 per cent of gasoline vapor.

"The range of complete combustion for mixtures of gasoline vapor and air is very narrow, and is between about 1.5 and 2.5 per cent. The amount of carbon dioxide produced reaches a maximum at 2.5 per cent of gasoline vapor. At this point, as the percentage of gasoline vapor increases, carbon monoxide begins to form. At 4.1 per cent of gasoline vapor there is produced 14.0 per cent of carbon monoxide."

The **Bausch & Lomb Optical Co.** received four Grand Prix, one medal of Honor and one Gold Medal at the Panama-Pacific Exposition for the excellence of their products. The four classes in which Grand Prix were received were optical instruments, balopticons, engineering instruments, and range finders. The Medal of Honor was awarded the photomicrographic apparatus and the Gold Medal was awarded the Zeiss lenses.

The Electrolytic Precipitation of Gold, Silver and Copper from Cyanide Solutions*

BY G. H. CLEVENGER

The present unsettled condition of the metal market, more particularly as regards zinc, which is used now almost exclusively as a precipitant in the cyanide process, makes a consideration of electrolytic precipitation, which is apparently the most feasible substitute, of particular interest at this time.

The electrolytic precipitation of gold, silver and copper from cyanide solutions in connection with the cyanide process of gold and silver extraction, has frequently been the subject of satisfactory laboratory experiment, but much less frequently of successful commercial application. This comes about through the fact that experiments carried on for a few hours in the laboratory give no true indication of the life of anodes, formation of by-products, etc., to be expected in continuous operation.

My purpose in presenting the present paper is not to give a theoretical discussion of the subject or to make new proposals for improved types of electrolytic precipitation apparatus, but rather to describe the few commercially successful installations which have been made, calling particular attention to the difficulties which have arisen in their operation, in the hope that it may prove useful to those who have to do with the installation of electrolytic precipitation equipment.

In order that those of our members who are not familiar with the cyanide process may properly appreciate the peculiar and difficult problem which the complete precipitation of gold and silver from dilute cyanide solutions presents, I will digress sufficiently to make this clear before taking up the description of the various attempts to solve the problem. The solutions which are precipitated in present-day cyanide practice may contain a great variety of compounds arising from the decomposition of the cyanide, as well as from its combination with elements occurring in the ore treated, or introduced by chemical methods of precipitation. The principal constituents of such solutions, if zinc precipitation were not used, would be: Simple alkaline cyanides, alkaline hydrate, gold and silver, and copper if it occurs in a soluble form in the ore undergoing treatment. The proportion of these various constituents present, particularly of the gold and silver, is extremely small compared with the amounts of metal present in solutions made by extraction processes in other industries.

In general the simple alkaline cyanide, as indicated by the Liebig titration test, will range in present-day practice from a trace to 0.25 per cent, or a maximum of 1/400 of the solution. In certain cases of sand treatment of silver ores stronger solutions are used, but in general the cyanide strength of the solutions precipitated will fall well below the upper limit given. The alkali generally added is lime, although caustic soda has been used. There is rarely over 100 points present and most generally much less than this, and in some cases practically no protective alkalinity. (One hundred points of alkali correspond to a saturated solution of lime in distilled water at 20 deg. C., i.e., 0.13 per cent.) The proportion of alkali present is therefore in many cases less than the cyanide.

The gold present will range from nothing to 0.5 ounce (15 grams) per ton, and the silver from a trace to 10.0 ounces (292 grams) per ton. In general the proportion of gold and silver in solution is much less than the upper limits given.

*A paper presented at the 28th general meeting of the American Electrochemical Society, in San Francisco, Sept. 16 to 18, 1915.

The grade of the ore treated does not always form a safe criterion of the gold and silver content of the solution, for the reason that the ratio of the weight of solution used to the weight of ore treated, or, as it is generally termed, "the dilution," varies greatly, but in general, as might be expected, is greater with high-grade ores. Thus, if three tons of solution are used in treating one ton of ore, we have a 3 to 1 dilution, and the recoverable value of the ore has been transferred to three parts of solution, the average value of which would be one-third of the recoverable value of the ore treated; or, to take the concrete case of an ore assaying 0.50 oz. (15 g.) of gold per ton (approximately $10 per ton) from which 90 per cent of the gold can be extracted by cyanide solution, there would be dissolved by the solution 0.45 oz. (13.2 g.) ($9) per ton of ore treated. With a 1 to 1 dilution the average content of the solution per ton would be 0.45 oz. (13.2 g.) ($9); with a 3 to 1 dilution the average content of the solution per ton would be 0.15 oz. (4.4 g.) ($3); with a 5 to 1 dilution the average content of the solution per ton would be 0.09 oz. (2.6 g.) ($1.80).

It will, therefore, be apparent that this stage of the cyanide process, the transference of the gold and silver from the solid state as occurring in the ore, to the liquid state as dissolved in the cyanide solution, is unlike most other steps in metallurgy, which are in general to successively concentrate the metal sought into a smaller weight of material. Exceedingly small as is the proportion of gold and silver present in ores which it is possible in present-day practice to profitably treat by cyanidation, the proportion of gold and silver in the solutions requiring precipitation are generally still smaller.

Perhaps a clearer idea of the small amount of metal involved, particularly in the case of gold, will be obtained by expressing the proportion fractionally. In solutions containing 0.50 oz. (14.6 g.) of gold per ton (approximately $10), an unusually high proportion, the gold would form only 14.6/1,000,000 or 1/58,332 part of the solution. In the case of waste solutions, which are or should be precipitated before they are discarded, it is not unusual to deal with solutions containing less than 0.01 oz. (0.29 g.) of gold per ton (20 cents), or only 1/2,916,600 of the total weight of the solution. Tail solutions containing only 1 or 2 cents values per ton are regular practice at many mills using zinc dust precipitation.

At the present market price of silver (about 50 cents per ounce) there would be required about forty times the weight of gold present to give an equivalent value in silver. Therefore, in the treatment of silver ores a much greater weight of metal would be involved, but still the relative proportion of metal to the total weight of solution is small. As gold and silver most frequently occur associated, the absolute weight of metal to be precipitated will depend upon the ratio of these two metals in the ore treated. The greater weight of metal involved in the treatment of silver ores or ores in which silver predominates, perhaps in a certain measure explains the greater ease with which solutions resulting from the treatment of such ores are handled by all precipitation processes.

Copper in solution is an incident of gold and silver extraction, as at present there is no effort made to recover copper in this way; however, this is an interesting possibility, and would be feasible provided the cyanide combined with the copper could be economically regenerated. In many cases the proportion of copper in solution will be less than that of the gold and silver, and, so far, even with electrolytic precipitation, there has been no serious attempt to treat gold and silver

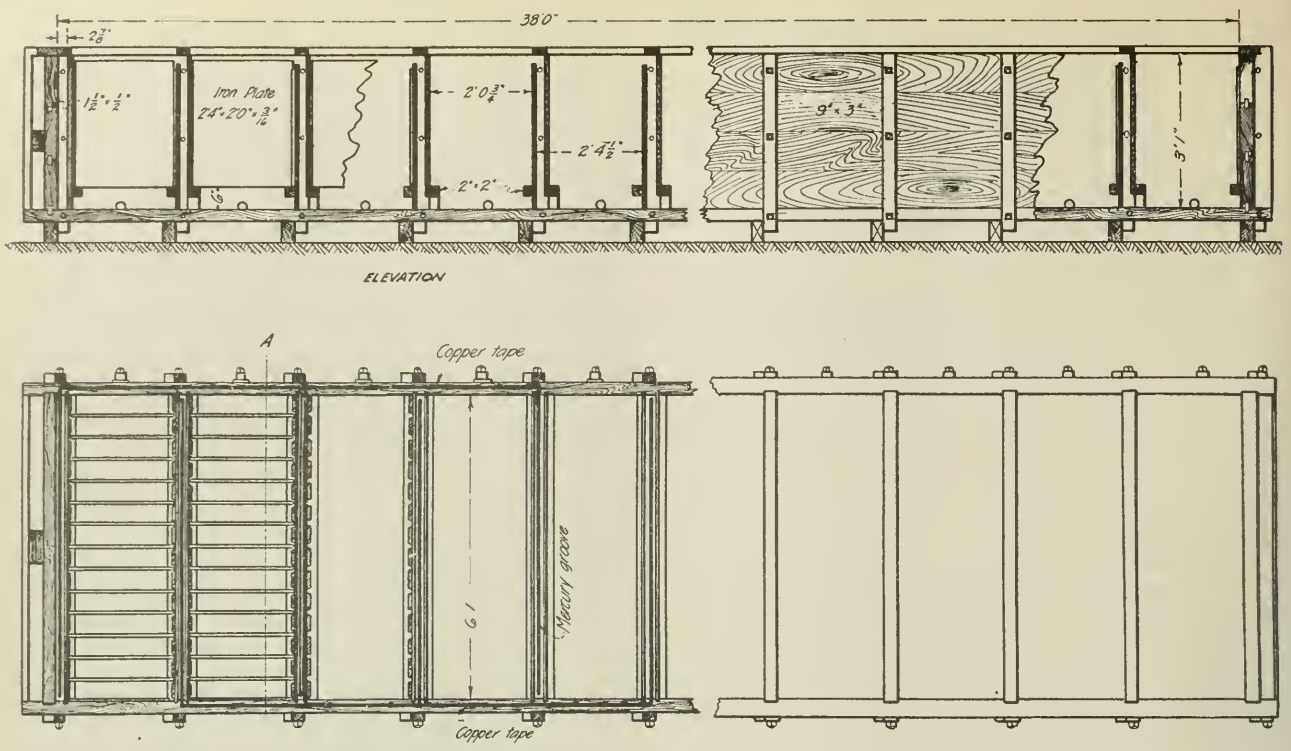

FIG. 1—CONSTRUCTION OF BOXES FOR SIEMENS-HALSKE PROCESS

ores by the cyanide process unless the proportion of readily soluble copper was considerably below 1.0 per cent. The interference of copper with other methods of precipitation, as well as its prejudical effect upon extraction, make a consideration of its behavior with electrolytic precipitation of particular interest, but beyond the province of the present paper.

The electrolytic precipitation of gold and silver from cyanide solutions, therefore, involves the practically total precipitation of an extremely small weight of metal from solutions containing a comparatively small proportion of soluble salts, and which are therefore poor electrical conductors. The fact that the alkaline cyanides are readily decomposed by electrolysis and that the economy of the cyanide process depends upon the continued re-use of the solvent make it imperative to precipitate with the minimum decomposition of cyanide, and preferably with a regeneration of cyanide. The difficulty of the problem at best will therefore be apparent.

Siemens-Halske Process, on the Rand, South Africa

The precipitation of gold and silver from cyanide solutions by electrolysis, employing a soluble anode of the metal to be deposited, had been practiced in electroplating long before the complete precipitation of gold and silver from the dilute solutions resulting from ore treatment was attempted by electrolysis, using an insoluble anode.

In 1887 a British patent was granted on the MacArthur-Forrest process of gold and silver extraction, involving the use of dilute solutions of potassium cyanide and zinc precipitation. In the same year, Dr. Siemens, working independently and acting upon observations made at his plating plant at Berlin, Germany, taken together with the statements of chemical authorities that gold was soluble in solutions of the alkaline cyanides, developed a process of gold and silver extraction involving the use of dilute solutions, more dilute than those at first used with the MacArthur-Forrest process, and electrolytic precipitation.

In the course of this work zinc filings had been tried as a precipitant, but with the very dilute solutions employed electrolytic precipitation proved more satisfactory. The first experimental plant was erected at Siebenburgen for extracting gold from concentrates, and although the process was in successful operation as early as 1888 in other mining localities it was not until a number of years later, in 1893, that the Siemens-Halske process was introduced into the Rand gold field of South Africa.

On the Rand, at first, only the sand portion of the ore pulp resulting from the stamp-crushing and plate-amalgamation process could be successfully treated by cyanidation, as leaching was the only method of treatment then in use. The solutions resulting from sand treatment contained sufficient free cyanide to give satisfactory results by ordinary zinc-shaving precipitation, as then practiced. This method of precipitation was, therefore, almost universally used for these solutions.

With the advent of the decantation method of treatment for the unleachable portion of the pulp, which had previously been allowed to accumulate on account of not being amenable to treatment by leaching, the problem at once arose of precipitating from large volumes of solution which were weak in both cyanide and gold on account of the high dilution necessary in treating slime by the decantation method.

At this time the ordinary zinc-shaving method of precipitation did not give satisfactory results when used with very weak solutions. The Siemens-Halske electrolytic process of precipitation, therefore, came into very general use for precipitating the solutions resulting from slime treatment.

The Siemens-Halske process was first introduced at the Worcester mine. Installations at other mines rapidly followed until at one time there were about twenty in operation on the Rand. In the Siemens-Halske process, iron anodes ⅛ to ¼ in. (0.3 to 0.6 cm.) thick, and lead-foil cathodes about 0.00032 in. (0.008 cm.) thick were used. In general, the anodes and cathodes were set vertically and about 1½ in. (4 cm.) apart. There was considerable variation in the size

and arrangement of the anodes and cathodes. At the Worcester plant they were 7 ft. long by 3 ft. wide (2.1 x 0.9 m.), but in later installations, to facilitate handling, they were made smaller, as shown in Fig. 1. The anodes were enclosed in sacks of textile material for the twofold purpose of preventing short circuits and of collecting the prussian blue and iron oxide formed from the iron anodes.

The lead-foil cathodes were frequently cut in narrow strips for the purpose of increasing the surface. These were strung upon iron wires mounted in light wooden frames. Another expedient which gave still greater surface was to cut the lead into shavings similar to zinc shavings. These were packed into the space between the covered anodes.

Various arrangements of the precipitation units were tried, but the one which seemed to be the most favored was to construct the containing box as shown in Fig. 1 and Fig. 1a, with alternate wide and narrow compartments, the narrow compartments serving for the downflow of the solution, while the anodes and cathodes were suspended in the wide compartments, through which the solution had an upward flow. This general arrangement will be recognized as being similar to that of the boxes used for zinc-shaving precipitation.

The current density used was from 0.03 to 0.06 amp. per square foot (0.33-0.66 amp, per sq. m.) of anode surface. The aim was to obtain a coherent plating of the gold upon the lead cathodes. After sufficient gold had accumulated upon the cathodes (2 to 12 per cent of their weight) they were removed, melted and the gold recovered by cupellation, either locally or at a central reduction plant.

There was a long and bitter controversy on the Rand regarding the relative merits of zinc and electrolytic precipitation. In 1898, Betty, by means of a drip of strong cyanide solution at the head of the zinc boxes, in conjunction with the zinc-lead couple, which was first proposed by MacArthur in 1894, demonstrated that zinc precipitation could be satisfactorily used for solutions low in both cyanide and gold. After satisfactory precipitation of these dilute solutions by zinc became possible, electrolytic precipitation rapidly lost ground and finally was entirely superseded by zinc precipitation.

Practice at Minas Prietas, Mexico

E. Andreoli, early in 1895, while working with the Siemens-Halske process in South Africa, accidentally discovered the lead peroxide anode, and although the advantages of peroxidized lead over iron as an anode material were at once recognized, it does not appear to have been used to any exent in that locality, possibly for the reason that electrolytic precipitation, at the time that this development was announced, was being rapidly displaced by zinc precipitation. After investigating many possible cathode materials, Andreoli sugested iron as being the best on account of its cheapness, strength, and the firm adherence of the gold to it. Borchers, however, states that from the electrochemical standpoint the use of iron cathodes is theoretically incorrect. Andreoli proposed recovering the gold from the iron cathodes by dipping them in a bath of molten lead. The gold was to be recovered from the lead by cupellation. The iron cathode used in this way does not appear to present any advantage over the lead-foil cathode, as it also involved the use of lead and necessitated the operation of cupellation.

In 1899, Charles Butters, who had been prominently identified with the introduction of the Siemens-Halske process in South Africa, assisted by two members of his former staff, H. T. Durant and E. M. Hamilton, developed a new electrolytic precipitation process which

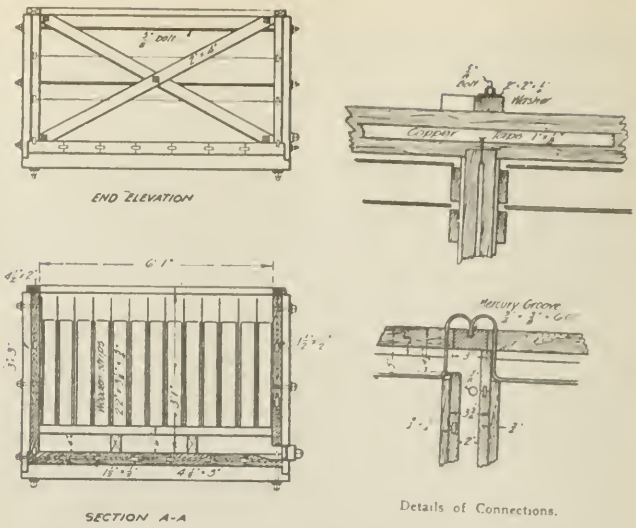

FIG. 1A—DETAILS OF SIEMENS-HALSKE BOXES

was first sucessfully used for a number of years in connection with the cyanidation of a large deposit of pan-amalgamation tailings, and later of ore directly, from the mine at Minas Prietas, Mexico.

The original installation for electrolytic precipitation consisted of six wooden boxes, as shown in Fig. 2, 30 ft. (9 m.) long by 10 ft. (3 m.) wide and 5 ft. (1.5 m.) deep, having a slope of 1 in. to the foot (8 cm. to 1 m.) toward one side, to facilitate the removal of precipitate. The boxes were divided by wooden partitions into alternate wide and narrow compartments, twelve of each. The partitions were so arranged as regards the bottom that the narrow compartments throughout the box served only for the downflow of the solution, whilst the wide compartments, in which were suspended the anodes and cathodes, served for the upward flow of solution.

This general arrangement of the compartments is the same as that used with the Siemens-Halske process. Each wide compartment was fitted with eighteen lead anodes whose surface was coated with lead peroxide, formed by electrolysis in a special cell, and seventeen cathodes composed of lead foil, cut in strips, strung upon wires supported by wooden frames similar to the cathodes used with the Siemens-Halske process in South Africa.

The current was supplied by two Siemens-Halske dynamos, each capable of developing 250 amp. at 30 volts, feeding into copper bus bars 1¼ x ¼ in. (3.1 x 0.6 cm.) laid on top of the boxes.

In order to insure good contacts, the wires leading from the individual anodes and cathodes were soldered to the bus bars, mercury-cup contacts having proved unsatisfactory.

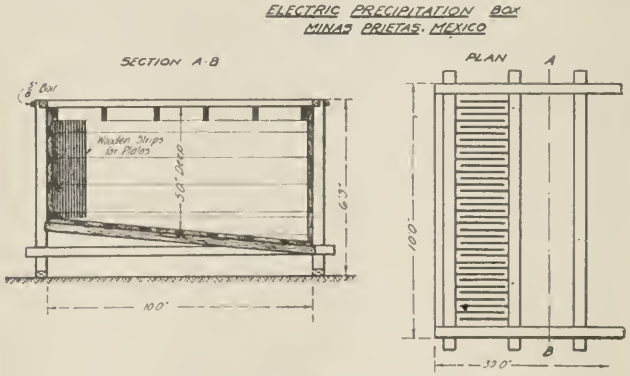

FIG. 2—PRACTICE AT MINAS PRIETAS, MEXICO

The solution passed through three sets of boxes, each set comprising two boxes set in tandem. One set of two boxes was used for precipitating the solution resulting from sand treatment and two sets of four boxes for precipitating the solution resulting from slime treatment.

The current density was so regulated that the metals were deposited as a flocculent precipitate which largely fell to the bottom of the compartments in the form of a fine slime, as in zinc-shaving precipitation, rather than as an adherent coating upon the cathodes as in the Siemens-Halske process.

After a short period of operation, it was found that the precipitate did not all fall to the bottom of the box, but that part of it formed as a rather loosely-adherent mass on the cathodes. This necessitated washing and shaking of the cathodes when it was desired to make a complete clean-up. It was soon apparent that the fragile lead-foil cathodes could not long withstand such treatment, so an investigation was started with the view of finding a more satisfactory cathode. This resulted in abandoning the lead-foil cathode in favor of a cathode made from ordinary tin-plate, which possessed the necessary strength and from which the precipitate could be readily brushed without removal of the cathodes from the containing box.

The pan-amalgamation tailing cyanided at this plant resulted from the treatment by raw pan-amalgamation of a comparatively simple siliceous silver-gold ore. The tailing contained copper, mercury and chlorides as a result of the chemicals added during amalgamation. After the tailing deposit had been exhausted, the low-grade ore which had been left in the mine was treated. The pulp was separated into sand and slime, the sand being treated by percolation and the slime by agitation, natural settlement and decantation. The volume of the solution precipitated varied as did also its metal content. The percentage of cyanide and alkali were less variable, but by no means constant.

Below are given average figures covering two months' operation, for solutions resulting from sand treatment when pan-amalgamation tailing was being treated. Average amount of solution precipitated per 24 hr., 216 tons. Current density 0.55 amp. per square foot (60 per sq. m.) of anode surface. The voltage across the anodes and cathodes varied in the different compartments, but averaged about 3. The head solution, or solution entering the precipitation boxes, contained: 0.147 oz. (4.14 g.) gold per ton; 3.51 oz. (102.4 g.) silver per ton, and 0.0792 per cent of cyanide in terms of potassium cyanide. The tail solution or solution leaving the electrolytic precipitation boxes contained 0.013 oz. (0.379 g.) gold per ton; 0.29 oz. (8.46 g.) silver per ton, and 0.0938 per cent cyanide. The gain in cyanide was 0.0146 per cent. As there was used 1.2 tons of solution in treating each ton of sand, the cyanide apparently regenerated amounted to 0.35 lb. (0.16 kg.) per ton of sand. The percentage of gold precipitated was 91.0 and the percentage of silver precipitated was 91.7. No attempt was made to lower the gold and silver in the tail solution, as none of it was used for final washes.

The following are average figures covering the same two-month period for the precipitation of solution resulting from slime treatment: Average amount of solution precipitated per 24 hr., 480 tons. Current density 0.3 amp. per square foot (3.3 per sq. m.) of anode surface. The voltage across the anodes and cathodes averaged 2.6. The head solution contained: 0.133 oz. (3.88 g.) gold per ton; 1.45 oz. (42.3 g.) silver per ton, and 0.0409 per cent cyanide. The tail solution contained: 0.055 oz. (0.160 g.) gold per ton; 0.15 oz. (4.37 g.) silver per ton, and 0.0527 per cent cyanide. The gain in cyanide was 0.0118 per cent. As there was used four tons of solution in treating each ton of slime, the cyanide apparently regenerated amounted to 0.94 lb. (0.43 kg.) per ton of slime. The percentage of gold precipitated was 88 and the percentage of silver 89.6. When the solution flow was cut down to two-thirds normal, the tails contained 0.0025 oz. (0.073 g.) gold and 0.06 oz. (1.75 g.) silver per ton. The regeneration of cyanide was doubtless greater with the solution resulting from the treatment of the slime on account of the greater percentage of copper which it contained. When treating ore directly from the mine, which contained little or no copper, the regeneration was not sufficient to be detected by ordinary titrations.

(To be concluded)

Paint*

BY G. B. HECKEL

Paint is a product of science and civilization, and a result of progress and evolution.

History of the use of paint by all races is practically the same. The first pigments used are the natural earth colors or simple vegetable dyes. They are devoted to personal decoration—commonly heraldic—and later their use is extended to other decorative purposes. It is only in a higher stage of development and civilization that the protective value of paint is recognized. This evolution is the natural accompaniment of change from the nomadic state, where dwellings are temporary, to the fixed life of civilized society.

Let us consider a typical high-grade paint formula. It contains the following ingredients:

Analysis of Pea Green
(United States Standard Measure)

	Per cent
Pigment by weight	48.00
Thinner by weight	52.00
	100.00
Thinner is composed of:	
Linseed oil	85.00
Asphaltum spirits	3.00
Turpentine	1.00
China wood oil	2.00
Japan dryer	9.00
	100.00
Composition of pigment:	
Basic carbonate white lead	15.00
Basic sulphate white lead	20.00
Zinc oxide	44.00
Magnesium silicate (asbestine)	3.00
Calcium carbonate	2.00
Barium sulphate (blanc fixe)	10.00
Aluminium silicate	3.00
Lead chromate	2.30
Ferric-ferro cyanide	.70
	100.00
Coloring is composed of:	
Pure chrome green	100.00
Composition of Japan dryer:	
Kauri gum	1.67
Oxide lead	8.45
Manganese peroxide (black oxide of manganese)	2.00
Linseed oil	26.44
Turpentine	61.44
	100.00

Besides these ingredients that are mentioned on the label, we may also notice that the container is made of tin plate; that the can is soldered; that the labels are printed with two colors of printing ink on white paper, and pasted on the can. Finally we may recall that such cans are packed with sawdust in wooden boxes nailed together with steel wire nails. Keeping in view the finished can and its contents, I think you will catch my drift when I say that all science and all civilization have contributed to the making of the can of paint bearing this label and that without science and civilization it would be unthinkable.

*An address made before the First National Exposition of Chemical Industries.

Components of Thinner

Let us consider briefly the ingredients, one by one: The first is **linseed oil**, a product of the flax plant *Linum usitatissimum*. The flax plant was not first cultivated by man for the seed or its oil. Its earliest use was for the making of linen cloth. The great masters of early European art knew nothing of linseed oil, and the first use of the seed was medicinal. To-day in the United States alone over 25,000,000 bushels of flaxseed are consumed annually in the manufacture of linseed oil, the great bulk of which goes to the production of paint and varnish. To produce so much seed requires from 2,000,000 to 2,500,000 acres of soil. Its cultivation requires many farmers and laborers, much special machinery; its storage and transportation utilizes elevators, railroads, steamships; its use for oil-making requires elaborate plants, much special machinery, and the treatment of the oil for its various uses involves chemistry and the mechanical arts. Moreover, the oil-growing flax is itself a product of agricultural science, a science which is to-day more ardently pursued by plant specialists than ever before. The proper preparation and use of linseed oil involves the results of profound study and investigation, which to-day are still far from completion.

In the manufacture of linseed oil the flaxseed, cleaned from foreign seed and other impurities, is first ground in a series of roller mills. The resultant meal is treated in a special heater with live steam to break up the oil cells. This hot meal is then pressed into the desired form and size for the oil presses, in a cake former, and a number of those cakes are stacked, one above the other, in camel's-hair or other fabric cloths, between the plates of a specially devised hydraulic press. An enormous pressure is applied and the expressed oil is filtered and collected in settling tanks where the moisture, plant mucilage, etc., settle to the bottom, while the clear oil collects on top and is drawn off and sold as raw linseed oil.

Linseed oil is a very complex organic chemical compound, but consists essentially of the glycerides of a number of fatty acids. Of these the most important in connection with our subject are the glycerides of linolic and linoleic acids, to which the oil owes its characteristic property of absorbing oxygen and thereby becoming converted to linoxin—the characteristic rubber-like product of "dried" linseed oil.

The presence of certain metals facilitates this process, and these metals are incorporated with the oil by heating their compounds with the raw oil. Recent investigations indicate that the three metals practically most effective for this purpose are lead, manganese and cobalt, and consequently advanced manufacturers have generally abandoned the use of other compounds.

It will be noted that the liquid portion of our paint contains 85 per cent of linseed oil. The fact is significant, for while linseed oil leaves something to be desired when we contemplate the ideal paint, it is nevertheless the most satisfactory paint oil for general use known to us up to the present time.

The remaining fixed oil in our formula is **China wood oil**, of which only 2 per cent is present. China wood oil is comparatively a recent addition to the raw materials of paint and varnish manufacture. It is pressed from a nut grown on a tree (*Aleurites cordata*) indigenous to the Yangtze Valley in China. The variety producing the oil nut is known to the Chinese as ying tzu tung (apple fruit Tung), and the tree is cultivated by the Chinese farmer for its oil. It grows to a height of about 25 ft., bears large green leaves, small pinkish flowers and large green fruit somewhat resembling an apple. The seeds are large and poisonous, and from them the oil is obtained. The machinery used is primitive, consisting essentially of a wooden press operated by wedges. The oil is traded, along with other agricultural products, to merchants at Hankow, Fatcheu and Canton. It has been used in China for ages, much for the same purposes as linseed oil is used in this country, and it is said that the extracted seed residues are the raw material for the manufacture of India ink.

But little is as yet known generally regarding the chemistry of this oil. It has drying properties similar to a certain extent to those of linseed oil, and the rate of hardening is accelerated by the same agencies that promote the oxidation of the more familiar oil. The chemical process appears, however, to differ, since while linseed oil hardens progressively from the surface inward, China wood oil seems to harden or set simultaneously throughout. This peculiarity led to rather expensive disasters in the earlier attempts to utilize the oil in this country. The drying salts are incorporated in practice at a comparatively low temperature, but in these earlier experiments the oil was treated at the temperature common in the treatment of linseed oil, with the result that the entire batch suddenly thickened to a consistency of rubber in the kettle.

While the use of this oil is still the subject of experiment, it has established itself an important place in the varnish industry, and is making rapid strides in the paint industry, especially in the manufacture of flat interior wall paints.

The two volatile ingredients of our formula are asphaltum spirits and turpentine. **Asphaltum spirits** is one of the lighter products of petroleums having an asphaltum base. It corresponds to the benzine which is produced from petroleums with a paraffin base.

The chemistry of these hydrocarbons, while interesting, plays no part in the chemical structure of the paint film, since their office is purely mechanical and they disappear completely in the drying of the paint. As is well known, the petroleums found in some localities yield, on distillation at high temperatures, residues containing paraffin, while similar oils from other localities yield asphaltums as residues. The best known petroleums of the latter class are those produced in Texas, California and the Island of Borneo. Petroleums are distilled by fractionating, the products passing over at the lower temperatures being classified progressively as petroleum ethers, naphthas and gasolines and benzines. At still higher temperatures the illuminating oils pass over, followed by the lubricating oils. Asphaltum spirit is the benzine of the asphaltum petroleums. It boils at a higher temperature than the corresponding paraffin product, has a higher specific gravity and is, on many accounts, far preferable as a volatile ingredient of paints. I personally believe that the formula before us is mechanically improved by the presence of this material and I am convinced that it is in no way injured by it.

Turpentine is the essential oil of certain pines, principally *Pinus Australis*, growing over large areas of our Southern States. It is distilled in a current of live steam from the sap of this tree, the residue being rosin. The industry, owing to the character of the labor available in the pine districts, is crude and wasteful both to the timber involved and to the product, though more conservative methods are coming into use through the effort of the United States Department of Agriculture.

The negro workman in a turpentine orchard cuts a so-called "box" on one side of the tree, in which the sap collects, and from which it is from time to time dipped and carried to the still. As the flow of sap decreases, the bark is removed and the wood scarified higher and higher above the "box." In the larger trees

several boxes are cut at different points on the circumference, weakening and in time killing the tree. The crude sap or gum is charged into a still with water, and on heating, the volatile turpentine passes with the steam to a worm condenser. The turpentine is decanted from the condensed steam on which it floats.

Turpentine in paint probably acts in two ways: First, as a volatile thinner, of which the effect is purely mechanical; and secondly, as a conveyor of oxygen, perhaps catalytically. At any rate it was the conclusion of a French technical commission who investigated the subject, that turpentine hastens the drying of paint to an extent not accounted for by its volatility.

The principal turpentine forests of to-day are located in Florida, southern Georgia and Louisiana, the immense forests that formerly covered vast areas in North and South Carolina and northern Georgia having been largely destroyed by the wasteful methods in vogue. Another form of turpentine has appeared in the market during comparatively recent years. It is familiarly known as wood turpentine, being produced, by various methods of distillation, from pine wood wastes. When properly prepared and purified, there appears to be no practical difference in its properties as a paint vehicle from those of sap turpentine.

The remaining liquid ingredient of our formula is **Japan dryer.** This consists essentially of the linoleates of lead and manganese, with a small percentage of Kauri gum. It is prepared by boiling linseed oil with the proper percentages of compounds of manganese and of lead, adding thereto a certain quantity of melted Kauri gum, and reducing the product while warm, with turpentine, benzine or a mixture of the two. The lead compound used in this dryer is red lead and the manganese compound is the black oxide, while the reducing agent is turpentine and Texas benzine—asphaltum spirit.

The manufacture of red lead leads us at once into the mining regions of the West, where in some districts lead is produced from practically pure ores, while in others it must be separated from its commingled silver, zinc, etc.

For the manufacture of the so-called Dutch process white lead it is necessary to have the metal free from silver, manganese and iron; but for the manufacture of the ordinary oxides purity is not so important. The metallic lead comes from the smelter in the form of pigs, which are melted in a low, flat oven in which the lead spreads out in a thin layer and is mechanically worked so as to expose continually fresh surfaces to the action of the air. The product is the monoxide of lead —massicot. This oxide is ground with water to remove metallic particles, which are returned to the furnace, while the oxide is collected in settling tanks. If the temperature in the furnace rises too high it becomes litharge—crystalline lead monoxide—which cannot be further oxidized.

The amorphous monoxide, being further treated in the same or a similar oven, at a low red heat, with free access of air and constant stirring, gradually takes up more oxygen and is converted into red lead—a combination of the monoxide and the dioxide, in the proportion of about two parts of the former to one of the latter. The product is usually stated as having the formula Pb_3O_4, but commercial red lead is, as noted, a mixture of oxides rather than a definite chemical compound.

The black oxide of manganese, known to mineralogists as pyrolusite, is a natural product, of which the principal sources of supply are in the Caucasus Mountains, in the Hartz Mountains and elsewhere. Chemically, it is the dioxide of the metal manganese. The miners are the wild mountaineers of eastern Europe, and the mineral before it reaches America, passes through southern Russia, the Black Sea, the Dardanelles, the Mediterranean and so across the Atlantic. For the use of the varnish and dryer manufacturer it is subjected to mechanical purification.

These two metallic oxides readily replace the glycerin in linseed oil at moderate temperatures, forming oleates and linoleates, while the glycerin is decomposed and driven off.

The addition of a resin—in this case Kauri gum—at a moderately high temperature also probably induces the formation of resin acid compounds of the metals.

The driers made with lead and with manganese have sharply distinguished properties, of which advantage is taken by the well-informed manufacturer, who knows that certain proportions of the two yield better average results than either alone. He also carefully calculates the percentage of the metal in the drier to the oil to be oxidized. Kauri gum, besides helping the quality of the japan, has also been shown by experience to serve a useful purpose in paints containing high percentages of zinc oxide. It is found only in New Zealand, where ancient forests of the tree which produced it—the *Dammara austaralis* and other varieties of Dammara—have been buried for ages in the earth. It is mined systemmatically by trenching and is cleaned, sorted and classified by hand.

Components of Pigment

We have now briefly covered the liquid portion of our formula and in the course of our survey have gone to North Dakota for flaxseed, to Florida for turpentine, to Texas for benzine, to China for wood oil, to Colorado and Montana for lead, to the Caucasus for manganese, and to New Zealand for Kauri gum. Even at this point we may begin to see that for this ordinary can of mixed paint the manufacturer has been under the necessity of calling upon many industries, several races and different quarters of the globe. It is no less so with the remaining items of our formula and the package in which it is sold. **Lead hydrocarbonate** is the first named of the solid ingredients. In this case it happens to be Dutch-process white lead.

Lead hydrocarbonate or basic lead carbonate is a molecular combination of the hydroxide and the carbonate of lead in about the proportion of two parts of the latter to one of the former, though these proportions are only approximated in actual practice. The accepted formula, however, is $2PbCO_3$, PbH_2O_2. Of the three processes used to any extent for the manufacture of this product, two employ acetic acid in an intermediary step of the chain of reactions, while the third dispenses with it.

The *old Dutch process,* so called—though it has undergone great improvement in English and American practice—starts with desilvered lead pigs, known in the trade as "soft lead." These are melted, and the molten lead is distributed in shallow molds on an endless-chain belt. The molds give the metal the form of a flat circular grating or buckle about 3/16 in. thick by 5 in. in diameter. These buckles are packed into earthenware pots, having at their bottom shallow wells containing each about half a pint of vinegar or dilute acetic acid.

The charged pots are arranged in tiers between layers of spent tan bark, where they are allowed to remain undisturbed for about 130 days. By the fermentation of the tan bark heat is generated and carbonic acid liberated. The heat vaporizes the acetic acid, which attacks the lead, coating the buckles with basic lead acetate. This in turn is attacked by the carbonic acid, producing the basic carbonate and liberating neu-

tral lead acetate, which attacks the metallic lead beneath, producing again the basic acetate.

The process thus continues progressively until most of the buckle has been altered to the basic carbonate. The buckles being removed from the pots are subjected to mechanical treatment which separates the corroded from the uncorroded portions. The white lead after being ground, washed, floated and dried, enters commerce as dry white lead. The special characteristics of corroded white lead are its excellent working properties and low oil consumption, giving a high degree of opacity or color-body in the finished paint.

The second process, commonly known as the "*quick process*," also starts with desilverized pig lead. This is melted and finely comminuted in a steam blast, and the granulated product is charged into large, slowly revolving wooden drums, where, after being moistened with dilute acetic acid it is subjected for some hours to the action of purified carbonic acid gas from burning coke. The slow revolution of the drums insures the exposure of the entire mass to the action of the gas.

The chain of chemical processes involved is probably identical with those described for the old Dutch process. The mechanical treatment of the crude corroded product is essentially the same. The finished product is more uniform in the size of particle than Dutch-process lead and finer in texture. This involves a larger oil consumption and a consequent decrease in opacity or color body of the completed paint.

The third process, known as the *mild process*, because of the fact that acetic acid is not used, is applicable to pig lead of any description. In this process, also, the metallic lead is finely comminuted in a steam blast. In both this and the preceding process there is a preliminary surface hydration produced by the action of the water vapor on the lead particles. The finer particles are charged into revolving drums containing water and there subjected to the action of air under low pressure for several hours. The lead is thereby converted into the basic hydroxide. This hydroxide is then subjected in similar drums to the action of purified carbonic acid gas for the requisite time, until the conversion to the basic carbonate has been carried to the proper point. The product is extremely white, uniform and pure, requiring only water-floating and drying to fit it for use.

The second pigment of our formula is **basic lead sulphate** or basic sulphate white lead. This is a sublimation product, and is produced directly from the native ores of Missouri—lead sulphide—by oxidation at a high temperature in a current of air. The comminuted ore is charged in a special furnace with coal or other fuel and is subjected to a hot-air blast. The sulphide takes up oxygen, volatilizes and is carried through a series of cooling flues to fabric bags, in which it is collected.

This is the process in outline, though not in detail. The reaction involved is simple; the lead sulphide, PbS, takes up four equivalents of oxygen from the air being converted into lead sulphate, $PbSO_4$. At the same time it is also claimed, with much probability, that there is formed a certain proportion of the basic lead sulphate, $Pb_3S_2O_9$. At any rate analysis always yields an excess of oxygen, which is usually calculated to lead oxide, the percentage of which ranges from fourteen to twenty. The product, furthermore, always contains a small percentage (five to six) of zinc oxide, which comes from the zinc sulphide associated with the ores used.

It may be said in passing that lead sulphate produced in the laboratory is a very unsatisfactory pigment, exhibiting none of the characteristics of the "sublimed" white lead. The latter, on the other hand, is extremely useful, and in certain combinations has come to be regarded as almost indispensable. The particles of this pigment are extremely fine and uniform, approaching the particles of zinc oxide in this respect. As a pigment, it stands between corroded white lead and zinc oxide in most of its characteristics. Paints made with it chalk more freely than paints made with the former, but on the other hand, they retain their color better, and do not "check" so freely. Proper combination with zinc oxide restrains the characteristic chalking while the hardening peculiar to zinc is in turn restrained.

Our third pigment is **zinc oxide**. Zinc is peculiar in that it is the only metal in common use produced by distillation. It is volatile at an easily attainable temperature and advantage is taken of this fact in recovering the metal from its ores. The hot metallic vapor is also readily oxidizable, and if exposed to the air, will take fire, burning with a green flame to zinc oxide.

The oxide is produced by two different processes. One, known as the French process, taking advantage of the fact just mentioned, volatilizes the metal in a current of air and collects the resultant oxide in closed chambers.

In the other process, known as the American process, the oxide is produced directly from the ores. On the nature of the ore used depend the individual characteristics of the resultant oxide.

In this process the comminuted ores are mixed with powdered anthracite and charged into closed furnaces having perforated grate bars. Combustion is started in the anthracite and a blast of air is forced through the perforations in the grate. The heat smelts the ore and volatilizes the zinc, and the metallic vapors promptly combine with the oxygen of the blast, producing zinc oxide. This oxide is carried through a series of cooling flues and collected in fabric bags.

The particular oxide used in this formula is made from New Jersey ore, and on that account is of some interest. This ore is unique in that it occurs in commercially available quantities, nowhere else in the world. It is known as franklinite, and consists of the oxides of zinc, manganese, and iron in molecular proportions—crystallizing as a true mineral. It is closely associated in the vein with other compounds of zinc—the anhydrous silicate, the oxide, etc. A peculiarity of the product is that the oxide recovered is practically free from impurities, averaging over 99 per cent pure oxide. The oxides produced from the ores mined in other localities usually contain from 5 to 15 per cent of lead sulphate, due to the presence of lead sulphide in the vein.

The characteristics of zinc oxide are too well known to require extended comment. It is the finest and whitest of all white pigments; is chemically quite stable, the only chemical changes possible in practice being to the sulphide or to the carbonate, while is also white. It is bulky and hence carries a high percentage of oil in the finished paint; and finally, when properly used, it is very durable. One is fairly safe in saying that if oxide of zinc had not been introduced as a pigment, there would have been no prepared paint. It was produced as a commercially available pigment, in answer to a demand that had been voiced in Europe from the closing years of the eighteenth century, to the time of its introduction about the middle of the nineteenth. This demand for a non-poisonous white pigment finally received a satisfactory response from a contracting painter of Paris, Le Claire, who was also celebrated as a philanthropist and is known to this day as "the father of profit sharing." Practically every great chemist of Europe from Lavoisier to Faraday had his try at the problem.

Our next pigment is **magnesium silicate** in the form

of asbestine. This product comes principally from Canada. Its usefulness in the paint formula depends entirely upon its physical form, which is acicular or rod-like. Its office in the paint film has been compared to that of the hair in plaster or the rods in reinforced concrete. It is without special value either for opacity or protection, but aids in holding the materials in suspension and very probably also in resisting stresses in the dried paint film.

Our fifth solid ingredient is **calcium carbonate**—in this case a natural product from Missouri—a dolomitic crystalline rock, finely ground for the purpose. Calcium carbonate, as used in paint manufacture, comes to us in two forms. Whiting, Paris white, etc., are the pulverized and floated chalk supplied principally by the chalk cliffs around Dover, England; the calcareous skeletons of innumerable diatoms that once populated the waters of an ocean covering that portion of the earth, ages before the advent of man; while the product used in this formula is from a similar geological source, but in succeeding epochs subjected to heat and pressure, which gave it a crystalline structure. As a rule manufacturers in selecting from these two forms are governed by the conditions; if the remaining inert pigments are crystalline, Paris white is selected; if not, then the so-called mineral primer is preferred.

Either will neutralize any free acid in the paint, but the mineral primer will in addition give the "tooth" which is thought desirable in the manual work of painting. The only other crystalline pigment in our formula is the asbestine, so mineral primer rather than a form of chalk has been selected for this formula.

Barium sulphate is the next on our list, and is used in the form of the chemical precipitate—blanc fixe. The sulphate of barium in the form of barytes is a natural, crystalline product, which retains its crystalline form, no matter how finely comminuted.

It is found associated with lead, zinc and other ores in most mineral regions. That used in the United States, however, comes principally from Missouri and the Alleghenies in Central Virginia, Tennessee, etc.,—Missouri furnishing the larger proportion. There its production is in the hands of farmers who collect and cart it to the railroads in the fall and winter, to be manufactured into pigment at St. Louis and neighboring points. In the Allegheny regions the mineral is procured by mining.

Blanc fixe is produced by transforming the natural product into a soluble compound and precipitating it from dilute solution with sulphuric acid or a soluble sulphate. The product is chemically identical with barytes, but physically quite different, being very finely divided and amorphous.

Silicate of alumina is the next ingredient of our white base. Technically it is a washed and floated China clay, naturally produced by the disintegration of certain feldspars, the soluble potassium and sodium salts having been washed away. The percentage here used is small, but it has a physical influence on the suspension of the other pigments, in the brushing qualities of the paint and on the quality of the paint film.

The remaining ingredients of our formula are the colors required to produce the desired tint. They have no influence on the quality of the paint. The yellow in this combination is **lead chromate**—chrome yellow. It is produced by the reaction of a soluble chromium salt, usually sodium bichromate, on a soluble lead salt, usually lead nitrate, both in solution. The neutral chromate of lead $PbCrO_4$, being insoluble, is precipitated. The production of this familiar pigment again takes us far afield. The chromium used in making the chromates is obtained from an ore of iron known as chromite. It is a chromate of iron, having the composition $FeCr_2O_4$. It is found in small quantities in Pennsylvania, Maryland, California and elsewhere in the United States, but the main sources of supply are Asia Minor and Australia. Large quantities of these ores are imported into England, Germany and the United States for the sole purpose of manufacturing the chromium salts of potassium and sodium. The process is intricate and difficult, so that the manufacturers are few in number. There is also some demand for the mineral in the manufacture of special steels.

The remaining pigment is **Prussian blue**—the potassio-ferro-ferri-cyanide of iron. This material brings us once more into the field of organic chemistry, the non-metallic component of the blue being cyanogen, which is most familiarly known as a component of hydrocyanic or prussic acid and the cyanides of potassium, etc. The chemical composition of the color is indicated by the formula $K_2Fe_2 2FeC_6N_6$.

The cyanides are obtained from organic wastes containing carbon and nitrogen, principally the residues from gas works.

In practice, in the manufacture of chrome green as used for tinting in the present instance, the colors are precipitated simultaneously from solution, either with or on the base, which in this case is the blanc fixe shown in the formula.

The Paint Factory

We have now glanced hastily at the characteristics of our several ingredients, but they are still only raw materials and require a long series of mechanical operations before our can of paint will be ready for use, not to mention the detailed work of the chemist to determine the quality of the materials themselves.

A modern paint factory is a complicated institution, and in the limits of such a paper as this can only be touched upon briefly and hastily. Power in the most modern plants is generated at a central point and is distributed to the units in the form of electrical energy. As a rule the raw materials are elevated to the highest point in the plant, so that the product, in its several steps toward completion, may fall by gravity from each point to the next in the process.

The dry pigments are ground separately to the form of a paste with linseed oil. The various components of the white base are then thoroughly incorporated with more oil, the whole is then mixed with the rest of the oil and the remaining thinners in a mechanical agitator, the tinting colors being added either here or at the preceding step, and the exact tint is attained by addition on the judgment of the expert tinter. The finished paint is measured mechanically into tin cans, which are also soldered and labeled by machinery, and finally these cans are packed in cases holding a given number and guarded from injury by sawdust placed between them. The boxes are then nailed, shut, marked and shipped to the distributors. This is the mechanical routine in the barest outline; but we may observe that it involves the use of building materials, fuel, copper wire, tinplate, paper, printing ink, paste, box lumber, sawdust, wire nails, etc.

The manufacture of tinplate is an important industry in itself, involving a branch of the steel industry in the production of the plates for this use. These plates are cleaned by chemical means, heated, and coated with metallic tin by dipping in a bath of the molten metal. To obtain the tin for this use we must again go to distant regions. The ores are found in small quantities in various parts of the United States.

Cornwall, from the time when the Phoenicians traded to Britain for tin to the days of the first McKinley tariff,

was the chief source of the world's tin supply. But the drain finally told on the natural resources, and the bulk of the tin consumed to-day comes from the Straits of Malacca and from Australasia. In the former locality it is recovered by placer mining methods and in the latter by the usual methods of underground mining. The ore is found in two forms, as the oxide, casserite, and as the sulphide, stannite, in which latter form it is associated with iron. The smelting of the ore for the metal is done principally in England and other parts of Europe.

The paper for our label is a product of sulphite wood pulp, as is most of the paper used for advertising paint. We need not enter further into this subject except to note that our industry involves also the paper manufacturing industry.

Similarly we may note in passing that the printing ink manufacturer and through him the lampblack manufacturer, the color maker and the varnish manufacturer are involved.

Finally, in the consumption of paste, we return once more to the farmer, on whom we called in the first instance for our linseed oil.

The manufacture of this important product, paint, formerly based on empirical experience, is more and more coming under the jurisdiction of the trained technical man. To him we owe the fact that we have now at our command special paints for many special purposes: Flat wall paint for interior decoration; paint for the protection and decoration of concrete; rust-inhibitive paint for the preservation of steel structures, etc.

We know a great deal about paint, in a general way. There is a mass of experimental data on hand to be correlated, interpreted and made the basis of broad general laws. To this phase of the subject the trained paint technologists are now turning their attention.

In conclusion, permit me to say that there is no subject more interesting or more important to us as citizens or as property owners. As citizens we owe largely to paint the beauty and wholesomeness of our surroundings and as property owners, the preservation of our structures.

Educational Bureau, Paint Mfrs. Asso. of U. S.

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

The Tonopah Plant of the Belmont Milling Co.—Cyanide practice at Tonopah was described in a paper by A. H. JONES, superintendent of mills for the Tonopah-Belmont Development Company, at the A. I. M. E. meeting in San Francisco. The cost of the plant, designed to handle 500 tons of ore per day, is shown in Table I.

A flow-sheet is shown in Fig. 1, giving details of machinery used.

The ore is crushed to 1-in. size and automatically sampled and weighed.

The consumption of wearing parts in the crushing plant amounts to 0.0325 lb. per ton of ore at an expense of $0.00555.

Sixty 1250-lb. stamps crush through 4 and 6-mesh Taylor ton-cap screens at the rate of 8.88 tons per stamp per 24 hours. Five tons solution is used per ton of ore stamped. The solution has a cyanide strength of 5 lb. and a lime strength of 1 lb. Metal consumption in stamping is as follows: Forged steel dies, 0.207 lb. per ton of ore; chrome steel shoes, 0.179; discarded iron in dies and shoes equals 0.064 lb. and 0.108 lb. per ton of ore respectively, making a total of 0.553 lb. per ton of ore, of which 0.386 lb. is consumed and the balance discarded. Average service for cam shafts has been 27,214 tons stamped.

Thermit welding of cam shafts has been tried at a cost per shaft of $42.53.

FIG. 1—FLOW-SHEET OF BELMONT MILL

Lime is added at the tube-mills in the form of milk of lime, and about one-half the total quantity of lead acetate used is also added here. About 75 per cent of the pulp is ground to minus 200-mesh size. The cost of silex lining was $395.84. It had a life of eight months, grinding 15,533 tons of ore. The cost of this lining per ton reground was $0.0583; per ton of ore milled, 0.048. With Komata manganese steel lining the cost per ton reground was $0.0457. The Belmont type of ribbed lining made of hard white iron has shown a service of nineteen months, and a cost of but $0.0346 per ton reground.

It is estimated that this lining will last two years and show a cost of but $0.0173 per ton reground. Danish pebbles are most economical.

A simple and accurate method of figuring return tonnage from tube-mill to classifier, in accordance with the accompanying table of screen analyses, is as follows:

Mesh	Battery Discharge		Tube-Mill Feed		Tube-Mill Discharge		Dorr Overflow	
	Per Cent	Cumulative, per Cent	Per Cent	Cumulative, per Cent	Per Cent	Cumulative, per Cent	Per Cent	Cumulative, per Cent
+ 10	10.3	12.3	5.4	5.4	....	.....	....	.....
+ 14	10.0	20.3	5.2	10.6	....	.....	....	.....
+ 20	10.2	30.5	5.3	15.9	....	.....	....	.....
+ 28	11.3	41.8	5.9	21.8	....	.....	....	.....
+ 35	7.7	49.5	4.9	26.7	1.0	1.0	....	.....
+ 48	7.1	56.6	6.5	33.2	3.1	4.1	....	.....
+ 65	5.6	62.2	8.1	41.3	6.5	10.6	....	.....
+100	6.0	68.2	20.0	61.3	20.0	30.6	1.0	1.0
+150	6.6	74.8	24.4	85.7	28.6	59.2	12.5	13.5
+200	4.0	78.8	7.8	93.5	12.7	71.9	14.2	27.7
−200	21.2	100.0	6.5	100.0	28.1	100.0	72.3	100.0

Tons crushed per day, 500. Feed per mill, 62.5 tons.

In the battery discharge there was 41.8 per cent., or 26.12 tons, which did not show in the tube-mill discharge. This material was represented in total tube-mill feed by 21.8 per cent. As we know this 21.8 per cent is represented by 26.12 tons, 100 per cent of the feed amounts to 119.8 tons.

Total feed, tons	119.8
Initial feed, tons	62.5
Return feed, tons	57.3
Ratio of return to initial feed	0.92 to 1

Concentration is practiced mainly for the purpose of removing only the heaviest and most refractory mineral. This gives a clean product but not a close concentration. For the fiscal year ended Feb. 28, 1915, concentration represented 0.67 per cent by weight and 11.5 per cent in extraction of the precious metals.

Pulp thickening is done in Dorr continuous thickeners, and agitation in tanks of the Pachuca type. Originally only 5.5 sq. ft. of settling area per ton of ore was allowed, but owing to changes in the ore this has had to be increased. Trays introduced into the Dorr thickeners increased the settling area to 8.47 sq. ft. They have given no serious troubles and have increased the capacity of the two thickeners in which they were installed about 75 per cent.

After continuous agitation the pulp is thinned by adding barren solution, and again thickened and agitated. This removes a large portion of the dissolved gold and silver and relieves the filters of this work. Solutions are heated to about 90 deg. Fahr. by steam coils placed in the air-lifts of the agitators. Extraction is improved about 2 per cent by use of warm solutions. The agitators are 15 ft. by 45 ft., and require 67½ cu. ft, of free air per minute at 30 lb. pressure.

A 250-leaf vacuum filter plant, constructed on the half-gravity system, is used for final displacement of solution from slime. Precipitation is by zinc dust. Only enough solution is completely precipitated to make the final barren-solution wash at the filters. The balance is precipitated to a value of 10 cents per ton and used in diluting at Dorr thickeners, tube-mill feed solution and for table wash. Zinc consumption is 0.7808 oz. per ounce of bullion. Precipitate is briquetted with 2.45 per cent borax, 6.05 per cent soda and 6 per cent sand and melted, the bullion averaging 93.23 per cent gold and silver.

Extraction is 96.2 per cent of the gold and 93 per cent of the silver.

The accompanying table shows the dissolution of gold and silver through the different steps in the process:

	Assays			Per Cent of Extraction in Each Department			Per Cent of Total Extraction in Each Department		
	Au	Ag	Value	Au	Ag	Total	Au	Ag	Total

Cyanide Practice of Churchill Milling Co.—The mill of the Churchill Milling Co. is situated at Wonder, Nev., 55 miles from Fallon, the nearest railroad point. Operations for the year ended Sept. 30, 1914, were described by E. E. CARPENTER in a paper before the American Institute of Mining Engineers in San Francisco. A flow-sheet is given in Fig. 2.

The ore treated is an unusually tough and hard oxidized quartz containing a small quantity of sulphides, rich in both gold and silver. The mill is built on a 30 deg. slope, and contains equipment in the following order:

1, 10 by 16 in. Blake crusher.
10, 1,400-lb. stamps.
1, 6 ft. Trent Chilean mill.
1, Dorr duplex classifier.
1, 5 by 22 ft. tube mill.
1, 24 by 14 ft. Dorr thickener.
4, 15 by 45 ft. Pachuca type agitators.
1, 28 by 10 ft. Dorr thickeners.
1, 28 ft. by 14 ft. stock tank with stirrer.
2, 8 by 11 ft. 6 in. Oliver filters.
5, Zinc boxes.
2, Melting furnaces.

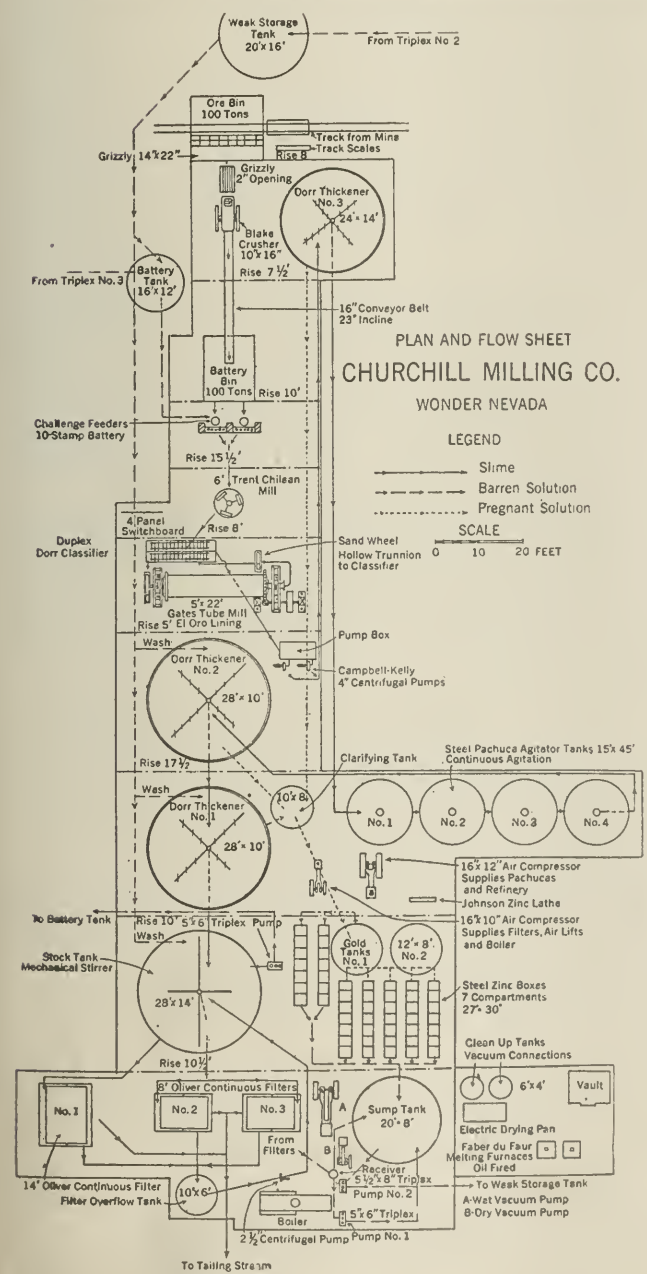

FIG. 2—FLOW-SHEET OF CYANIDE PLANT, CHURCHILL MILLING COMPANY

The annual report for 1914 shows a gold recovery of 95.1 per cent and a silver recovery of 92.4 per cent, or 93.2 per cent of the gross value. The average value of mill feed was 0.216 oz. gold and 19.48 oz. silver per ton.

TABLE I.—TONNAGE, COST AND RECOVERY DATA

Months	Tons per Month	Tons per Day	Total Direct Cost	Cost to Date	Gold Recovery, per Cent	Silver Recovery per Cent	Value Recovery, per Cent
Oct., 1913	4,160	134.2	$2 825	$2 825	95.3	92.8	93 6

Sept., 1914	4,335	144.5	2.771	2.743	97.3	92.7	94.0
Averages or totals	48,570	133 1	2 743	2.743	95.1	92 4	93.2

Stamps weighing 1400 lb. crush through ⅜-in aperature. Using chrome steel shoes and dies the consumption of steel per ton of ore ground was: Shoes, 0.232 lb; dies, 0.107; total, 0.339 lb.; cost per ton, $0.018.

In a Trent 6-ft. Chilean mill the average consumption of chrome steel was 0.5 lb. per ton of ore ground, costing $0.034. El Oro lining in a 5-ft. by 22-ft. Allis-Chalmers tube-mill cost $0.022 per ton ground, based on twelve months' operation with the liners still in use and worn practically smooth, with a prospect of three months' more use. Consumption of pebbles was 3.39 lb., costing $0.08 per ton of ore ground.

On an average tonnage of 133 per day, a 14-ft. by 24-ft. Dorr thickener takes care of the entire flow, giving 3.4 sq. ft. of settling area per ton of ore thickened.

Silver goes into solution very readily. Part of the lime and lead acetate is added at the Challenge feeders and the balance at No. 1 agitator. Sodium cyanide is added at No. 1 agitator.

The following table gives average extractions as obtained at different points in the process:

	EXTRACTION IN TANKS		TOTAL EXTRACTION	
	Gold, per Cent	Silver, per Cent	Gold, per Cent	Silver, per Cent
Up to No. 1 agitator	....	....	76.5	72.2
Disch. from No. 1	9.7	11.5	86.2	83.7
Disch. from No. 2	4.6	5.0	90.8	88.7
Disch. from No. 3	2.8	2.8	93.6	91.5
Disch. from No. 4	0.9	1.2	94.5	92.7
Filter	1.4	0 5	95.9	93.2

A saving of 0.23 lb. of cyanide was made by changing the method of washing the cake on the Oliver filter, using water on both ascending and descending sides, instead of barren solution on the former and water on the latter. In order to prevent excessive dilution of solution by this double use of water, a rubber apron is placed against the cake on the ascending side to divert the surface water to the slime-discharge launder. Similarly on the descending side an iron apron 18 in. wide was placed so that its upper edge was just above the blow-off section. This apron scraped off about 1/16 in. of the cake surface and removed considerable wash water, diverting the pulp to the usual discharge launder without interfering with the regular operation of the blow-off. This method makes it possible to keep the cake covered with a sheet of water on both sides without allowing an excessive amount to enter mill solution. Sampling and assaying of filter tailings shows a loss of

0.85 lb. cyanide per ton of ore, and a loss of soluble gold and silver of $0.18 per ton of ore.

Precipitation on zinc in boxes shows an average efficiency of 95.2 per cent, the average value of head and tail solutions being $2.227 and $0.107 respectively. The precipitate is refined without acid treatment; it is dried and mixed with 7 per cent each of the following fluxes: Borax glass, soda and sand.

Lead

Lead Smelting at El Paso.—A paper by H. F. Easter, assistant superintendent of the El Paso Smelting Works, El Paso, Tex., was presented at the San Francisco meeting of the American Institute of Mining Engineers, describing the plant and practice in the lead-smelting department. Lead-ore supply in recent years has been precarious, with a general tendency toward excess of silica and shortage of iron. To supply the latter a considerable amount of roasted leady copper matte from Chihuahua and converter matte from El Paso have been used. These materials, together with complex lead-copper ores from Arizona, have introduced an unusual amount of copper into the plant and have had an important bearing on the smelting practice.

Unloading is done by contract at rates based on the character of the car and the distance to which the ore must be wheeled. When the initial sampling is done by hand the rates include the cutting of the sample and wheeling it to the sample storage platform. An extra allowance is made for spreading the ore in the bin itself, as this must be done carefully by hand because of the different character of the numerous small lots which are bedded together. Hand sampling is done by taking every tenth shovel of the fines and setting aside the coarse lumps, from 6 in. up, for automatic sampling. The automatic plant contains the usual sampling equipment. The automatic sample is added to the hand-cut sample of fines, and the combined sample is then put through a smaller automatic sampling equipment. A sample from one car amounts to from 400 to 500 lb. It is circled, coned and quartered by hand until reduced to proper size for the bucking room. In the case of high-grade ore the whole lot is sampled automatically. Concentrates are shovel-sampled.

All ores requiring roasting are bedded. In general the best results are obtained when the mixture contains 20 per cent silicious sulphides with leady copper matte. Three Godfrey 30-ton roasting furnaces are used for the preliminary roast. Two are oil-fired and consume 0.22 bbl. of oil per ton roasted; the coil-fired furnace consumes 0.11 ton of coal per ton roasted, all of which, however, is not chargeable to roasting, as some half-burned material is drawn off for the Huntington-Heberlein pots. The pots handle two charges of 6 to 7 tons in twenty-four hours. Air pressure for the pots is 10 oz. The fine material in the sintered product amounts to from 5 to 10 per cent of the charge, and is added to the next charge. Sulphur in the final product averages about 5 per cent.

The hearth area of the blast furnaces at the tuyeres is 46 in. by 162 in. The average capacity is about 180 tons of charge per furnace day, although with a coarse charge it has frequently been better than 200 tons. Production of flue dust averages from 1½ to 2 per cent of the charge smelted. The flue system is 800 ft. long, of which the first 375 ft. is provided with hoppers that collect the greatest part of the dust. These hoppers are discharged into tram cars. The flue dust is briquetted with 10 per cent burned lime, and the briquets are allowed to dry for from three to six weeks.

The author devoted considerable attention to the difficulties experienced at El Paso in settling and separating leady copper matte from the slag, as this problem has been most vexing at the El Paso plant. Originally this operation was accomplished in a Rhodes separator, or small reverberatory furnace. This was satisfactory in the days of large lead tonnage, but has proved unsatisfactory with the present small tonnage of lead ores. These furnaces are now permanently abandoned. Experiments with small settlers in front of the furnaces were not satisfactory, as they tended to fill with zinc mush that seriously interfered with settling of matte. This condition was finally remedied by changing the charge so as to use less of the Huntington-Heberlein roast, and since that time similar troubles have been overcome by changes in the furnace and roaster charges.

The latest arrangement of settling devices is to have a rectangular box in front of and at an angle of 45 deg. with each furnace, and a large, oil-fired settler to serve each two furnaces. The furnace is connected with the rectangular box and the box with the settler by short water-coil spouts. The boxes are lined with magnesite brick all around. The settler measures 10 ft. by 20 ft. and is supported on rails running crosswise. Air spaces are provided beneath the bottom pan to keep seeping lead from progressing downward into the foundation. The sides and ends are lined with magnesite brick. A matte tap is provided on each side close to the front and a single lead tap in the middle at the rear end. Every effort is made to prevent lead getting into the settler, as experience with the Rhodes settler had shown the inadvisability of keeping a bath of molten lead in contact with matte. The settler requires about 7 bbl. of oil per day.

The Salida Smelter.—A description of the plant and lead-smelting practice at the plant of the Ohio & Colorado S. & R. Company, at Salida, Col., by F. D. Weeks, was presented at the San Francisco meeting of the American Institute of Mining Engineers. Some of the most interesting points in the paper are those relating to errors in construction and early operation. This smelter was one of the first to make a commercial installation of the Dwight-Lloyd sinter-roasting process, a description of which appeared in this journal, February, 1912. One of the results of the use of this process was to increase the capacity of a 48-in. by 180-in. blast furnace from 180 to 250 tons per day. Speaking of some of the peculiarities of construction of the original plant, the author says:

> Originally, a brick wall, with a narrow door in front of each blast furnace, was constructed. How the work was to be done behind this wall is not known, but it shows that the designer did not know how to do the work.
>
> The water jackets were held in place by a 12-in. I-beam running the length of the furnace, thus effectually preventing any one from examining a tuyere or jacket.
>
> The shaft walls on the feed floor were so thick that the feeders were shoving ore into one end of a tunnel, and, since the opening was not as wide as the shaft, the ends of the furnace could not be fed except by throwing the charge around a corner which, of course, was not done.
>
> The proposal to concentrate matte carrying 20 per cent lead and 5 per cent copper, in a copper-matting furnace was intended to do away with the necessity of roasting equipment.
>
> The largest Corliss engine on the plant was the exhibition engine at one of our world's fairs held some years ago. When repairs were needed, it was discovered that this was the only engine of the kind ever built, and the drawings of it were lost; so each repair part called for an accurate drawing.
>
> In the track plan of the works, all the ore, coke, and limestone had to be unloaded from one track. This track also held the cars which were to be unloaded at the oxide crusher as well as at the sulphide mill. The problem of dispersing some of this congestion was not simple. It was solved by building two trestles in place of one; by having the limestone brought in dump cars so that unloading took little

time; and by building an oxide crushing and screening plant on new tracks.

Referring again to the Dwight-Lloyd sintering plant, an important improvement has been made by placing an adjustable rail by the side of the pallets so that the weight of the pallets and their charge is carried on rollers and no dragged across the top of the wind box.

Recent Chemical and Metallurgical Patents

Electrolytic Processes

Caustic Soda and Chlorine.—An electrolytic cell of concrete for the production of caustic soda and chlorine is patented by Messrs. EDWARD A. ALLEN and HERBERT I. ALLEN of Maine (assigned to the Electron Chemical Company, Portland, Me.). Fig. 1 shows a perspective view of the cell and Fig. 2 a cross section. The cell consists of a main body containing the anodes 50, held by carbon rods 31, supported at the top of the cell. These carbon rods pass through the elliptical openings 17, which are made that shape to allow for the upward passage of the chlorine gas. The main body of the cell which comprises the anode chamber is open at its opposite ends, and against these open ends are placed the cathodes 20, held in place by clamps. The trough 15 is provided for catching the caustic soda solution which trickles down the cathodes. It may be drawn off through opening 16. The opening 30 is provided for introducing the brine solution. The cell may be made in two parts, one part consisting of the bottom and end pieces 11, and the other part the top piece with the anode openings, provided with a sliding connection. As it is only the cell which is patented the manner of operating or material of which the anodes and cathodes are made is not stated. (1,148,274, July 27, 1915.)

Caustic Soda and Chlorine.—A diaphragm cell for caustic soda and chlorine production is patented by Mr. HARRY R. NELSON of Elizabeth, N. J. This cell is shown in Fig. 3 in which 1 represents the outer casing which serves as a support at 3 and 4, for the cell proper 2. The cell proper contains the diaphragm 5 of asbestos and the cathode 6 and anodes 7, below the dome chlorine chamber 9 of slate or other non-conducting material. The cathode 6 of perforated iron is pressed against the outside surface of the diaphragm. The outer casing is made gas-tight at the angle 13, and the inlet pipes 14, 15 are provided for supplying steam, which is controlled by the valves 16. Outside of the cathode are screens 17 and 18 held in place by the strips 20. The removable strips 21 are provided for catching any solid matter. In the operation of the cell sodium chloride solution is supplied from the top through a pipe between the cathodes, the evolved chlorine is collected in chamber 9, and discharged through opening 28. "The cation sodium encounters the steam supplied through the inlet pipes 14, 15 and forms caustic liquor of high concentration, with the evolution of hydrogen." The pressure of the steam at the inlet pipes 14, 15 is such as to maintain a "faint" cloud within the casing 1. The evolved hydrogen passes upward along the outer side of the cathode 6 and is discharged. The caustic liquor formed trickles down the outside of the cathode 6, and is caught in the tilting pan 22, which empties into the larger pan 23, provided with the discharge 25. Dry steam is preferably used and for this purpose the trap 31 is provided. The use of steam is claimed to give greater efficiency of production. (1,149,210 and 1,149,211, Aug. 10, 1915.)

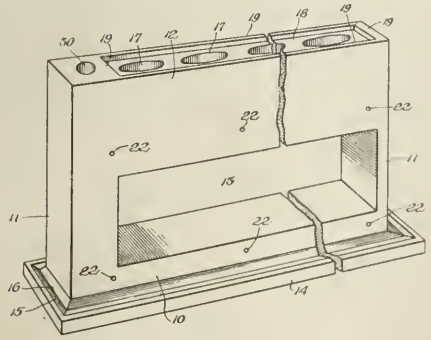

FIG. 1—ELECTROLYTIC CELL FOR CAUSTIC SODA AND CHLORINE

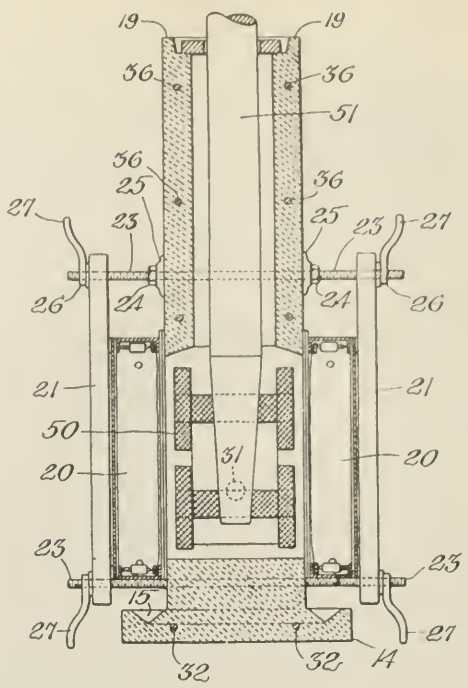

FIG. 2—CROSS-SECTION OF ELECTROLYTIC CELL FOR CAUSTIC SODA AND CHLORINE

Caustic Soda and Chlorine.—An electrolytic cell of the bell type ("gravity cell") is patented by Mr. HENRY CHARLES JENKINS of London, England. In this cell

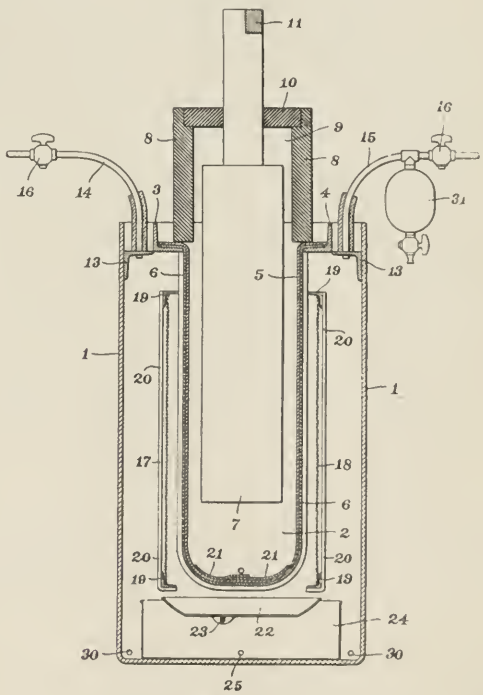

FIG. 3—DIAPHRAGM CELL FOR CAUSTIC SODA AND CHLORINE

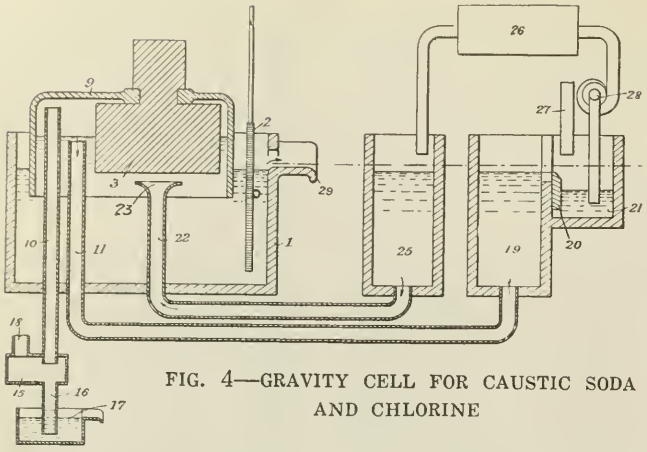

FIG. 4—GRAVITY CELL FOR CAUSTIC SODA AND CHLORINE

which is shown in Fig. 4, a bell 9 dips down into the casing 1, the bell being open at the bottom. The anode 3 is fastened to the bell by an air-tight connection. The cathode 2 is arranged as shown and may be made in any suitable manner so as to provide for the removal of gases formed thereon. For introducing fresh brine solution pipe 22 is provided, connected to tank 25, the fresh solution being delivered directly beneath the anode. For conducting solution away and thus circulating the electrolyte, pipe 11 is provided, connected to tank 19 which has an adjustable weir 20. In this manner the liquid in the cell may be kept at any desired height. At 28 is indicated a pump for circulating the electrolyte and at 26 a heating apparatus. Fresh brine solution may be introduced in 21 by pipe 27. For conducting away the chlorine gas formed in the bell, pipe 10 is provided, connected to a device for separating any liquid from the gas at 16. The caustic soda solution overflows at 29. (1,150,370, Aug. 17, 1915.)

Improvements in Electrolytic Copper Refining.—A patent for a new method of handling the solutions in electrolytic refining has been granted to Messrs. Francis R. Pyne and Henry M. Green and assigned to the U. S. Metals Refining Company of Chrome, N. J. In the usual electrolytic copper refining process, the solution is circulated by introducing and withdrawing the liquid to provide an even distribution. The solution withdrawn from the tank is then treated in a second tank or series of tanks to recover more of the copper, before treating the solution further to recover secondary constituents known as impurities. In this second treatment it is necessary to use insoluble anodes and consequently a higher voltage and more energy. The deposit in the second electrolysis is usually inferior to the first deposit. The solution after second treatment is then used to recover the secondary constituents.

The present patent proposes to utilize the fact that solutions stratify when the current is passing, and to allow the solution to stratify, withdrawing same from different levels. In this manner the solutions withdrawn may be regulated so that the primary solution is sufficiently strong in copper to be led into a second tank, where it is treated same as before, while the secondary solution is so poor in copper that it may be directly treated for recovery of the secondary constituents. This effects a saving in power owing to the elimination of the insoluble anode treatment. In Fig. 5, a tank is shown with entry for solution at *B*. It was found that the copper solution was purest on the lower level at *C*, and the concentration of impurities greatest at the upper level *D*. *E* is a pipe for withdrawing primary solution for second tank and *F* and *F'* pipes for withdrawing solution rich in impurities. A certain amount of circulation is necessary but is not usually as rapid as in the old process. The process produces a greater output of merchantable product than heretofore by enabling the series of tanks to operate under conditions similar to the first series, effecting a saving in electrical energy. (1,148,798, Aug. 3, 1915.)

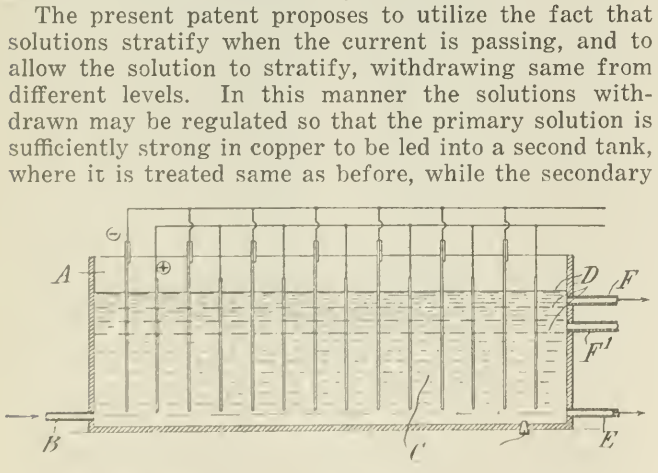

FIG. 5—ELECTROLYTIC COPPER REFINING TANK

Regenerating Electrolyte in Copper Refining.—A process for purifying the sulphuric acid electrolyte used in copper refining and for recovering arsenic contained in it is patented by Oliver Curtis Martin and Frederick Jaeger of Perth Amboy, N. J. The electrolyte is first nearly freed from copper by electrolyzing with an insoluble anode or by evaporation and crystallization or both. It is preferred to remove as much copper as possible with the insoluble anode. After removing the copper one method is to evaporate the solution until it contains 74 per cent sulphuric acid, and then boil with charcoal by which some of the sulphuric acid is reduced to sulphurous. The latter attacks the arsenic acid reducing it to arsenious. Carbonic acid is liberated. The solution is then diluted to 38 per cent sulphuric acid and allowed to cool, causing the arsenious acid to be precipitated. This method is preferably used when the copper is removed by evaporation.

Another method which is preferably used where the copper is removed by electrolysis is to subject the solution to sulphurous acid gas and concentrate or dilute to 38 per cent, when upon cooling the arsenious anhydride separates out, which may be purified by sublimation giving a marketable product.—(1,148,522, Aug. 3, 1915.)

Method of Cleaning Articles.—A process for removing tarnish and stains from silverware and other metals is patented by Mr. Elbert L. Couch of Hartford, Conn. (assigned to the Couch-Dean Corporation, of the same place). In this process the articles to be cleaned are placed on a traveling belt having a surface of tin or aluminium and sprayed by suitable means with an electrolyte. In this manner a short-circuited couple is formed and the oxide tarnishes are reduced to metal. The apparatus in which the cleaning is carried out is essentially the same as that in patent 1,068,568, July 29, 1913, granted to Mr. Couch and the electrolyte used, termed "silverease" was also patented by him in patent 674,254 of May 14, 1901. (1,150,101, Aug. 17, 1915.)

Electric Furnaces

Manufacturing Articles from Silica, Magnesia, Etc.—In a process patented by Prescott M. Hulbert of Detroit, Mich., finely divided refractory material such as silica is compressed in a mold of graphite and the mold is heated in an electric arc furnace to a temperature near the fusing point of the material. This causes the particles to integrate and form a solid compact form, the shape of the mold. No binder is necessary and the integration may be carried to any degree according to the heat employed. An artificial graphite cylinder may be placed in the center and extending nearly through the mold, and connected to electric terminals. The refractory material is inside and surrounding this cylinder and thus a means is provided for further heating of the material. A certain amount of shrinkage will occur,

which will, however, be lessened by using finely ground material.—(1,155,358, Oct. 5, 1915.)

Manufacture of Pure Carbon.—Pure carbon can be made from tar oils or other hydrocarbons for use in the manufacture of electrodes or other electrical conductors according to a patent of HENRI HENNEBUTTE of Paris, France (assigned to Société Anonyme des Combustibles Industriels of Paris, France). In this process the hydrocarbon to be used is left standing, or is filtered to remove any mineral dust. It is then passed either in a liquid or gaseous state into a still from the top. A steam coil in the still heats the oil and air is forced in to dehydrogenate the mass. A solvent such as benzine is then admitted and the dissolved portion is led away at the bottom through a pipe to another still. The insoluble oxidized mass of material which has been dehydrogenated is then heated further until it is thoroughly carbonized. The material in the second still may be distilled and the residue treated in the first still. The temperatures used in all cases depend on the raw materials used.—(1,155,419, Oct. 5, 1915.)

Reduction of Zinc Oxide in an Electric Furnace.—A process for the production of pure zinc from oxide or blue powder is patented by FRANK WILLIAM HIGHFIELD of Caversham, England. The oxide is fed into a furnace from the top, onto a bed of coke which forms the resistor for the furnace. The coke is heated to redness by the current and forms an atmosphere of carbon monoxide which together with the glowing carbon reduces the oxide to metal. The metal is condensed and trickles down through the coke and is led through a cooling chamber in which oxygen is excluded and is then discharged. The temperature should be about 1050 deg. C. A cross-section of the furnace is shown in Fig. 6. The oxide is fed in at *C* by the conical feed and passes through the tube *D* which is of fireclay so as to be porous to carbon monoxide. The bed of coke rests on bars *F* and is in contact with the electrodes *E*. The tube *D* is intended to provide a condensing surface. The condensed metal is caught at *A*, and led through the cooling chamber. The advantages of this method are claimed to be that it gives a large condensation surface which is necessary on account of the low vapor pressure of the metal and, by starting with the oxide instead of treating zinc ores direct for the recovering of pure zinc many difficulties are overcome.—(1,153,786, Sept. 14, 1915.)

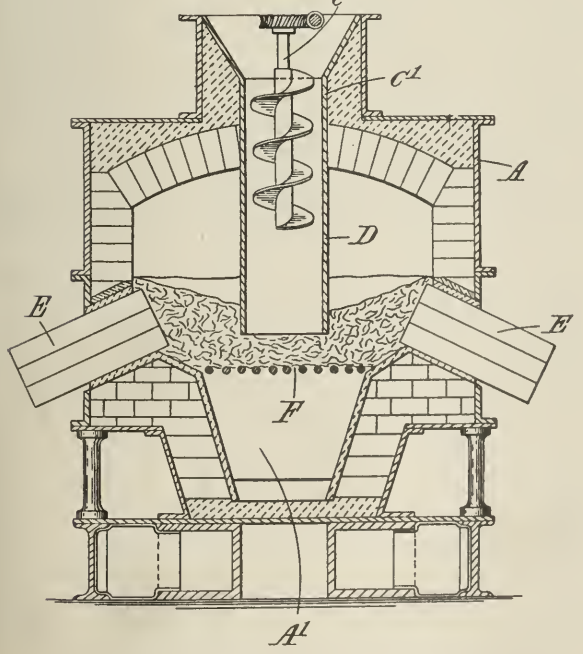

FIG. 6—ELECTRIC ZINC FURNACE

Chemical Engineering

Apparatus for Distillation of Peat.—In order to extract valuable ingredients from peat and produce coke a distillation apparatus has been patented by ELLIS BARTHOLOMEW of Toledo, Ohio (assigned to the National Peat Refining Company, Cleveland, Ohio). In this apparatus peat is fed from a closed bin 1 by a screw conveyor 4 to a cylinder called a separator shown in Fig. 7 at 10. The bottom of this separator is made hopper-shape and directs the peat on to a grate of electrically heated resistance bars 23. The heat of the bars drives off the gases from the heat converting it into coke. The gases pass up and out through openings 39 and the coke is shaken through the grate by suitable means, dropping into another conveyor, whence it is led to a bin. The separator and peat bin are kept full of the gas from the peat, so as to exclude air. For this purpose a reservoir of the gas is connected to valve 41. The gases which pass out through 39 are passed through suitable condensers where the lighter and heavier liquids are obtained.—(1,156,387, Oct. 12, 1915.)

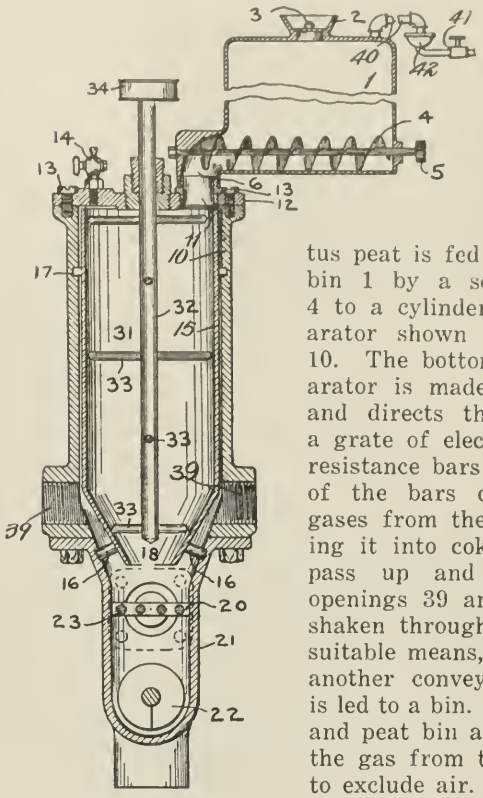

FIG. 7—DISTILLATION OF PEAT

Iron and Steel

Manufacture of Steel.—In adding the necessary additional elements to refined molten iron for making steel it is claimed to be advantageous if the additions are first dissolved in a separate subsidiary bath of refined iron and then this separate bath added to the main bath of refined iron in the casting ladle where they become mixed together. A patent which comprises these features has been granted to JEGOR ISRAEL BRONN of Rombach, Germany (one-half assigned to Rombacher Hüttenwerke, Rombach, Germany). The dissolving furnace is charged with molten refined iron which is usually available in steel works and then the desired additions such as carbon, manganese, silicon, titanium, etc., are made either in the pure state or as ferro-alloys. This gives an exact method of making additions, whereas in making additions directly to the main bath, losses of carbon and other constituents occur through the slag and gasification. It also provides a means for making carbon steels almost free from manganese or manganese steels poor in carbon, which was more difficult by the old method because in spiegeleisen or ferro-manganese which were generally used the proportion between the contained manganese and carbon is almost fixed. Another advantage occurs when it is desired to add only very small amounts of a metal such as titanium or vanadium. In the old method the small amounts of added metal might not become thoroughly diffused

throughout the bath, while in this process the chance that they will is much greater since the original bath to which they are added is so much smaller.—(1,156,051, Oct. 12, 1915.)

Lead

Treatment of Carbonaceous Fuel for Metal Reduction Furnaces.—In a process patented by William D. Kilbourn of Tooele, Utah, it is proposed to form a coating on the coke or other combustible material, for the purpose of preventing combustion in the zones of the furnace where it is undesirable. In shaft furnaces, by selecting a coating which melts at the right temperature, combustion of the fuel can obviously be made to take place at any point. In this manner hot-tops, wall accretions in the upper part of the furnace, and consequent heat losses at the top may be prevented. For lead blast-furnace practice it has been found that a good coating may be made from a mixture of lead sulphate, lead oxide and a varying percentage of impurities, the mixture to contain about 60 per cent lead. This makes a good pigment which sticks to the coke and protects it from the fire until it reaches the lower part of the furnace. Thus fuel of a size adapted to be charged into a blast furnace may be treated without briquetting.—(1,148,782, Aug. 3, 1915.)

Conveyor Belt Calculating Chart

At the San Francisco meeting of the American Institute of Mining Engineers, September, 1915, Messrs. J. D. Mooney and D. L. Darnell of the B. F. Goodrich Company, Akron, Ohio, presented the following chart and discussion.

The chart has been drawn for the convenience of engineers as a means of quickly determining the correct number of plies of conveyor belts operating under specific conditions.

The calculations are based on the average safe strength (factor of safety, 15) of the various standard rubber conveyor belts.

The calculations assume maximum loading conditions; that is, the belt is considered as carrying the greatest load that it will handle without spillage at ordinary belt speeds. This not only produces the most economical operating conditions, but also the maximum tension in the belt.

The chart is a graphical representation of the formula:

$$p = kgW(L + 10H)$$

Where p = the correct number of plies.
k = a constant, depending on the type of drive.
g = the weight in pounds per cubic foot of material handled.
W = the width of the belt in inches.
L = the length of the belt in feet (approximately twice the center distance).
H = the difference in elevation between the head and tail pulleys, in feet.

For a simple drive, with a bare pulley,

$$k = \frac{1}{250{,}000}$$

For a simple drive, with a rubber-lagged pulley,

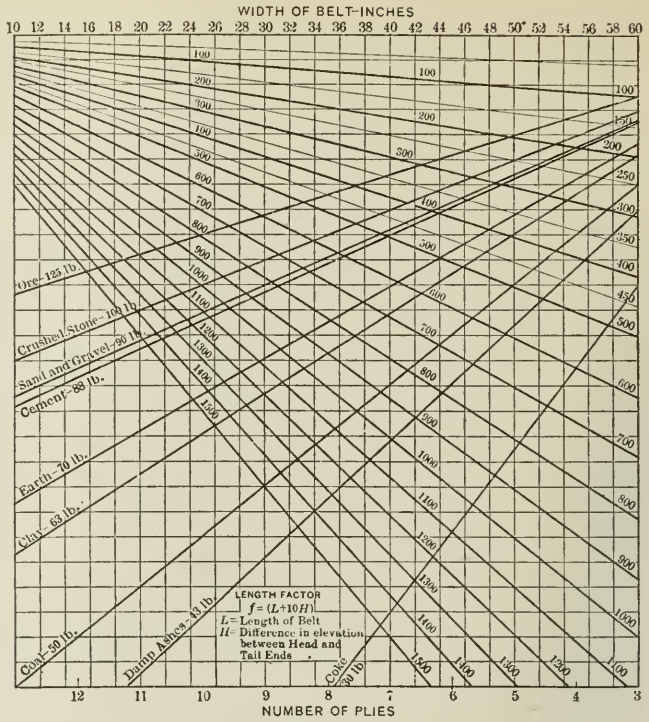
$$k = \frac{1}{300{,}000}$$

For a tandem driver, with bare pulleys,

$$k = \frac{1}{375{,}000}$$

For a tandem drive, with rubber-lagged pulleys,

$$k = \frac{1}{455{,}000}$$



WIDTH OF BELT-INCHES
10 12 14 16 18 20 22 24 26 28 30 32 34 36 38 40 42 44 46 48 50 52 54 56 58 60
Ore-125 lb.
Crushed Stone-100 lb.
Sand and Gravel-90 lb.
Cement-88 lb.
Earth-70 lb.
Clay-63 lb.
Coal-50 lb.
Damp Ashes-43 lb.
Coke-30 lb.
LENGTH FACTOR
f = (L+10H)
L= Length of Belt
H= Difference in elevation between Head and Tail Ends
12 11 10 9 8 7 6 5 4 3
NUMBER OF PLIES

FIG. 1—CONVEYOR BELT CALCULATING CHART

The chart is drawn for a simple drive, with a bare pulley $\left(k = \frac{1}{250{,}000}\right)$; therefore, the number of plies obtained from the chart should be multiplied by the factor 0.83 or 5/6 for simple, lagged drive; the factor 0.67 or 2/3 for tandem, bare, and the factor 0.55 or 11/20, for tandem, lagged.

The formula $p = kgW(L + 10H)$ has been developed mathematically from the following formulas, which have been found to work very satisfactorily in average good practice:

$$U = \frac{0.08W^2Sg}{5000}$$

$$HP = \left(\frac{0.02l}{100} + \frac{0.01H}{10}\right)U$$

$$T = \frac{C \times HP \times 100}{S}$$

$$p = \frac{T}{24W}$$

Where U = Capacity in tons per hour,
W = Width of belt in inches,
S = Belt speed in feet per minute,
g = Weight per cubic foot of material handled,
HP = Horsepower developed in driving conveyor belt,
l = Length of the conveyor, in feet (approximately $\frac{1}{2}L$),
H = The difference in elevation between the head and tail pulleys, in feet,
T = The total tension in the belt, in pounds,
p = Correct number of plies,
C = The constant of the drive.

For a simple drive, bare pulley, $C = 600$
For a simple drive, rubber-lagged pulley, $C = 500$
For a tandem drive, bare pulleys, $C = 400$
For a tandem drive, rubber-lagged pulleys, $C = 330$

The length factor, $f = (L + 10H)$, represented on the chart by the lines 500, 600, 700, etc., is a developed factor equal to the sum of the length of the belt and ten times the difference in elevation between the head and tail pulleys.

To find the correct number of plies for a conveyor belt, knowing the width, the length, the difference in elevation between the head and tail ends, and the kind of material to be handled:

Start from the width given at the top of the chart and move down until this line intersects the line corresponding to the proper length factor; then move either right or left until the line corresponding to the given material is met; then move down again to the scale of plies, where the next largest figure will give the correct number of plies.

For example: To find the correct number of plies for a conveyor belt 36 in. wide and 300 ft. long, with 20 ft. difference in elevation, handling sand and gravel:

Follow the line from the 36-in. width downward until it intersects the 500 length factor line; then follow to the right until the sand and gravel line is intersected; then down to the ply scale, where the ply will be found to be 7.

New Portable Direct-Current and Alternating-Current Electrodynamometer Instruments

Problems hitherto considered impossible of solution have been solved in the design of the new electrodynamometer instruments of the Weston Electrical Instrument Co. of Newark, N. J. They are the latest development of instruments of this type and embody characteristics never before attained. There are four instruments of this type.

The portable electrodynamometer **wattmeter**, model 310, is adapted to measurements of precision on alternating-current or direct-current circuits and is guaranteed to an accuracy of ¼ to 1 per cent of full scale value, either on direct or single-phase alternating-current circuits of any frequency to 133 cycles per second and any wave form. It can be used on circuits of any commercial frequency, even as high as 500 cycles per second, with very slight error due to phase displacement. Double ranges are provided for both current and voltage circuits. All current ranges can be used for 100 per cent overload indefinitely without introducing error.

The movable system has an extremely low moment of inertia and is very effectively damped. Indications are independent of room temperature and of the heating effect of current passing through the windings, and the instruments are shielded from external magnetic influences.

The scales, which are 5¼ in. long, are uniform throughout their entire length, a characteristic of great importance. Each scale is hand-calibrated and is provided with a mirror over which the knife-edge pointer travels, and the pointers are equipped with a simple zero setting device.

Special model 310 wattmeters can be furnished for very low power factors, for instance, for the determination of the core losses in transformers, giving full-scale deflection for 20 per cent power factor; that is, the scale value in watts is 20 per cent of the volt-amperes applied. Temperature errors are very small and can be corrected by reference to the certificate that accompanies all Weston instruments. Scales are uniform and the instruments have otherwise the same general characteristics as the regular model.

While model 310 is a direct-current or single-phase wattmeter, model 329 is a polyphase wattmeter; otherwise the above remarks agree likewise to model 329.

FIG. 1—OUTSIDE VIEW OF ELECTRODYNAMOMETER VOLTMETER

Model 341 is a direct-current or alternating-current portable electrodynamometer **voltmeter** and model 370 is a direct-current or alternating-current portable electrodynamometer **ammeter.** Their accuracy is the same as that of the wattmeter.

The scales of the voltmeter and ammeter are 5¼ in. long. Owing to the principle of operation these instruments cannot be made with scales that are uniform throughout their entire length, but the upper four-fifths portion of the scale is remarkably legible and uniform.

Undoubtedly the perfection of this new kind of instrument marks a distinct advance in the science and practice of electrical measurements.

New Riffling for Concentrating Tables

Progress in the art of concentration or ore-dressing has developed a number of new methods of riffling tables for special purposes. Several new types of riffling for Wilfley tables have been brought out by the Mine & Smelter Supply Company, Denver, Col., one of these; known as the No. 10 deck, being shown in two views in Figs. 1 and 2. The particular deck shown is installed in the metallurgical laboratory of the Colorado School of Mines, where it has been used successfully in making close separations with greater efficiency than could be obtained on the ordinary Wilfley deck.

In the No. 10 type of deck, three riffles extend parallel with, and the full length of, the lower edge of the table. Above these, the riffles which perform the main work of stratification are laid diagonally from the head-motion end toward the feed and wash-water boxes. These riffles terminate in a diagonal line, and every alternate one is extended a few inches at a smaller inclination toward the discharge end of the deck. These extensions also terminate in a diagonal line, except

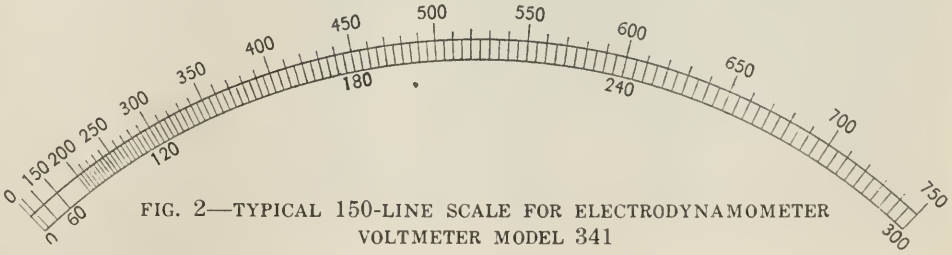


FIG. 2—TYPICAL 150-LINE SCALE FOR ELECTRODYNAMOMETER VOLTMETER MODEL 341

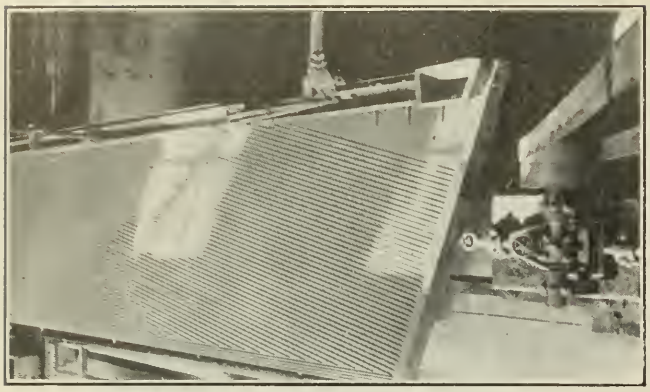

FIG. 1—NEW ARRANGEMENT OF RIFFLES

those near the lower side of the table, which extend to the discharge end. A feature essential to the proper distribution and stratification of the pulp is the three wooden cleats shown near the feed-box.

The improvement shown by the new deck over previous models is primarily an enormous increase in capacity, although greater efficiency has been found in separating minerals of nearly the same specific gravity. Under suitable conditions, where only a one-mineral separation is required, this table will handle up to five times as much unclassified-sand feed as earlier models. A relative increase in tonnage is obtainable with a classified feed for two-mineral separation. This increase in capacity is not gained at the sacrifice of quality in work done. The table is not a "rougher" in the usual sense of that term, for it delivers a finished product, combining the capacity of a roughing table with the efficiency of a finishing table.

A novelty in roughing tables is in use at Silverton, Col., where tables 12 ft. wide and 45 ft. long are handling a tremendous tonnage of old tailings that are being retreated. The feed is classified into coarse and fine grades, and both are fed to the same table—the coarse at the usual feed box and the fine near the discharge end.

Another development in rough concentration is the use of tables for the work formerly done by jigs in coal washing. The deck of a coal-washing table is 7 ft. by 16 ft., riffled horizontally over its entire surface. The capacity is from four to six tons per hour of feed broken to pass a ¼-in. ring. It is claimed that the table does more efficient work than the jig.

For concentration of classified-sand pulp on the ordinary Wilfley deck, some modifications of riffling have been introduced with good effect. With an unclassified feed every third or fourth riffle can be made higher than the others, producing a pond or lake in which stratification and separation can be made more effective. With this type of riffling the vortex usually formed when the pulp flows over each riffle is confined only to the high riffles, while the intervening area is undisturbed by these currents.

FIG. 2—ANOTHER VIEW OF NEW ARRANGEMENT OF RIFFLES

Personal

Mr. Charles W. Baker, formerly New York manager of sales of the Carnegie Steel Company, has been elected a director of the American Zinc, Lead & Smelting Co.

Mr. J. L. W. Birkinbine has been selected as consulting engineer of the Bureau of Mines and will prepare a monograph on the manufacture of iron and steel in this country.

Mr. G. Montague Butler is now Dean of the College of Mines and Engineering of the University of Arizona, Tucson, having resigned his position as professor of geology in the School of Mines, Corvallis, Oregon.

Mr. L. Collins of the Metal Coating Co. of America will lecture on November 18 before the Buffalo branch of the American Society of Mechanical Engineers on their process of coating metals (Schoop process) and on the following two days will demonstrate their process at the plant of the J. P. Devine Co. at Buffalo.

Mr. J. D. Connor, metallurgist of the South Australian Government, has recently arrived in this country to investigate the leaching of copper ores.

Mr. J. V. N. Dorr and **Mr. George E. Collins** will represent the Colorado Scientific Society in Washington on December 16 at a convention to be held under the auspices of the Mining and Metallurgical Society of America for the purpose of presenting to Congress the necessity of changes in the mining laws. Mr. Dorr is at present in Denver but expects to return to New York City about Thanksgiving time.

Dr. Francis C. Frary, formerly assistant professor of chemistry in the University of Minnesota, is now research chemist for the Oldbury Electrochemical Co., Niagara Falls, N. Y.

Mr. Edward Hamilton, formerly assistant superintendent of the Duquesne Works of the Carnegie Steel Co., is now general superintendent, succeeding **Mr. Homer D. Williams,** the recently elected president.

Mr. Henry D. Hibbard of Plainfield, N. J., has gone to Australia on a business trip.

Mr. H. O. Howard of San Francisco is in Nevada making an investigation of the districts around Lovelock.

Mr. Wasata Kondo and **Mr. M. Yamashita** of Japan have recently come to this country to make a study of metallurgical practice.

Mr. James F. McCarthy has been appointed manager of the National Copper Mining Co., Mullan, Idaho.

Mr. Edward McFarlan has been placed in charge of the New York office of the Metals Coating Co. of America, recently opened at 30 Church Street. This company owns the patents for the Schoop spray process.

Mr. F. E. Marcy of the Mine & Smelter Supply Co., Denver, Colo., has resigned to go into business of his own.

Mr. J. J. Rockwell has rejoined the staff of the McGraw Publishing Company, publisher of "Metallurgical and Chemical Engineering," "Electrical World," "Electric Railway Journal," and "Engineering Record," as advertising counselor.

Mr. Richard K. Meade of Baltimore, Md., has been retained by the D. M. Bare Paper Company of Roaring Springs, Pa., to prepare plans and to superintend the construction of a lime recovery plant for converting the lime waste or sludge now discarded into lime of the highest quality. The kiln will be a giant revolv-

ing cylinder 6 ft. in diameter and 100 ft. long, and the lime as it falls red hot from this kiln will be automatically cooled and conveyed to the lime house. Novel features will be introduced in the heating of the kiln and all of the machinery will be motor-driven.

Mr. C. A. Menk of the Homestead Works of the Carnegie Steel Co., was elected second vice-president of the Association of Iron and Steel Electrical Engineers at its recent Detroit convention.

Mr. Thos. M. Skinner, Jr., has completed his work pertaining to the handling of the alkali waters of Owens Lake, Cal., and has returned to Denver, Colo.

Mr. Acheson Smith, general manager of the International Acheson Graphite Company, has been nominated as one of the commissioners for the proposed commission government of Niagara Falls, N. Y. Mr. Smith has the best wishes of his many friends in the electrochemical and electrometallurgical industries of this country for his election on Nov. 2.

Mr. C. W. Whitley of the American Smelting & Refining Co., was elected chairman of the Utah Section of the A. I. M. E. at their first annual meeting on Oct. 4, in Salt Lake City.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath Apparatus

(*Continued*)

151,892, June 9, 1874, Henry Lovejoy, Henry W. Lovejoy and James H. Ferguson of Brooklyn and Michael J. Creegan of New York, N. Y.

Relates to an apparatus for electroplating, consisting of a hanger or hook for suspending articles to be plated, such as molds for electrotypes, etc. The hanger consists of a metallic bar, having a ring at the top for handling, and a hook by which the bar is suspended from the conducting rod. The bottom of the bar is divided so as to form two arms extending laterally a short distance on both sides, and turning toward the front, their ends forming bearers for the mold. Between the arms is secured insulating material, which supports a hook by which the mold is suspended. (This patent was reissued under No. 8726, dated May 27, 1879.)

158,972, Jan. 19, 1875, Henry E. Osborn of Wallingford, Conn.

Relates to racks for electroplating, and consists in a thin, flat bar, suspended horizontally by hooks hanging from a conductor above the bath, the flat bar being slotted longitudinally, the slot being notched on each side by rounded saw-tooth notches, the notches on one side being opposite those on the other. Spoon handlers, and the like, are inserted flat-wire in the slot, and then turned at right angles and placed in the notches, the spoon being thereby suspended and electrically connected for plating. They may be arranged to support a dozen or more spoons at one time.

169,878, Nov. 9, 1875, Stephen W. Wood of Cornwall, N. Y.

Relates to the manufacture of metal tubing by electrodeposition, and the removal of the tubing from the mandrel upon which it was deposited. A metallic mandrel having a polished dense surface is used as the cathode, and metal deposited thereon to a desired thickness. The coated mandrel is then subjected to a rolling, burnishing, or drawing process to loosen the deposit, the patent illustrating a system of rollers which are said to answer the purpose. The rolling action expands the deposited metal which thereby separates from the mandrel. After its removal the tube may be drawn to any suitable size.

192,112, June 19, 1877, William B. Closson of Boston, Mass.

Relates to the production of molds for the duplication of medals, etc., from an original. The medal desired to be reproduced is surrounded with two split frames of thin metal, having smooth surfaces which are pressed tightly together. Holes are previously made in one piece, and corresponding indentations in the other piece of metal registering with the holes. The combined metal sheets and medal are provided with wax masses on each side at one point to form sprue holes or openings for molten metal. The medal and the wax are covered with graphite, and the assembled form electroplated. After a sufficient deposit has been formed, it is removed, the edges around the metal sheets filed off and the two sheets of metal separated, each supporting one-half of the deposit, and the medal removed. The two parts of the mold may be readily assembled, the indentations registering with the holes. The sides may be reinforced by molten lead, plaster of paris, etc.

195,443, Sept. 25, 1877, William B. Closson of Boston, Mass.

Relates to a method of forming electroplated molds for casting articles of statuary, etc. The object to be duplicated is coated with wax, a portion is then uncovered, leaving perpendicular walls on the wax coating. The article and walls of the wax are then coated with graphite, and then electroplated. Then a second portion of the mold is uncovered, leaving perpendicular sides on the wax remaining, and using one wall of the prior deposit as a surface for a new wall. This is then coated with graphite and electroplated. The entire object to be reproduced is treated in this manner, care being taken that the several portions uncovered and on which deposits are made shall form readily removable mold sections. These several sections, when completed, are to be assembled to form a complete mold.

197,408, Nov. 20, 1877, Julius W. Rogers of West Meriden, Conn.

Relates to frames for holding articles to be electroplated. It consists of an expansible grid, adjustable so as to hold articles of different sizes, the grid consisting of a plurality of parallel rods below which are attached flat springs, a spring on one rod pressing against a spring on the next rod. Articles to be plated, such as screws and the like, are pressed between the springs, the head of the screw remaining exposed and may be immersed in the solution without immersing the springs. For large articles the frame is expanded, giving a wider space between the springs.

Reissue 8726, May 27, 1879, Henry Lovejoy, Henry W. Lovejoy and James H. Ferguson of Brooklyn and Michael J. Creegan of New York, N. Y.

This patent contains a more complete description of the hanger described in the original patent (No. 151,892).

218,473, Aug. 12, 1879. Robert Barrie of Chelsea, Mass.

Relates to making duplicates of statuary, etc., and consists in first making a mold, preferably sectional, by coating the object with wax, exposing a portion and leaving deep perpendicular sides on the wax edges, coating the wax and object with graphite, and electroplating, the perpendicular sides of the wax forming flanges for the sections of the mold. After the entire object has been treated in this manner the flanges are drilled for

the reception of bolts to aid in reassembling, and the several sections then removed from the object, and after reassembling, is dusted with graphite inside and electroplated with any metal of which the duplicate is desired. When completed, the mold sections are removed, and the article finished by buffing, etc., or otherwise.

224,478, Feb. 10, 1880, Julius W. Rogers of West Meriden, Conn.

Relates to frames for supporting articles to be electroplated, the frame consisting of a suitable holder such as a drilled metal ring or rectangle of any shape, with arms for suspending the same, the outer surfaces of the ring and arms being covered with a glazing of vitrified material such as glass, etc., which prevents the deposition of metal on the ring.

Book Reviews

The Mineral Industry. Its Statistics, Technology and Trade during 1914. Edited by **G. A. Roush**, M.S. Large octavo, XVIII + 998 pages. Price $10. New York: McGraw-Hill Book Company, Inc.

At the present time each successive volume of this annual has a more difficult task in living up to the reputation and standard of its predecessors. Yet the present editor seems equal to the task, and the present volume is the best which has appeared in recent years. Besides the contributions from the "old standbys," which need no further comment, we must record the addition of many familiar names to the list of contributors. Heading such a list is an introductory article by the director of the U. S. Geological Survey, Mr. George Otis Smith, which discusses the dislocation and readjustment of various mineral industries resulting from the present world war. Dr. David T. Day writes authoritatively on his specialty, petroleum and natural gas; Prof. James F. Kemp on platinum, Dr. F. G. Cottrell and Linn Bradley on the smoke problem, Clifford Richardson on asphalt, Kenneth Seaver on refractory materials, and so the list could be extended, including many prominent specialists in the mining, metallurgical, and chemical fields. It is a symphony of experts whose work it were presumptuous to criticise rashly, yet we must express regret that Professor Richards is unable to furnish anything more reliable than estimates (or perhaps they are "guesstimates") of the annual production of aluminium, and perhaps there are a few other discordant notes in the symphony. But criticism is really captious, since the strong points of the work so utterly outnumber its minor shortcomings. It deserves, as a whole, the heartiest recommendation to all who wish to keep abreast of the latest developments in the mining and metallurgical industries.

Abridged Scientific Publications from the Research Laboratory of the Eastman Kodak Company, 1913-1914. 76 pages, illustrated. Rochester, N. Y.: Eastman Kodak Company.

"Research work in any field is of many different grades, ranging from the investigation of the fundamental problems of a science to the working out of the purely practical problems in production. Research problems show a tendency to fall into three chief classes: (1) Problems of purely scientific interest; (2) problems in applied science, largely the determination of exact data and the working out of methods of testing, (3) engineering problems in the application of scientific data and laws and routine testing. Industrial research laboratories usually cover the first two classes of research in any given field, the third class is taken care of by individual departments of the works.

"The Research Laboratory of the Eastman Kodak Company is organized in accordance with these principles. Some work is being carried on along lines leading to results of no apparent practical importance whatever. On the other hand, practical problems of a very recondite nature are referred to it at times by the manufacturing department. But the great bulk of its work lies in the middle ground of the investigation of the properties of materials, including the determination of precise physical and chemical data, a large proportion of the investigation being initiated by the men within the laboratory.

"There are three chief departments of the laboratory: Chemistry, physics and photography, about equally balanced as regards number of men and space occupied. The chemical department contains subdivisions dealing chiefly with problems in inorganic, organic and colloid chemistry. The work of the physics department is chiefly along the lines of photometry, spectroscopy, lens optics, visual and photographic optics, colorimetry, and allied subjects. Photographic research covers photographic chemistry and the various photographic processes. Many problems are, of course, investigated by two or more departments in co-operation. Technical research, routine tests of product, the investigation of works troubles and the development of new works processes are fully provided for outside the Research Laboratory.

"The Laboratory was organized in 1912, and work was in full swing in the new building early in 1913. The more important scientific results of general interest that have been obtained have been published in various scientific journals. Some of these are not available to many who wish these results and hence an abstract journal is being published which shall contain all of the more important results of each paper. This number contains abstracts of all scientific papers published during 1913 and 1914."

There are twenty-two papers in number, namely: The Absorption of Light in Heterogeneous Media, by P. G. Nutting; The Physical Chemistry of Photographic Development, by C. E. K. Mees; The Sensitometry of Process Plates, by C. E. K. Mees; Calculation of Exposure, by C. E. K. Mees; The Triple Projection Process of Color Photography, by C. E. K. Mees; Brightness and Contrast in Optical Images, by P. G. Nutting; The Correction of Process Lenses for Light in the Extreme Violet, by P. G. Nutting; The Distribution of the Silver Grain in the Developed Image, by Orin Tugman; A New Standard Light Source, by L. A. Jones; Color Analyses of Two Component Mixtures, by L. A. Jones; Photographic Resolving Power, by P. G. Nutting; Light Filters for Use in Photometry, by C. E. K. Mees; The Color of Illuminants, by L. A. Jones; Transmission and Reflection Photometer for Small Areas, by P. G. Nutting and L. A. Jones; Reflecting Power Standards, by P. G. Nutting, L. A. Jones and F. A. Elliott; Axial Chromatic Aberration of the Human Eye, by P. G. Nutting; The Visibility of Radiation, by P. G. Nutting; Mixed Specular and Diffuse Reflection, by P. G. Nutting; The Sensitometry of Photographic Papers, by P. G. Nutting, L. A. Jones and C. E. K. Mees, and The Physics of the Photographic Process, by C. E. K. Mees.

Dr. Mees and his co-workers must be sincerely congratulated on the fine showing of this first volume. The papers were originally published in quite a number of different independent journals and are here collected somewhat abstracted. This is the correct practice if the object of papers is dissemination of knowledge rather than glorification of the laboratory or bureau from which they originated. There are some State and Government bureaus, and even others, that have still to learn this simple obvious truth.

Metallurgical and Chemical Engineering

A Consolidation of
Electrochemical and Metallurgical Industry and Iron and Steel Magazine

Vol. XIII NEW YORK, NOVEMBER 15, 1915 No. 14

Second Exposition of Chemical Industries

Le roi est mort, vive le roi. When the exceedingly successful First National Exposition of Chemical Industries passed into eternity a few weeks ago, quick action in preparing the next one became imperative, and we are glad to announce that at a meeting of the Exposition Management and its Advisory Board, held last week, it was definitely settled that the Second Exposition will be held from Monday to Saturday, September 25 to 30, 1916. The management will start at once in its work. But it seems to us that now is the time also for the different national chemical societies, representing the American chemical profession, to start in some preparatory work of their own. The Second National Exposition will undoubtedly be visited by a great many more chemists and engineers from all over the country than have come together anywhere in the United States for a long time. It would seem the logical thing for the national chemical societies to hold, each of them, a meeting—a regular or a special one—at the time of the Exposition in New York. Such a Chemical Convocation Week would be a delightful affair and would emphasize that with all their characteristic individualities which should be faithfully conserved, the different American chemical societies are a harmonious and enthusiastic unit in their ultimate endeavor.

Unprecedented Times in Steel

For the present situation in the steel industry there are no parallels in history. It is easy to make the comparison to test the accuracy of such a statement, for the steel industry as the principal purveyor of a wrought ferrous material is only about a quarter century old. It is scarcely twenty-five years, in other words, since the number of puddling furnaces in operation began to decrease.

Last November and December witnessed greater stagnation in the steel-making industry than had ever before been witnessed. The production of finished steel in December represented less than 35 per cent of the productive capacity. The production of crude steel slightly exceeded the production of finished material, as a few concerns were stocking ingots or billets. The production of pig iron reached a somewhat lower ebb still, as there was considerable stocking of pig.

Thus the market movement in steel is barely eleven months old, but wonderful things have occurred in that period. Since 1907 there have been two major movements in the steel market, in 1909 and 1912, but the present movement has already overtopped them. In the earlier stages of the present movement steel prices advanced at about the same rate as in those movements, but prices have now been advancing for

a longer period and the advance has become more rapid. Finished steel prices, on an average, are now about $2 a ton above the top reached in 1912, and are level with the top reached in 1909, and the curve of prices, instead of showing signs of soon rounding an apex, is trending still more sharply upward. Next we must consider the 1905-6-7 movement. Its top was $4 to $5 a ton above the present price level, but more than two years were required even to approximate that top. In the next preceding price movement, 1901-2, the advances were far from spectacular. In 1899 there occurred a "runaway market" but the spectacular feature was simply the fancy prices that were paid for relatively small quantities of steel for prompt shipment.

An outstanding feature of the present steel market is that as the weeks pass the steel mills are more and more reserved in the matter of booking contracts for forward delivery. Their transactions are being confined more and more to the making of specific sales, the buyer furnishing specifications and all details as to making shipment, which is to occur practically at mill convenience. This change in sales policy paves the way for rapid price advances.

Views as to the fundamental causes of the heavy pressure upon the steel mills have been changing rapidly in the past two or three weeks. When steel demand began to increase, in last December and the first two or three months of the present year, the common thought was that a reaction had naturally occurred, from an unprecedentedly stagnant condition, and there was doubt as to whether the improvement would last long. Later, in the summer, the demand for steel was regarded as very largely a "war demand." The development of the very recent past is that there is a very strong demand from strictly domestic sources for peace purposes, and the steel industry now staggers under its load, for the demand for war purposes is increasing rather than decreasing.

We shall now see tried out on a large scale the experience of a positive demand for steel with no restraint as to prices. For many years the policy of the steel trade had been to view the steel market as something that should be held steady, extreme advances or declines being regarded as highly objectionable. Price advances were likely to curtail consumption and price declines likely to disturb confidence, both therefore inviting disaster. From another viewpoint it might be argued that if the demand for steel is real, the need of each particular consumer should be weighed against the general demand; if it was less in intensity, that buyer should wait until he could buy at a lower figure, and thus there might be great fluctuations in prices, but little fluctuation in production. Such a theory has not found much support in steel selling circles, but a runaway market has been forced upon the industry and through no choice of anyone the experiment is going to be tried. As prices are now advancing, levels will be reached at which some consumers will certainly find it necessary to defer their purchases. Eventually they will have an opportunity to buy at lower prices, and if they take advantage of the opportunity the production of steel will be kept at a steadier rate than has been the case in the past. It may require years for the full period of the experiment but its progress will certainly be watched with intense interest.

A Little Confusion of Thought and Speech

In the profession of mining engineering there are such phrases as "ore in sight," "ore blocked out," "positive ore," "probable ore," "possible ore," to denote the differences between the expected and the actual and to help one to estimate in the mind the degree of certainty of evidence or of proof. The old adage, "There is nothing certain except death and taxes," leads us to believe that there is nothing given man between a reasonable expectation and futuristic determinism. In the chemical and metallurgical professions, where we all know the rapid change that is taking place, there is a similar difference between things as we hope they will be, things as we try to make them, and things as they actually turn out.

Possibly the forceful character of the American nation cannot often discriminate between things as people desire them in the future and things as they really prove to be. If a man repeatedly says, "I will get there" and "This shall happen," he in time may instill into his mind a certain self-confidence now so aptly termed "auto-suggestion." Possibly, indeed very likely, the widespread national looseness about the use of "will" and "shall" is derived from our somewhat egotistical state of mind. In the first person, "will" means "wish" or "desire," "shall" simple futurity, whereas in the second and third person the meanings are reversed and "shall" denotes desire or determination, while "will" means simple futurity. In colloquial speech, not one person in a hundred makes any distinction in the use of "will" and "shall," and the reason is probably that there is no difference noticed in the mind.

Indeed, it is not hard to detect in this fault of speech the fault of looseness of thought and immoderate egotism. Between the intense desire to have the future happen as one wills it and active efforts to make it, there is in one aspect—that of the personal equation—no difference. Fortunately, in the spoken word, the inflection of the voice tells much of the meaning of the speaker. In the written form a certain purity and precision of diction should tell one to be careful, for "nobody shall help me from mistakes of the pen, and I will drown in literary fashion," to paraphrase the classical example of the rhetorician, and in a scientific profession like that of the chemical and metallurgical engineer his language should be as precise as his thoughts.

Saving Trouble in Handling Units

In view of the universal present endeavor to do everything in the shortest possible time and to effect a standardization wherever possible, the psychological moment seems to have come to adopt single systems of units which will be used by everyone. Every engineer knows the extra work which he has had to perform in trans-

ferring from one to another system then back to the first system, and so on, thus increasing the probability of error every time a transfer is made. A good forward step in the right direction in regard to metallurgical practice has been taken by the Mining and Metallurgical Society of America, a preliminary report of whose committee will be found on page 828 of this issue. While everyone may not agree with all of the recommendations made, yet everyone will admit that the single system is the only system for rapid and efficient work and accurate intercourse.

The recommendations to use the metric system of weights and state the gold and silver contents of ores in decimal fractions, or in percentages and decimal fractions, wherever the metric system has been adopted as legal and in all Spanish-American countries, and the recommendation to use degrees Centigrade in a like manner are timely, as everyone who has used these systems knows their immense superiority. The ton, which in this country is so elastic, is recommended to be placed at 2000 lb. The bullion and assay value units should prove a great boon if commonly used. Several units which are in very common use, and have been so for a long time, could be changed in general practice only with greatest difficulty, and this is a great pity. It is to be deplored that the gallon is in such common use that it had to be recommended as a standard, also the "fluid ton," in the case of cyanide solutions, which is stated to closely approximate 2000 lb., instead of exactly equalling 2000 lb.

The recommendations are not intended radically to convert long-used units into units which have not been in general use in metallurgy, since, as before stated, it almost seems practically impossible to change current practice. The idea is to have one system, to adhere to that system, and to endeavor to bring it into general use. There are, however, so many different systems represented in the different units that it is hard to see how many laborious calculations can be avoided in the use of the present recommendations. They are, no doubt, the best for the present, but it is to be hoped that in the course of time we may talk only of liters, kilograms and other metric units.

While You Learn from Mistakes, Make Your Mistakes on a Small Scale

It is an easy and fascinating task to talk about the glories of a research or an invention—how the inventor sees a vision, goes into a trance, and does some quick, hard thinking, and lo and behold, he makes a model and a million dollars. Good brilliant ideas are easy and delightful, but the practicalization of these ideas is, as Rudyard Kipling says, "another story." Actually the popular imagination is far wrong; it sees only the glitter and glamor, not the tedious hard experimenting, not the financial troubles, not the difficulties that beset the path of the research pioneer.

What, indeed, is the keynote of success of a successful invention? And where shall we find the wisdom of the successful one and the understanding that, actuated by a will of iron, persists till the goal of commercial operation is reached? How does the idea become crystallized? There are many answers to this, all correlated and interdependent.

Possibly Edison's classic and laconic answer, "Genius is 2 per cent inspiration and 98 per cent perspiration," is as good a one as can be devised. What we would propose in the psychological atmosphere of the present days is somewhat different, and reads like this: "Make your mistakes on a small scale!"

This is good advice from a business standpoint, for all successful processes are founded on mistakes, and it is necessary to know by actual test where the pitfalls are in order to avoid them. If we assume the wisdom and truth of the slogan "make your mistakes on a small scale," we can adduce as a consequence this: act on your mistakes by the use of your imagination. The human mind is supposed to have several parts, or better expressed, different powers, by which it acts, but for progress or for full delight of life nothing is more a requisite than imagination, tempered by reason and controlled by common sense, for it is that mental ability that enables the possessor to project thoughts like a cinematograph on the screen of the soul. Without this ability to project, to extrapolate a curve far beyond the known, to take the known facts and find out and prove the existence of new facts, no inventor would succeed. And so in scientific transcendentalism do we find the peculiar mental trait that utilizes the past mistakes as stepping-stones to victory.

Now all this operation must be done commercially, for if the invention costs as much to produce as it is worth to society, there should and cannot be on the average any profit in the venture. So the truth of the remark: "Make your mistakes on a small scale."

While a strong motive in building on mistakes may be the personal gain of the interested parties, yet the secondary and often primary motive, if we are to judge by the effects, is the good that society will gain. This must be where the will to believe and the will to conquer has its source.

The personal equation naturally is the driving force. The ability to fight, to sacrifice himself and may be his family, to work with a smile at a thankless task—these are the victories of peace and "the moral equivalent of war." With the imagination apperceiving, there is associated a feeling or intuition, a full development of the feminine kind of thought that tells the inventor how to meet emergencies and how to foresee the future. A successful inventor tells us that at most critical times he acted against the advice of his friends and against his own logical judgment and was right. For in truth can it profit a man to make mistakes on a small scale or on a large scale and not learn from them?

It is in the commercial consideration of the subject that the element of cost must be held in mind. Large mistakes are expensive, small ones are cheap, but the inventor must learn. And he only learns and advances by use of a "will-pervaded" imagination that sees the unknown and attains the impossible. With all this idealistic side, the homely sentence, "make your mistakes on a small scale," blends in harmonious thought.

Chemical Engineering as an Independent University Course at Purdue

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I note with interest the editorial comment in your issue of Sept. 1, relative to chemical engineering.

Supplementing the information contained therein, it may not be amiss to state that at this institution, Purdue University, the School of Chemical Engineering has since 1911 existed as a separate school on an equal basis with the other engineering schools of the university, and now numbers sixty-one graduates.

The course is attracting a superior class of men, and in spite of a very strict interpretation of entrance requirements, the present enrollment is 168.

The curriculum of the School of Chemical Engineering may be found on page 84 of the catalog of the university. It may be said in regard to the work of the junior and senior years that these are now in a period of transition which will result in physical chemistry being administered as a required subject, beginning with next year.

H. C. Peffer.

School of Chemical Engineering,
Purdue University, Lafayette, Indiana.

Tube-Milling: Closed Circuit

To the Editor of Metallurgical & Chemical Engineering:

Sir:—The discussion on tube-milling in your February number is interesting. Closed circuit would seem to be with us to stay, at least for quite a while; so were fine feeds and high discharges, but after a while they went their way.

There is no doubt that the economical result obtained should guide, and as shown in the discussion of the article by Mr. Haynes and his table of results, a cumulative load of 570 tons will give a net grinding to minus 200 of 58.59 tons. And the relative time that each ore particle is in the tube-mill may be fourteen minutes, that is, for each round; but does it not circulate six or seven times and in the end be eighty-four to 100 minutes in the tube-mill anyway? Is there any advantage in circulating pulp so much if the same result can be had without so doing? It costs something to return pulp to the tube-mill, even when using drag classifiers. Is there not something radically wrong with any system of crushing when it is necessary to return the pulp so many times in order to reach a desired result?

As there can be no argument over the crushing machine used; i.e., that the tube-mill, with its load of pebbles, furnishes all the elements necessary to successfully break or grind sand of six or finer mesh down to minus 200, we must look into the condition of the feed in order to find some condition that can be changed so that better results may be had.

In the earlier years of tube-mill experience it was generally thought that the feed—the battery discharge—had to be relatively fine in order that the tube-mill might be able to do its work. Thirty-mesh screen on the batteries was quite common. Nowadays most mills use coarse screen, six, eight, ten or twelve-mesh on the batteries. This change in general custom may be considered proof that tube-mills can successfully grind more net tons of coarse feed than they can of fine feed. It is in order then to find the reason why this should be so.

May it be that between two pebbles equal volumes of coarse pulp and of fine pulp will be caught, and in each case the total volume be reduced to ultimate size; and that the volume of coarse pulp weighing more than the same volume of fine pulp, there is a greater resulting tonnage ground in the case of the coarse pulp? I believe that this is what takes place, and while total volumes are not really ground at once to ultimate size yet equal proportions of such volumes will be ground, so the same relative result is obtained; more coarse pulp is reduced in the operation than would have been the case had the pulp been fine. This, of course, implies coarse feed, reasonable in size, such as the six-mesh and nearby sizes, when compared with the sizing of the pulp returned from the mill when fed with overload.

I cannot agree with any theory that a six-mesh particle of ore must go through a tube-mill five to seven times, being somewhat reduced on each passage, until it will finally emerge a 200-mesh particle. I think that if it once lodges between two pebbles in action it will at once be ground or broken so that the larger portion of it will be ground to minus 200, and the remainder will be approaching that size and must again be caught between other pebbles in order to be finished to 200-mesh. Poor grinding occurs because ore particles go through the mill without being caught between grinding surfaces and not because the force applied is insufficient to reduce the particles at one operation; there is an excess of force applied, but much of it is not utilized, as only those particles of ore actually between the rubbing surfaces are fully ground, and those particles that lodge just outside the points of contact get only partial grinding.

With pulps of mixed sizes of ore particles, the coarse sand will come into play or be exposed to grinding conditions before the accompanying fine sands. The coarse sand parts with its water more readily and clings better to the pebbles; its comparative diameter also is greater and there is less chance of its passing between the pebbles; a fine particle might escape entirely where a large one would be caught, and being caught it is at once reduced greatly to a finer mesh. In the succeeding part of the mill all ore particles are approximately of the same size, most of the fine feed going through without any grinding, and to that is added the fine stuff left from breaking down the coarse part of the feed, so we go on accumulating return load until the gross load fed to the mill is something out of all reason.

When we reduce an ore sample in a mortar with a pestle we reach a point in the operation where we can no longer apply force of impact and get any results: we must resort to force of abrasion. When we put the pulverized sample on the bucking board we do not strike the pulp with the muller, we rub it or rather grind it by abrasion. It is universal custom to reduce sands and ore pulps for assay purposes to sixty, eighty or 100-mesh by abrasion, yet in tube-milling many seem to think that to reduce such pulps to 200-mesh force by impact should be applied. And so they contend that the mill revolutions should be such that the pebbles fall clear of the upcoming load. With the body of the mill half full of fluid pulp there cannot be much force by impact expended when the falling pebbles reach bottom after passing through the thick pulp floating in the mill. With pulps as dilute as 38 to 40 per cent moisture most of the fine parts of the ore will be in suspension, due to the violent agitation, and the coarse sands will have settled to the bottom where they are ground by abrasion, not impact.

Grinding pans are in many places considered superior

to tube-mills for producing minus 200-mesh pulp; they crush by abrasive force, not by impact. If we wish to obtain abrasive grinding in tube-mills the revolutions must be so adjusted that the pebbles just begin to cascade, but the main body slides back over itself without falling clear.

Battery sand is of relatively small size when compared with the irregularities or projections on the surfaces of tube-mill pebbles. Sand caught between two pebbles struck together is more likely to escape crushing than to receive it; if the same two pebbles were rubbed together the sand would more likely be crushed than to escape, as the inequalities on the two pebble surfaces would more likely fit into one another than to rest on the points while in motion.

As to sufficiency of force applied, I think that the weight of the load of pebbles, coupled with the dragging exerted by the liners causing the pebbles to push one against another, is ample to crush ordinary six-mesh and finer sizes. If crushing of ¼-in. and larger sizes be attempted force by impact may be necessary.

In order to secure the fullest results in grinding, the character of the pulp should be such that no segregation of parts can occur; coarse sands, fine sands and the water should remain evenly mixed, then all sizes get an equal chance of entering the grinding zones. With dilute pulps the coarse sands separate and settle to the bottom, where they come into close contact with the pebbles. The fine sands tend to be held in suspension, float up in the main body of the mill, and get only casual contact with the pebbles. With pulps of around 30 per cent moisture no segregation of parts takes place—the whole pulp clings to the surface of the pebbles, is carried along with them throughout their travel, and gets every opportunity for being caught in the grinding zones. There will be less floating load in the body of the mill as most of the pulp will be traveling with the pebbles. It will probably cause an unbalanced load and require more power to turn the mill, but there will be no cushioning of the grinding forces if "cascading" be practiced—every pebble works every moment. I think that with cascading of the pebbles 90 per cent of the grinding done is accomplished by abrasive force exerted between the pebbles in the bottom of mill and on the uphill movement. With 38 per cent moisture no clinging of the pulp to the pebbles can occur; sands settle out quickly and are ground while in the bottom of the mill, the fine product then rising to float in suspension with the main body of the pulp.

Scoop-feeding solved all the troubles incidental to charging thick pulps into tube-mills; low discharges solve those incidental to passing thick pulps through tube-mills. Thirty per cent moisture pulps will not flow freely in launders, but screw conveyors will pass them. Thirty per cent pulp comes out of the tube-mill as a thick ooze, lining the chamber 2 in. thick, but this can be diluted by a hose playing on the outside of the cylindrical screen. We found that 25 per cent moisture pulp would work through a mill having 18-in. discharge end, but could not maintain an even flow with as much tonnage as the mill would fully grind; we could maintain the flow for hours at a time, long enough to determine to our satisfaction that such low moisture would be desirable if we could overcome the mechanical difficulties of handling it. We thought that with lower discharge we could have obtained the tonnage desired, and with open circuit. With 30 per cent moisture we could maintain an even flow of pulp, but the tonnage desired could not be reached, though we did obtain better than 80 per cent through 200 mesh.

According to the experiments of W. B. Easton, with a mill equipped with lifter devices he obtained 70 per cent through 200 when passing 144 tons through it with open circuit, and with 240 tons gross, closed circuit, he obtained 72 per cent through 200 mesh. These are figures that I believe have never been equalled in tube-mill practice. I would take it that the moisture contents were 38 per cent and 40 per cent, and would like to have seen his results when passing pulp of low moisture. His experiments would indicate that, with low discharge, sufficient feed of any moisture can be passed through a mill in quantity to overload, and that consequently the closed circuit cannot be dispensed with entirely; but when net grinding to minus 200 reaches such figures as 70-odd per cent it would seem that it would be better to work one or perhaps two tube-mills, following in series to take the concentrated return from all the primary mills.

The figures given by Mr. Easton concerning minus 200-mesh product are all in conjunction with 38 per cent. and 40 per cent moisture pulps; we would like to have had some of his figures or results of passing low-moisture pulps. His comments on low moistures would infer that he favored them for their grinding effects; he declares himself in favor of them as regards their requiring lower power consumption, and he also states that fuller loads develop lower power consumption. I am inclined to think that the effect of the lifters will be to extract the top of the floating load in the mill first, and thereby lower the moisture content of the charge of pulp in the mill at a given moment. I consider the lifter device the greatest improvement in tube-mill design that we have seen in a long time.

Guadalajara, Mexico. W. J. PENTLAND.

The Naval Consulting Board

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I have read with interest the current literature and news in regard to the Naval Consulting Board and it has occurred to me that the question might well be raised in connection with this whole matter as to why the Consulting Board should devote its attention only to naval matters, as apparently intended, rather than to both Navy and Army needs. The step taken is in the right direction and will undoubtedly produce splendid results, will promote patriotism and promote in general a personal interest in the affairs of our country such as has been lacking to a large extent in the recent past. In general it seems that our government has been left too much to the politicians.

Without doubt the wonderful success of the Germans at the present time is due to the fact that they make the most of the technical skill and scientific brains available in the German Empire. In our own country Army and Navy matters have been left largely to inexperienced men and those who may be in more or less of a rut in the government service. The best men of the country have been employed in industrial pursuits almost entirely and have not apparently devoted much attention to our national protection, and national protection should came first in as much as our industrial success is dependent upon this.

Why should not the Consulting Board's Navy Research Laboratory be a joint Navy and Army undertaking? It would seem that there could be only one answer to such a question. L. F. VOGT.

Standard Chemical Co.,
Canonsburg, Pa.

Mineral production in California in 1914.—The complete detailed report of the mineral yield of California for 1914 compiled under the direction of Fletcher Hamilton, State mineralogist, is now ready for distribution in the form of Bulletin 70 of the State Mining Bureau.

Benzol and Toluol from California Oils

The Standard Oil Company of California is producing now on a small commercial scale the much cherished benzol and toluol.

Strictest secrecy is maintained as to methods applied in producing from the California crude oil, which has an asphaltum base, these materials so much needed in the dye industry, as well as in the explosive manufacture.

Apparently there is a very handsome profit in the manufacture, and there is some talk of the oil company eventually entering into the dye industry.

Another new product the Standard Oil Company of California has to its credit is a product sold under the trade name of "*calol*," a perfectly water-white, tasteless and stable oil used for medicinal purposes.

The famous British surgeon, Sir Arbethnot Lane, who discovered "kinks" in the intestines of human beings, found that in milder cases it was not necessary to operate, but that the "kinks" could be overcome if a suitable internal lubricant could be supplied. "Russian oil" was the remedy, but since the war this supply has been cut off, and many inferior substitutes have been placed on the market. After lengthy experiments an oil has been produced by this company which is equally good and has even been pronounced better than the Russian product.

The demand for the product is great, and while the large plant is being built a small temporary plant is operating to its capacity, not beginning to be able to fill orders.

The world's demand of this internal lubricant is being supplied at present from California and from California crude oil.

Nitrogen Fixation in Russia

It is reported in Scandinavian papers that a large company with strong capital backing has been formed in Russia for the purpose of manufacturing nitrates from the nitrogen of the air.

The process to be used is the well-known Birkeland and Eyde process.

All arrangements with the Norwegian company, owners of the Birkeland and Eyde patents, have been made and a plant is being built in the North of European Russia, off the White Sea.

It is interesting to note Russia's entering the electrochemical field in this manner, and also that through dire necessity of war an industry is started that in time of peace produces products that are a blessing to the inhabitants of its country, and in war times produces the same products, but they are then no blessing, but rather a curse to the inhabitants of adjoining countries, "Les extreme ce touche."

The Willard Gibbs Professorship of Research in Pure Chemistry

In course of the academic year 1914-1915, a new department was established on a permanent basis in the Mellon Institute of Industrial Research of the University of Pittsburgh, namely, a Department of Research in Pure Chemistry. The headship of this department is to be known as the Willard Gibbs Professorship of Research in Pure Chemistry, "to ever proclaim the ideal which the incumbents of the chair and the groups of research workers to be associated with them will be expected to follow." It constitutes a chair in the Graduate School of the University of Pittsburgh as well as in the Mellon Institute.

Dr. Martin A. Rosanoff, who had built up and for years headed the Graduate Department of Chemistry in Clark University, was formally inaugurated as the first permanent incumbent of this professorship, at exercises held in the Assembly Hall of the Mellon Institute on Oct. 26. The exercises included addresses by Prof. James McKeen Cattell and Prof. Marston Taylor Bogert, both of Columbia University, and by Dr. Rosanoff, followed by a reception and an inspection of the Mellon Institute.

Chancellor Samuel Black McCormick presided at the exercises. He explained the circumstances connected with the establishment of the chair and thanked the donors whose generosity had made possible the endowment, of which the income is to constitute the salary of the incumbent of the chair. He then introduced Dr. Cattell.

Standardization of Metallurgical Units

A preliminary report of the Committee on Standardization of the Mining and Metallurgical Society of America contains suggestions pertaining both to mining and metallurgical matters. We give below those recommendations relating particularly to metallurgy.

Mesh of Wire Cloth.—The standard mesh of the Mining and Metallurgical Society of America shall be the standard screen of the W. S. Tyler Company of Cleveland, Ohio, as described in that company's catalog No. 36. The basic screen of this scale has an opening of 0.0029 in., which is assumed to be equal to 200 mesh. The opening in each successive screen increases in the ratio of the square root of 2, or 1.414.

This furnishes a standard screen scale in which the area of each successive opening in the scale is doubled that of the second preceding.

The dimensions of the Tyler screens are as follows:

Openings		
Millimeters	Inch	Mesh
26.67	1.050	
18.85	0.742	
13.33	.525	
9.423	.371	
6.680	.263	3
4.699	.185	4
3.327	.131	6
2.362	.093	8
1.651	.065	10
1.168	.046	14
0.833	.0328	20
.589	.0232	28
.417	.0164	35
.295	.0116	48
.208	.0082	65
.147	.0058	100
.104	.0041	150
.074	.0029	200

Weights and Measures.—1. For all Spanish-American countries, and all other countries where the metric system of weights is the legal one, a statement concerning measures and weights of whatsoever kind shall be in the metric system.

All references to temperature shall be in degrees Centigrade.

In Spanish-American countries and in all other countries which have adopted as their legal standard of weight and measures the metric system, the gold and silver contents of ores, alloys, bullion or other materials, must be stated in decimal fractions of the weight of the material, or in percentages and decimal fractions thereof or else in kilos of silver and grammes of gold per metric ton of material.

2. The word "ton" shall represent a weight of 2000 lb. avoirdupois (29,166.6 oz. troy).

It is advisable to abandon the use of such terms as "hundredweights" and "quarters," and to express fractions of a ton in pounds or decimals of a ton.

3. The term "miner's inch" shall represent a flow of 1.5 cu. ft. of water per minute. Where this unit is not customary and currently acknowledged, the flow of water shall be expressed in cubic feet per minute or per second.

4. In the United States the unit of liquid measure is the standard gallon of 231 cu. in. In England, and the British colonies which have legalized the unit, the "Imperial gallon" measure of 10 lb. of water is to be used.

In every case all reports should state definitely which gallon is used therein.

5. Temperature should be expressed in degrees Centigrade. Subsidiary use of the Fahrenheit scale is admissible; but only conjointly with the Centigrade scale and not alone.

6. Returns of gold and silver shall be expressed in terms of fine gold and silver respectively, not as "bullion."

7. Gold and silver contents of ores determined by assay may be expressed in money values per ton of 2000 lb. avoirdupois, as well as in weight per ton. In this connection the value of gold shall be taken at 85s., sterling, or $20.67 U. S. currency, per troy ounce of fine gold.

All other constituents of alloys, metallurgical products, or other material must be given in percentages of the substances analyzed.

It is to be noted that certain commodities, such as pig iron, steel rails or large sections, etc., are dealt in in various arbitrary units. Where it is a recognized custom of the trade to use such special unit, statements therein are permissible, but provided, however, that it is always clearly stated what the unit be in some other and standard unit.

Bullion and Assay Values.—The following is proposed concerning these terms:

1. All samples should be dried at 100 deg. C. before being submitted to assay or analysis and reports should definitely state that this precaution has been taken.

2. Assay values of gold and silver ore and products should be represented in ounces and decimals and not in ounces, pennyweights and grains. They shall always be expressed in terms of fine gold and silver respectively and not as "bullion."

3. Assay values of alluvials shall be reported in grains and decimals of a grain of fine gold, or in pence (at 2d. per grain of fine gold), or in cents per cubic yard.

It is recommended that, in the absence of specific information as to boulders, etc., 1 cu. yd. of ordinary alluvial be taken as equivalent to 3000 lb. (1.5 short tons).

4. In reporting assay values of cyanide and other solutions, the results shall be given in parts by weight in a stated volume of the solution.

In the case of cyanide solutions, the use of the "fluid ton of 32 cu. ft." is recommended. It closely approximates to 2000 lb. and is in common use.

5. When it is necessary to state or estimate the money value of an ore, etc. (other than gold), the contents shall be given in percentages of the base metals, and in ounces of gold and ounces of silver.

If it becomes necessary to estimate the value of the ore in money the first step would be a deduction from these percentages to allow for metallurgical losses and the next following step the calculation of the value of the recoverable metals at definite fixed prices. If the net value of the ore is required then from the above should be deducted the working and realization costs.

6. We recommend for all laboratory sieving the Tyler standard screens.

The Aniline Dye Situation

In the account of Mr. I. F. Stone's paper before the New York Section of the American Chemical Society in our issue of Oct. 15 (page 710), the statement on the increase of aniline dyes manufactured in this country was incorrectly reported. We quote the section in question verbatim from Mr. Stone's complete paper:

"Another large increase in production through the present conditions is the manufacture of aniline colors and other coal-tar products in this country, which will be much to the relief of consumers, who at the present time are unable to get anything like the supply of colors which they need in the conduct of their business. The five factories already established in this country before the war are all extending their production to their utmost capacity in keeping with safety for their investment, and I believe that in 1916 the production of aniline colors in this country will be at least three to four times the production before the war.

"This production could again be largely increased if the manufacturers were sure of some protection from the Government in the way of higher tariff or Government manufacture of intermediate materials, which would enable them to get the same at the same price as paid by European manufacturers, and then again, the putting into effect of some anti-dumping clause, which is now promised by the Government, to prevent the dumping into this country of colors at lower prices than they are sold elsewhere for the purpose of preventing their development and manufacture here.

"Whatever the Government may finally decide to do toward the protection of this industry, there remains the fact that a great impetus in the development is already under way, with the hope of Government protection, so that the Europeans will find them strongly entrenched in any event after the close of the war. I am speaking now of the factories already in operation, but in addition to these there are many new factories projected and some in operation. I have a list of twenty-three new factories, the last of them with a proposed capital of $15,000,000, and while a good many of these may not materialize, something will surely come of some of them.

"Up to now none have actually manufactured any aniline colors, but some are operating with a production of some intermediate products like aniline oil, beta-naphthol, paranitranilin, etc., and speaking of aniline oil, with the one factory established before the war and the increase in its works since the war, and the number of new factories making or about to make aniline oil, it looks as if the production of this product would be 8000 to 10,000 tons, as against the normal consumption of about 4000 tons; in other words, the proposed manufacture seems larger than the consumption, but as the consumption is also increased possibly the whole amount projected can be used. At any rate, there will be enough manufactured in this country to take care of the whole consumption, so that Europe need not be depended upon."

* * *

With respect to the report of Dr. THOMAS H. NORTON'S paper before the New York Section of the Society of Chemical Industry (page 780 of our issue of Nov. 1) it should be stated that Dr. Norton made no direct recommendation of a Government factory for the production of coal-tar intermediates. What he did say in reference to Mr. Stone's plan in this respect was as follows: "The various admirable features of the plan, including the well-organized preparedness for the speedy manufacture of explosives and munitions generally, in case the nation be menaced by invasion, render the project worthy of the most careful study."

As to the proposed league of American consumers of dyestuffs, Dr. Norton did not recommend that all consumers who would purchase imported dyes at dumping prices should be penalized or ruled out altogether. He said: "It can also be easily seen that a powerful weapon is put into the hands of those who collectively represent the consumers of colors, to rigidly rule out from the

sources of supply any manufacturer, foreign or domestic, who would deliberately make an attempt to undersell his American rivals, or who would resort to any method of unfair restriction of trade."

American Iron and Steel Institute Meeting at Cleveland

The ninth general meeting of the American Iron and Steel Institute held in Cleveland, Oct. 22 and 23, was a success in every particular. The meeting was a record breaker in attendance, about 680 having registered during the two days. The reduced number of papers was a pleasing feature and helped to sustain the interest and discussion. On Friday evening a banquet was held at the Hotel Statler, at which moving pictures were shown of manufacturing processes at the plants of the National Tube Company and the American Steel and Wire Company. After this feature, Judge Gary called on a number of prominent members for short addresses. Saturday morning several hundred of the members enjoyed a visit to the plant of the White Company, and a special train was provided to take the members to the Pennsylvania ore dock, where the unloading of the "J. P. Morgan" of the Pittsburgh Steamship Company, was witnessed.

The first session was opened Friday morning with an address by Judge Elbert H. Gary, in which he laid special emphasis on publicity, on the harm done to large corporations through their failure to take the public into their confidence. "The general public and private individuals have been in the past too far apart for the good of both. Lack of knowledge often breeds unnecessary and hurtful antagonisms, and many have suffered even though they were not personally at fault." . . . "There should be published whatever of business matters the public is legally entitled to know and also whatever may affect the public interest and may be exposed without detriment to the corporation or individual concerned." Judge Gary said we should have protection against the results of cheap labor and impoverished conditions abroad, in order to enjoy continued prosperity after the war.

Mr. Samuel Mather, chairman of the local committee, was the first speaker called on by Judge Gary. Mr. Mather spoke of the history of Cleveland and the development of the steel industry. Cleveland ranks fifth among the cities of the country in the value of manufactured products. It was owing to the discovery of copper and iron ore in the upper peninsula of Michigan in 1844 and the opening of the Sault Ste. Marie canal in 1855 that the great growth of Cleveland ensued, for this city then became the natural meeting place of the bituminous coal from the coal fields of southern Ohio, Pennsylvania and West Virginia, and the iron ore from the Lake Superior district. At Cleveland there are ten blast furnaces with an average output of 120,000 tons monthly, and an exceedingly great variety of manufactured products.

In a paper on, "Modern Methods of Burning Blast Furnace Gas in Stoves and Boilers," Mr. Ambrose N. Diehl gave the results of exhaustive investigations made of stove and boiler operation. The lack of accurate data among those using blast furnace gas made the problem more difficult. In considering the efficiency of a burner it is necessary to distinguish between the performance of the burner alone and that of the unit consisting of the burner and stove. A standard of efficiency which could serve as a basis of comparison was defined as follows: "A gas burner is operated at 100 per cent combustion efficiency when the analysis of a sample drawn from a point 2 ft. beyond the point of ignition, shows perfect combustion." Mr. Diehl's paper was exceptionally complete and the data presented are of considerable value, since the proper utilization of blast-furnace gas with relation to burner construction is an important subject which is receiving more attention. Mr. Diehl's paper was presented in abstract. Burners were classified into six types and their application to hot-blast stoves was first considered and a record of a number of tests was given in detail, with a similar treatment of gas burners for boilers. Most of the tests failed to show data in which the burner was isolated from the boiler or stove so that the data could only serve as a basis for study or adaptation to local conditions.

In the discussion of this paper Mr. H. P. Howland concluded that "for use on stoves we believe the pressure burner to be preferable. Regarding boiler burners, first, the point of automatic regulation as emphasized by Mr. Diehl, does not seem to us to be vitally essential; second, it should be admitted by all that a big step in advance has been taken in equipping a boiler house with burners capable of easy hand regulation in the place of the so-called common burner."

Mr. A. E. Maccoun agreed with Mr. Diehl that there was no type that has so far been developed which might safely be called the most efficient burner, but that only testing out would decide the best type to use.

In a paper on "The Development of Commercial Alloy Steels," Mr. Edgar D. Rogers: reviewed the history of alloy steels and showed how they came into commercial use. He said that Hadfield justly designates the year 1888 as the beginning of a thorough knowledge of alloy steels, when the use of silicon and manganese for the improvement of the physical and magnetic qualities was made practical. The chromium steel industry was founded in America by Julius Baur, and its use has become very extensive. Nickel steel was given an impetus in 1889 by Mr. Riley's paper before the British Iron and Steel Institute, and its use is established and increasing especially in automobile construction. Vanadium for steel was made commercially available when a vast deposit was unearthed in South America in 1905, and its properties are well known, in high-speed and anti-fatigue metal.

As to specifications Mr. Rogers said it had been his experience to receive orders on which certain chemical limits that were commercially possible were outlined, and then physical results demanded that were absolutely impossible with the prescribed analysis. The discrepancies are in a good measure due to the steel makers themselves because only a few years ago the data at hand on alloy steels were obtained through tests in which the type of steel was the only variable. He predicted that the next few years would show a greatly increased demand for alloy steels, and said the electric furnace has enabled the manufacturer to duplicate many steels which were formerly made in the crucible and at a reduced cost.

A paper on "Heat Treatment in Automatic Electric Furnaces" was presented by Mr. Thaddeus F. Baily. Mr. Baily reviewed the development of heat treatment and showed how it became necessary to devise an automatic electric furnace in order to remove the human element as much as possible. He then described a complete equipment and its operation. "The important element in the operation is the temperature measuring devices adopted to take the temperature of the material under treatment itself, not the furnace temperature." These special pyrometers actuate the interlocked electrically operated hydraulic valves when the proper temperature has been reached and discharge the material for quenching.

In the discussion Mr. S. T. Wellman suggested that the mechanism be operated electrically.

Dr. J. W. RICHARDS said that automatic heat treatment eliminating the personal factor of the workman, is a great step in advance. With proper design and heat insulation, electric furnaces of the Baily type should be capable of putting into the articles to be treated 50 per cent of the heating energy of the current. A combined fuel and electric furnace with electric heating for the last 100 or 200 deg. might be much cheaper in some localities. There seems no doubt that some such device would improve rolling practice by discharging ingots from the furnace always at the proper temperature.

Mr. Baily, in replying to the discussion, stated that their furnaces under observation had shown a thermal efficiency of 92½ per cent. In reply to a question by Dr. A. S. Cushman as to the arrangement of pyrometers, Mr. Baily advised placing the tube ½ in. from the metal at the point of discharge, and to Dr. Cushman's statement that surface temperatures were not a correct indication of interior temperatures, Mr. Baily said they allowed such a liberal period for heating that the piece was heated throughout uniformly.

A paper on "Control of Piping and Segregation in Ingots," was presented by Dr. HENRY M. HOWE, explaining the more important elementary principles by which piping and segregation in steel ingots may be lessened, in his characteristic lucid style.

In discussing this paper Mr. E. R. KEENEY said: "Dr. Howe has given us an explanation of many of the features which we have observed in the cooling of ingots, and in the main his reasoning is corroborated by our observations. His statement that during the whole of the preneutral period (i. e. the period during which the outer parts cool faster than the inner) the contraction of the outer parts tends to be more rapid than that of the central ones, is not necessarily true. It would depend on the relative coefficients of contraction of the two parts." Another point on which Mr. Keeney was not convinced was the effect on segregation of the upward currents caused by the gas bubbles in rising steel.

A paper on the "Mechanical Development in Sintering Materials" was presented by Mr. BETHUNE G. KLUGH, showing the intricate problems which were overcome in working out a simple process and describing the progress made in developing the continuous down-draft sintering machine of Dwight and Lloyd. In the discussion Messrs. Robert E. Brooke and Hermann A. Brassert gave their experiences with the Dwight-Lloyd machine. A paper on "Under-Advertising of the Steel Business" was presented by Mr. GEORGE H. JONES.

Non-Ferrous Metal Market

Copper.—The last week in October and the first week in November saw little change in copper prices with only a fair demand. Electrolytic rose slightly on Oct. 28, being quoted at 17.75@18 delivered terms. On Nov. 1 it rose slightly again and producers were asking 18@18.25, which price remained steady during the first week in November. Some authorities think the price was raised to induce buying instead of the usual practice of allowing concessions; in other words, what is known as a bull campaign was thought to be on. There have been 10,000,000 lb. removed from the regular monthly supply on account of the shut down of Greene-Cananea and the strike at Clifton, Ariz. The total exports from Atlantic ports during the month of October were 23,657 tons of 2240 lb. (compiled by N. Y. Metal Exchange). The output of the northern Michigan mines for October was 24,949,000 lb., the largest for any month this year. Exports so far this month have been very low, only 79 tons having been reported up to Nov. 5. Prices quoted on Nov. 5 were: Prime Lake, 18@18.25; Electrolytic, 18@18.25; Casting, 17.50@17.75. Standard in London was still £15 below Electrolytic.

Tin.—The tin market during the last of October and first week in November showed a gain of approximately 3 cents per pound. Quotations of the N. Y. Metal Exchange Oct. 20 for spot were 33.12½@33.50. On the 27th it rose to 33.62½@33.87½. By Nov. 1 it was 35.50@36.50, and on Nov. 6 Straits or Malacca tin was quoted at 35.95@36.37½. During this period the London market showed a steady advance, Straits tin rising from £153 to £162 5s. from Oct. 20 to Nov. 6, with a corresponding advance in Standard. The continued advance in London was thought to have been caused by the scare of shipments being endangered. The talk here of an export duty and the endangering of shipments probably also had its effect. Arrivals during October were only 2000 tons, with arrivals in November up to the 6th, 865 tons. The next two months are normally considered dull ones in volume of consumption.

Lead.—Lead has seen three advances since Oct. 20. On the 21st the Trust price was advanced 0.25 cent to 4.75. On the 29th a 0.15 cent advance was made to 4.90, and on Nov. 4 another advance was made to 5.00. The reasons given for these advances were the continued demand for export, and also an increasing demand for home consumption, the sheet lead trade being reported as very good. Lead was quoted Nov. 5 at 4.92½ at St. Louis, which is the usual differential. The total exports for October were 4106 tons with exports so far in November very low.

Zinc.—Spelter has advanced considerably since Oct. 20, when it was quoted at 13.50@13.75 for spot, with November at 13.00 and December at 12.50. During the last week in October large tonnages were sold for export and the price rose steadily to 14.67½@14.80. Towards the first of November the market became dull, but remained firm, however, and on Nov. 4 the demand became more active with prices at 15.17½@15.42½ spot and futures higher than previously.

Other Metals.—Of the other metals aluminium advanced during the last two weeks and is now quoted 56@58 for Virgin metal. Antimony rose from 30.50 on Oct. 20 to 35@35.50 on Nov. 6. Silver was then quoted at 50, nickel at 45@50, and quicksilver at $100 flask.

The Iron and Steel Market

Spectacular movements are occurring in the iron and steel markets. All precedents are violated and physical conditions, not trade practices or theories as to what is the best for the industry, are making the market from day to day. There are two dominant factors, that steel is extremely scarce, and that there is a heavy demand for special steel, chiefly for war purposes. The unprecedentedly heavy demand for steel as a whole makes it that finished steel products advance rapidly in price, and the commodities advance *pari passu*, because it is not the demand for the particular finished product, but the scarcity of the crude steel, that causes the advance. The large demand for special steel makes it that the ordinarily self contained operations, producing steel for their own consumption, in many cases buy soft steel for their own finishing mills and use their steel making equipment for the production of special steel, chiefly in the form of billets. The Pittsburgh Steel Company has bought about 40,000 tons of Bessemer billets, for use in its wire departments, thus releasing some open-hearth capacity for the manufacture of special steels. Several steel and sheet mill interests have bought sheet bars for their sheet mills and are selling special billets.

The war demand for steel is increasing, and is running to new products, there being offered large orders

for steel sheets, for trench covering and other purposes. The strictly domestic demand has increased sharply, the railroads being the most conspicuous buyers.

The making of contracts for future delivery of finished steel, subject to specifications to be furnished at intervals, has been greatly decreased. Many mills, perhaps the majority, have stopped making contracts entirely and are accepting business only in the form of specific orders.

Finished steel prices have been advancing rapidly, and by an average of not far from $2 a ton in the single fortnight. Unfinished steel is advancing likewise, but close comparisons cannot be made as the market is not well defined. Some consumers are regular customers and are given preference, while there is a sharp divergence between Bessemer and open-hearth steel, and another and still sharper divergence between ordinary soft open-hearth steel and steel that is in any respect special either as to composition or method of rolling.

Pig Iron

In the first few days of November there was a wave of buying of Bessemer and basic pig iron by central western mills, at but slight advances over the market previously current. Subsequent to these purchases the market has advanced rather sharply, the point being reached at which doubts arose whether the production of pig iron by merchant furnaces could be materially increased. In the earlier months of the general market movement there was always in sight a large number of idle merchant furnaces. While steel prices are now as high as at any time since the 1905-6-7 movement, pig iron has not yet reached levels attained in the 1909 and 1912 movements. With the present very sensitive market, however, new price levels may be attained very shortly. The market is now quotable as follows: No. 2 foundry iron, delivered Philadelphia, $16.50 to $16.75; f.o.b. furnace, Buffalo, $16 to $16.50; delivered Cleveland, $16.30; f.o.b. furnace, Chicago, $17 to $17.50; f.o.b. Birmingham, $13 for prompt and $13.50 for first quarter; f.o.b. valley furnaces, 95 cents higher delivered Pittsburgh; Bessemer, $17; basic, $16; foundry and malleable, $15.50 to $16; forge, $15 to $15.50.

Steel

The large purchases of Bessemer billets by the Pittsburgh Steel Company, about 40,000 tons, together with the diversion of much finishing capacity to the use of Bessemer instead of open-hearth steel, has served to make a real and an advanced market for Bessemer billets, at $25.50 to $26.50, maker's mill, Pittsburgh or Youngstown. Bessemer sheet bars are about 50 cents higher. Open-hearth steel is about $1 a ton higher than Bessemer, but the curious condition exists that billets are likely to show a larger spread than this and sheet bars a smaller, peculiar conditions existing as some steel mills have recognized regular customers for sheet bars, while ordinary purchasers of billets do not have recognized sources of supply to the same extent. Ordinary forging billets command $42 to $45, while war billets command $50 to $60. Wire rods are about $35.

Finished Steel

Nearly all finished steel prices have advanced in the past fortnight. Prices now quoted are chiefly for shipment at mill convenience, against specific orders, there being few contracts. Premiums are frequently paid for particularly prompt shipment. Prices quoted are f.o.b. Pittsburgh unless otherwise noted:

Rails, standard sections, 1.25c for Bessemer, 1.34c for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.60c.

Shapes, 1.60c.

Steel bars and bands, 1.60c, base; hoops, 1.75c.

Iron bars, 1.659c to 1.759c, Philadelphia; 1.45c, Chicago; 1.50c to 1.60c, Pittsburgh.

Plain wire, 1.70c; wire nails, $1.85 per keg, base; painted barb wire, 2.00c; galvanized barb wire, 2.70c; fabricated wire fence, 69½ per cent off list, in carload lots.

Sheets, blue annealed, 10 gage, 1.80c to 1.90c; black, 28 gage, 2.25c to 2.35c; galvanized, 28 gage, 3.80c to 3.90c; painted corrugated, 28 gage, 2.45c to 2.50c; galvanized corrugated, 28 gage, 3.85c to 3.95c.

Tin plate, $3.30 for 100-lb. cokes.

Steel pipe, ¾ to 3-in., black, 78 per cent off list; galvanized, 63½ per cent off list.

Boiler tubes (less than carloads) 3½ to 4½-in., 69 per cent off list.

Structural rivets, 2.25c; boiler rivets, 2.35c.

The Chicago Pneumatic Tool Co. has issued a small booklet describing its Simplate flat disc valves which are used in its pneumatic compressors.

The Bristol Company of Waterbury, Conn, was awarded the Grand Prize at the Panama-Pacific Exposition for its exhibit of recording instruments. This exhibit was described in our issue of June, 1915.

The Swenson Evaporator Co., Chicago, Ill., reports that its evaporators are or will be soon installed for producing potash in the United States from all sources, viz., kelp, liquor, natural western lake waters, bittern, feldspar, molasses waste, and alumnite.

Gas Manufacture.—In Technical Paper 120 recently issued by the Bureau of Mines a bibliography of the chemistry of gas manufacture is given. It is intended to serve as a reference guide for those interested in gas making. The authors are W. F. Rittman and M. C. Whitaker.

Aluminium.—It has been reported that the Southern Aluminium Company's plant, work on which was stopped at the beginning of the war on account of the preponderance of foreign capital, has been sold to the Aluminum Company of America. The consideration was said to be about $6,500,000, and work is reported to have been started to finish the plant.

The Simonds Mfg. Co., of Fitchburg, Mass., has signed contracts with the United States Steel Corporation for license of a 5 to 6 gross ton Heroult three-phase electric melting furnace. Results obtained in experimenting and practical use of electric furnaces in the past five years have indicated the desirability of installing the present furnace, which is expected to be under power by January, 1916.

Coal and Mining Laws.—It has been estimated that there are more than 3,500,000,000,000 short tons of coal in the United States, exclusive of Alaska. In mining a comparison with the practices of other countries is helpful. Geological Survey Bulletin 505, "Mining Laws of Australia and New Zealand," contains much suggestive information. This report may be obtained free from the Director of the Geological Survey at Washington, D. C.

Lime Production in 1914.—The total lime manufactured and sold in the United States in 1914 was 3,380,928 short tons, according to the U. S. Geological Survey. This was valued at $1,400,686. Both the quantity and value for 1914 are less than for any previous year since 1908. Lime for chemical works showed a decrease of 20,872 tons from 1913, and a decrease in value of $137,050, owing to a drop of 18 cents in the average price per ton. Both quantity and value, however, exceeded those of 1910, 1911 and 1912.

Thermal Principles of the Blast Furnace

BY J. E. JOHNSON, JR.

(*Continued from page* 792)

Returning now for a moment to the comparison of the theory of the blast furnace with thermodynamics it may be shown that what may be called the availability factor can be expressed in the same mathematical terms in both cases.

The second law of thermodynamics is expressed by the formula $Q \times \frac{T_1 - T_2}{T_1}$, in which Q is the total quantity of heat concerned in the transformation, T_1 is the temperature at which it is applied and T_2 is that at which the unused portion is rejected.

Now in the blast furnace if the whole quantity of heat developed in the hearth be Q, the theoretical combustion temperature be T_1 and the critical temperature be T_2, since the heat given out by a gas in cooling is proportional to the temperature drop $T_1 - T_2$, the portion of the whole which can be utilized in the hearth is $\frac{T_1 - T_2}{T_1} \times Q$, exactly the same as in the case of steam engine.

This is in one sense only a matter of casual interest, but in view of the increasing connection recognized between chemistry and thermodynamics it is highly suggestive. It will be noted that the idea that there are two heat balances for each furnace, one for the shaft, the other for the hearth and bosh, is set forth very plainly in the quotation before given from "Notes on the Physical Action of the Blast Furnace," but the difficulty of getting at the debit side of the account seemed almost insuperable, and on this account I did not for several years use the chart of hearth heat for any but comparative purposes to show the heat obtainable per pound of coke with different blast and critical temperatures and different percentages of moisture in the blast, because the furnaces of which I had the management were coke furnaces on relatively lean ores, and in such cases the hearth heat obtainable per pound of coke exerts exclusive control of the economy of the furnace when other details of operation receive proper attention.

A few years ago when I undertook the management of a charcoal furnace using rich ores I attempted to apply the same principles and methods of calculation to it, but soon found that there were many features of its operation which could not be explained on that basis.

For instance, covering in the ends of the blowing cylinder and piping the air to it from out of doors in a very dry climate yielded no better results than taking the air from the engine room, although figures from the chart of hearth heat based on the humidity in the engine room indicated that a considerable saving should result. Similarly, changes of blast temperature exerted little or no influence on the running of the furnace compared with what similar changes would do on a coke furnace, and in particular it seemed impossible to save the furnace by the use of more blast heat when it started to run cold. It was absolutely necessary to put more fuel down into the hearth.

Finally it occurred to me that the hearth heat per pound of iron generated in that practice might be greater than was needed, and that a comparison of that developed in charcoal practice with that developed in coke practice might be illuminating. I had been taking observations of the free-running temperature of the slag, so I knew approximately what it was; this, with the blast temperature and the fixed carbon in the charcoal per pound of iron, supplied the necessary data for the calculation, which showed 1300 B.t.u. of hearth heat developed per pound of iron, while that developed in coke practice at the Isabella furnaces was only about 1000 B.t.u.

This astonishing result was the more remarkable because about 1200 lb. of slag per ton of iron were made in the coke practice and only about 500 in the charcoal. This could only be interpreted in one way, that more hearth heat was being developed than the furnace needed, and the excess was passing up into the shaft of the furnace and finding utilization there, but only in doing relatively low-temperature work. This in turn could only mean that the heat developed in the shaft was deficient in comparison with the hearth heat, and that if means could be found to increase the shaft heat the increase would prepare for final smelting in the hearth a greater proportion of ore, of which the excess of hearth heat could take care, so that the burden could be increased and the fuel consumption reduced, and incidentally, as we shall later see, the quality of the iron improved.

The ore used was a clayey Gogebic ore carrying normally 13-14 per cent of moisture, and a preliminary calculation showed that the abstraction of the heat required to evaporate this moisture from the small volume of gas which a charcoal furnace produces must lower the temperature of the gas about 400 deg., and as it was being discharged at about 200 deg. Fahr. it seemed as though the gas temperature would be high enough to do considerably more reduction, especially as the gas was amply rich for this purpose, if it did not have to drive off this water.

This seemed then to be a case in which the fuel economy of the furnace was controlled exclusively by the shaft heat developed per pound of fuel, the hearth heat playing a purely secondary rôle.

In order to ascertain whether this could be true detailed calculations were made covering the operation of the furnace as it was running and as it was believed it could run with dry ore. A similar set of calculations was then made covering the operation of a coke furnace which had made an excellent run to see how the existing and assumed charcoal cases compared with it.

The results of the whole investigation, which covered several months of laboratory work and all my time which could be spared from other work for three months or more, were embodied in a report to the executive of the company.

The major portion of this report is given here, as it covers the situation better than can be done in any other way.

THE EFFECT OF WET ORE ON CHARCOAL-FURNACE PRACTICE

"The conception that the great quantity of moisture present in the soft ores used in the charcoal practice of this district might affect the working of the furnace by undue cooling of the top gradually took shape in my mind from observing the top temperatures at a time when our fuel consumption was high.

"According to all previous experience high fuel goes with a high top temperature, but last fall when we were having fuel consumptions of 95 to 100 bushels our top temperature was down around 200 to 250 deg.

"A brief calculation based on the volume of gas and the quantity of moisture in the ore showed that the heat required to evaporate the water was sufficient to lower the temperature of the gas 300 to 400 deg. We had also found, by a good many analyses, that our top gases were as rich in CO as those of a coke furnace, although burning as we do much less fuel per ton of iron than in coke practice this should not be the case. An analysis

of the conditions was begun, based on three considerations:

"1. The ability of the gas to carry off all the oxygen of the ore with a given fuel consumption. This depends on the extent to which CO can be oxidized to CO_2 in the presence of iron ore at different temperatures.

"2. The total amount of heat developed in the furnace by the oxidation of the fuel to the extent at which it passes out in the top gases.

"3. The development of a sufficient amount of heat in the hearth to carry on the reactions which can only take place above the temperature at which the cinder runs freely.

"The importance of this last point rises from the following consideration: The fuel, say at the free-running temperature of the cinder, is burned by the blast at its incoming temperature with the development of a certain amount of heat, which, in the absence of burden, would heat the gases to a temperature known as the theoretical combustion temperature. When the burden is present, these gases are cooled down by it and give out their heat as they cool, but it is obvious that they cannot supply any heat at or above the free-running temperature of the slag (known as the critical temperature) after they are cooled down to that temperature. The amount of heat which they give out in cooling from the theoretical combustion temperature to the critical temperature may therefore be called the hearth or high-temperature heat. In coke practice the amount of this heat developed is generally smaller proportionately to the needs of the furnace than the total heat developed, and, consequently, it is the amount of this heat available which limits the fuel economy of a coke furnace. But in charcoal practice the critical temperature, that is, the free-running temperature of the slag, is so much lower than that of coke furnaces that the range from theoretical combustion temperature to critical temperature is much greater, and, therefore, the amount of hearth heat developed per pound of carbon is much higher, and it has been found by calculating the amount of high temperature heat developed per hundred pounds of iron in good coke practice, and the amount developed in our practice, that the latter was considerably *higher* than the former, although the slag volume to be melted and other work to be done in the hearth is much lower in our case.

"This indicated to my mind that we were developing more hearth heat than we needed, and making our iron hotter and of poorer quality in consequence, and I thought at that time that we should have some way of increasing the oxidation of the top gases so that we could increase the amount of heat in the upper part of the furnace, which, for lack of a better term, I call the shaft heat—shaft being the only name I know of for the portion of the furnace from the bosh to the top.

"After I had made the calculation showing how much the temperature of the gas was lowered by having to evaporate the moisture in the ore, it seemed to me that if the ore were thoroughly dried the top temperature would go up so much that the gases would be oxidized a good deal further, which would develop more heat per pound of carbon in the shaft, and as we had a surplus in the hearth this would enable more burden to be carried.

"In order to make reasonably accurate calculations, it was necessary to investigate along three lines as a preliminary: (1) the free-running temperature of the cinder; (2) the exact composition of the charcoal; (3) the extent to which the CO could be oxidized in the presence of iron ore at given temperatures.

"1. We have been carrying on, to the best of our ability, investigations of temperature of the running iron and cinder for over two years, and while they have not been completely satisfactory, they seem to indicate a temperature of 2300 deg. Fahr. as that at which a normal charcoal slag will run sufficiently freely for the furnace to work. Similar observations on coke furnaces several years ago indicated a temperature of about 2700 deg. Fahr. as that of a good slag in Bessemer practice.

"2. The composition of the charcoal. This was a matter on which we had made experiments in the past, but they were not successful enough to be considered reliable. We, therefore, put a piece of charcoal in an alundum boat in a silica tube heated by an electric furnace, surrounded it with an atmosphere of CO and heated it until no more gas came off. The gas was caught in rubber bags, its volume measured and its analysis obtained. The volume of CO used to fill the furnace was deducted from the total volume and the analysis of the gas was figured back to what it would have been if the CO had not been added in advance. Such a determination was made for birch and one for maple. The results checked exceedingly closely. As a further check the specific gravity of the gas was taken by weighing a small gas bag full of it, and this was compared with the specific gravity calculated from its analysis. The check was excellent. The charcoal remaining was weighed and then burned. The weight as taken from the electric furnace less the weight of the ash was considered to be the fixed carbon of the coal. From the analysis and volume of the gas evolved the weight of each gaseous component was figured and these were reduced to percentages by weight of the original sample of charcoal. The variations between birch and maple were very slight, and were averaged to obtain the figures given in Table IV.

Table IV.—Average Charcoal Analysis for Birch and Maple

	Per Cent
CO_2	4.50
O_2	0.67
CO	11.10
H_2	1.65
CH_4	3.40
N_2	7.77
Fixed carbon	68.50
Ash	1.00

"3. The extent to which the CO could be oxidized in the presence of iron ore at given temperatures. After overcoming the worst of the difficulties in this determination, we were unable from lack of time to get a long series of these determinations at different temperatures, as we had hoped, but we demonstrated by several runs that at a temperature of about 700 deg. Fahr. 62 per cent of CO_2 were in equilibrium with 38 per cent of CO. This means that if sufficient time were allowed it would be possible to oxidize the top gases so that the CO_2 would hold this ratio to the CO at this temperature. We also proved conclusively that the equilibrium percentage was much higher in CO_2 as the temperature arose. At 800 deg. it is about 70 per cent to 75 per cent, and at about 900 deg. it is around 80 per cent CO_2, but these figures are not exact.

"These were the data on which our calculations had to be based. It was decided first to take the conditions which prevailed with this furnace at the time these calculations were started. Ninety-five bushels of coal, 50 per cent ore yield, 13.50 per cent moisture in the ore, 400 lb. of limestone per ton of iron. From the tonnage made and the revolutions of the blowing engine the amount of blast per hundred pounds of iron was obtained, and by temperature observations of the air going into the cylinder and coming out it was possible to get a rough check on the displacement of the air cylinder. All gas volumes are reduced to 30 in. barom-

eter and 32 deg. Fahr. The specific volumes of gas are those given in Kent, and heats of combustion are taken from the same source, but the specific heats of the different components in the operation are taken from Richard's "Metallurgical Calculations." The specific heats given in Kent are not exact for high temperatures.

"It is necessary to call attention to one fact of much importance. The charcoal gas contains appreciable quantities of hydrogen and methane. Hydrogen requires for its combustion eight times its weight of oxygen, and methane for combustion to water and CO_2 requires four times its weight of oxygen. These are both very active reducing agents and will take up oxygen from the ore with great rapidity at a reasonably high temperature, 600 to 800 deg., but with the conditions under which the furnace works the top temperature is so low that they pass off largely without action on the ore. Our analyses have repeatedly proven them to be present in top gases. The quantity of oxygen which they can absorb is so great that the question whether they are oxidized completely or not affects the composition of the top gas tremendously.

"I have assumed that in a furnace using wet ore and 95 bushels of coal three-fourths of the hydrogen was burned and none of the methane, because this gives results which check out well with the actual gas analyses we obtained from the furnace, but, unfortunately, we did not get any during the exact period covered by the above assumption. However, the analysis of the gas in both CO_2 and CO, as well as in hydrogen and methane, is so close to what we actually found that no material error can be introduced into the heat calculations by any inaccuracy in these assumptions.

"A further fact is that the heat developed by combustion of CO and that developed by hydrogen per pound of oxygen consumed is nearly the same. Therefore, it is a matter of slight importance in regard to the development of heat whether the oxygen to be disposed of is consumed by hydrogen or by CO.

"Having made the calculation for 95 bushels of coal, I then made an exactly similar one assuming 75 bushels of coal with the ore thoroughly dried, and in this calculation I assumed that the gases would pass off at 400 deg. higher temperature than in the other, 632 deg. as against 232 deg., assumed as a fair average of the actual temperatures for 95 bushels with wet ore. This assumption was made because of the fact before mentioned that the amount of moisture present in the ore is sufficient to cool down the gases about 400 deg. In this case I assumed that the hydrogen and methane were completely oxidized because previous investigation on a furnace with a moderately warm top had shown this to be the case.

"In order to get some comparative figures from another source, I have made a similar analysis of the run of a coke furnace described by A. K. Reese, in Vol. 27 of the *Transactions* of the American Institute of Mining Engineers. This was a six months' run on the furnace at Canal Dover, Ohio. In order to check out the quantity of wind blown with the gas analysis given, it was necessary to assume that the volatile matter in the coke in this latter case consisted of methane and hydrogen, and that these were oxidized in the top of the furnace, as above described.

"Before proceeding to discussion of the results obtained in the three cases, it will be well to point out that the method of calculation of the total heat developed in the furnace is the time-tried and accepted one. The method of calculating the heat in the hearth has been used for the last seven or eight years, and has proven itself so reliable in giving relative figures in comparative cases that it is now generally accepted. See METALLURGICAL AND CHEMICAL ENGINEERING, March, 1913, page 147-8, "The Gayley Dry Blast," by H. M. Howe.

"In regard to the degree of oxidation of the gases in any given case, it is not commonly realized that this can be figured with considerable accuracy. The amount of blast blown supplies a given quantity of oxygen and the ore charged supplies another quantity. A slight additional amount comes from the gas given off by the charcoal, and a somewhat larger amount from the CO_2 of the limestone. All these have to come out of the stack, combined with the carbon which goes in in the form of fuel and in the form of CO_2 in the limestone, except for that which comes out combined with the hydrogen of the fuel. This, of course, is in the form of water and disappears in the gas analysis.

"As we know, with considerable accuracy, all of these weights of carbon, and hydrogen, and of oxygen, the degree of oxidation of the products of combustion can be accurately calculated and the heat developed determined with corresponding accuracy.

"All of the ores in this district are hematites, and therefore each seventy units of iron contain thirty units of oxygen, and the oxygen combined with the iron can be accurately figured from this. To this must be added the oxygen which comes from the silicon going into the iron, and due account must be taken of the fact that iron contains only about ninety-five units of Fe. I have assumed about 1.00 per cent to 1.25 per cent silicon, and have neglected the manganese in all cases, as the amount of oxygen accompanying it is too small in proportion to the possible variations in the larger quantities to be given serious consideration. This gives 42 lb. of oxygen released from the ore and silica per hundred pounds of iron. (It is very desirable to have a symbol which shall represent pig iron as distinguished from chemically pure iron, Fe, and for this purpose I have used the letter "I," because iodine does not enter into the discussion and no confusion can result.)

"The volume of blast blown was estimated from the displacement of the blowing cylinder, some allowances being made for the suction in the cylinder when the valves close and for the re-expansion of the compressed air into the clearance space, both of which tend to reduce the actual pounds of air blown. The temperature of the air being discharged from the cylinder was taken at the discharge head, and simultaneously that of the outside air, with which the engine was supplied. The heating of the discharge air was about 20 deg. higher than the theoretical for the pressure blown at the time, 6 lb., and this was assumed to take place before compression began and to make a further reduction of the weight of air delivered. The weight of air blown, derived from the displacement, with these corrections and with slight allowances for the loss in changing stoves and leakage, was used in the gas calculations, and checked out very satisfactorily with the actual analysis of top gas found. It may be well to remark here in passing that if incorrect assumptions be made, the calculated top gas will vary widely from the actual top gas analysis, and will at once indicate that something is wrong.

"It will be noticed that in the tables the weight of fixed carbon in the fuel per hundred pound of iron is given, and from this is made a deduction of 4 lb. to correspond with the 3.50 per cent or 4.00 per cent of carbon combined with the iron and some slight loss of solid carbon at cast and at flush time.

"The result of the calculations are each represented on a separate table, Tables V, VI and VII, in which it has been attempted to epitomize the calculation and to indicate the various reactions that lead to the top gas as finally discharged. In a general way the table gives,

in its upper left-hand corner, the details of what goes on in the hearth and bosh, and works gradually toward the final result in gas composition and heat development at the right-hand end and bottom of the table. It is feared that these charts may not be perfectly comprehensible at first glance, but no effort has been spared to make them as logical and clear as possible, so as to save the reader an enormous amount of effort in going over written details of these calculations.

"Coming now to the final results in heat development, we find that Table V, giving the actual conditions with wet ore, shows a development of hearth heat of 125,500 B.t.u. and a development of shaft heat of 379,800 B.t.u., a total per pound of iron of 505,300 B.t.u.

"The coke furnace in which, by the way, the theoretical gas analysis checks remarkably well with the actual results, shows a development of hearth heat of 117,000 B.t.u. and of shaft heat of 515,600 B.t.u., a total of 632,600 B.t.u. The assumed case, Table VII, dry ore and 75 bushels of coal, shows a development of hearth heat of 113,500 B.t.u., of shaft heat of 411,200 B.t.u., a total of 524,700 B.t.u. These are arranged in condensed tabular form below:

	Coke Practice, 1664 Lb. Coke	Actual Practice, Wet Ore, 95 Bu. Coal	Assumed Case, Dry Ore, 75 Bu. Coal
Hearth heat	117,000 B.t.u.	125,500 B.t.u.	113,500 B.t.u.
Shaft heat	515,600 B.t.u.	379,800 B.t.u.	411,200 B.t.u.
Total heat	632,600 B.t.u.	505,300 B.t.u.	524,700 B.t.u.

"Before proceeding to a discussion of these figures, it should be stated that in the case of the coke furnace it was assumed that the air blown contained four-tenths of a pound of moisture per thousand cubic feet of air, all of which moisture was dissociated in the hearth with corresponding absorption of heat. Further, that the hydrogen evolved by the dissociation of the water passed out of the top of the bosh at the same temperature as the other gases and abstracted a corresponding amount of heat from the hearth. The dissociation absorbs 9300 thermal units and the hydrogen absorbs 1800, a total of 11,100 thermal units. This assumption as to the amount of moisture present is based on previous experience of the moisture in engine houses during the winter months. It is not possible that the air was taken from outside the engine room, as no mention is made of that fact and it was not customary at that time (1879).

"To be strictly accurate, allowance for the oxygen from this source should be made in the gas calculations, and as the hydrogen generally recombines in the top of the furnace with oxygen from the ore, the 11,100 thermal units subtracted from the hearth heat might, with propriety, be added to the shaft heat. These corrections have not been made because their magnitude is not of sufficient importance to affect the general result, and they would greatly complicate the tables to show them. No allowance for moisture is made for our practice, because we take our air from out of doors and the amount of moisture present in the air in winter time in this climate is a negligible quantity.

"Comparing first the two actual cases, coke and 95 bushels of charcoal, we see that the heat developed in the hearth with the charcoal is considerably greater, while the heat developed in the shaft is very much less than with coke. The difference in the latter condition of over 100,000 thermal units is very striking. The explanation of the major part of the difference lies in higher temperature to which the materials must be heated in the shaft of the coke furnace than in the charcoal, and also the much greater amount of limestone to be decarbonated in the coke than in the charcoal. Only approximate calculations are possible on this subject for lack of accurate data as to specific heats of the materials at these high temperatures, but such calculations indicate that most of the difference can readily be accounted for in this way.

"Turning now to the high temperature, or hearth heat, the conditions are extraordinary. The coke furnace, with a considerably greater quantity of slag, greater radiation losses and every disadvantage compared with a charcoal furnace, develops about 7 per cent less high-temperature heat than the charcoal furnace. Moreover, an examination of the table will show that while 58 lb. of fixed carbon are brought into the furnace by the charcoal, only about 50 lb. are consumed in the hearth—4 by absorption in the iron and 46 by combustion with the blast. This shows that about 8 lb. out of 58, or 14 per cent, of the total fixed carbon are dissolved by the oxygen of the ore. If this carbon came down into the hearth as it should, the excess of high-temperature heat for the charcoal furnace would be very much greater than it is.

"It seems well to point out here one curious fact. When CO is oxidized to CO_2 by oxygen taken from the ore, heat is given out by the reaction; but when carbon is burnt to CO by oxygen from the ore, an enormous amount of heat is *absorbed* for every pound of oxygen which is transferred from the ore to the carbon. This is because a unit of oxygen develops over twice as much heat in burning CO to CO_2 as it does in burning C to CO. Knowing the amount of carbon which is thus burnt directly, we can easily figure the heat absorbed. This amounts to 33,000 thermal units per 100 lb. of iron. We do not know where this reaction takes place, but the action of this furnace and the frequent observation of forge cinder at or below the level of the tuyeres when the furnace is in normal operation causes the belief that a great portion of this combustion of fixed carbon with oxygen from the ore takes place in the hearth itself, and thereby robs the hearth of the excess heat which it develops.

"Extensive investigations have been made in Germany on the equilibrium between FeO and Fe_3O_4 with CO and CO_2. These investigations proved that at temperatures of 1800 deg. to 2000 deg. CO could contain a considerable percentage of CO_2 and still deprive FeO of all its oxygen; but if the temperature went higher than this the affinity of the iron for oxygen increased so much that pure CO or incandescent carbon would be required to deoxidize it completely. This means that at the top of the bosh where the combustion of the blast to CO is complete the temperature should not be too high, as high temperature prevents complete deoxidation by the CO, and requires the use of solid carbon for that purpose, with consequent waste of fuel. Thus it may actually be that excess fuel leading to high temperature in the hearth exercises an unfavorable action on the final reduction of the ore.

"It is perfectly obvious that the effect of wet ore on gas is to cool it down with extreme rapidity as it approaches the top of the furnace, and while the physical heat thus lost is of some importance, a condition of vastly greater importance results from it. This is that the temperature of the gas is so far reduced that it can no longer react on the ore. This means that oxygen which should be removed from the ore near the top of the furnace with decided evolution of heat descends to lower levels, and that which should be reduced in the central zone descends to or above the top of the bosh before it is finally removed. This involves the reaction with solid carbon, above pointed out, and the destruction of fuel economy.

"The effect of the excess heat in the hearth I believe to be bad also for the quality of the iron, because in the region around the tuyeres the temperature developed is excessive, this temperature being given up by the

gas to the stock in a slightly higher zone, in order to overcome the cooling effect produced through the direct reaction of the oxygen of the ore by the incandescent fuel. These high temperatures at the tuyeres tend strongly to superheat the iron as it drips down through this zone. This increases its affinity for carbon, which the presence of an excess quantity of carbon permits it to satisfy. Therefore, the tendency of this working is to produce a hot-made high-carbon iron, although the silicon may not be high, due to the scouring action of the oxide which comes down to, or nearly to, the zone of the tuyeres.

"Turning now to the assumed case of correct top conditions and a fuel consumption of 75 bushels of coal, we find that the heat developed in the hearth is the same, or virtually the same, as that in the coke furnace (although the requirements as above pointed out are not so great), while the heat developed in the shaft of the furnace is very materially greater than with 95 bushels of coal and wet ore, about 407,000 thermal units against 378,000.

"The critical point in this assumption is the ratio of the top gases. It will be seen that this works out to 17 per cent of CO_2 and 20.3 per cent of CO, as compared with the actual results in the coke furnace of 15.6 per cent of CO_2 and 20.7 per cent of CO, a ratio of 0.75 : 1 for the coke furnace to 0.84 : 1 for the assumed charcoal conditions. This is not a very much higher ratio of CO_2, and is far lower than the equilibrium ratio, which is 1.63 : 1; that is, 62 CO_2 to 38 CO. In other words, it is possible for ore to oxidize the carbon gas to a very much higher degree than would be required for 75 bushels of coal under the given conditions.

"In regard to the time allowed for this reaction, it is well to note that the volume of the furnace in proportion to the volume of gas passing through it is very much greater in the charcoal furnace than in the coke one, which allows a correspondingly longer time for reaction.

"The development of more heat in the shaft of the furnace with over 20 per cent less fuel than in the actual case may appear to indicate erroneous figures, but this is not the case if we admit the possibility of the degree of oxidation just explained. The amount of oxygen from the ore for a hundred pounds of iron is virtually constant. For the same analysis of iron and same kind of ore it is exactly constant.

"This constant quantity of oxygen would oxidize the same quantity of CO to CO_2 in either case and develop the same amount of heat in doing so if all the fixed carbon were burnt to CO by the blast, but the smaller the quantity of fuel burned in the hearth per pound of iron, the greater the proportion of this which is oxidized to CO_2, and therefore the greater development of heat per pound of fuel. Moreover, in cases where all the carbon is not burnt to CO in the hearth by the blast (the case of wet ore, for instance), a part of this oxygen from the ore expended in burning C to CO, which, as explained above, generates less than one-half the heat per pound of oxygen consumed that is generated by the oxidation of CO to CO_2, hence not only a less proportion of the total CO is oxidized in the case of the larger fuel consumption, but the total supply of oxygen available for this purpose is reduced about one-fourth to satisfy the fixed carbon of the fuel, hence only three-fourths as much is available for oxidation of CO to CO_2 as in the case of smaller fuel consumption. Thus not only the relative but also the absolute oxidation of CO to CO_2 is much smaller with the larger fuel consumption. This, of course, is only true within the limits of possible oxidation of carbon gas above described.

"It might be thought that this whole line of argument was fallacious because it was the hearth heat which limited the fuel economy, as it undoubtedly is in most coke practice. If this were so we could produce an enormous change in the burden-carrying capacity by changing the temperature of the blast. The heat brought in by the blast for 95 bushels of coal at 800 deg. is 50,000 thermal units, at 1000 deg., as given in the table, 63,700, and at 1200 deg. 78,700. The high-temperature heat being 124,800 B.t.u. for 1000 deg. blast temperature would become 111,100 for 800 deg. and 138,800 B.t.u. for 1200 deg.; therefore, raising or lowering the blast temperature 200 deg. would produce a difference of about 11 per cent either way, or there would be an economy with 1200 deg. of blast temperature over that at 800 deg. of about 24 per cent. As a matter of fact, the difference which we find in fuel consumption for such a change in blast temperature is about 5 per cent. This corresponds approximately to the difference in total heat supplied to the furnace in the two cases, which figures about 5.50 per cent.

"It may be taken as established, therefore, that the amount of hearth-heat produced is not the limiting condition in regular charcoal practice, but that this limitation comes from the amount of shaft heat developed per pound of carbon burnt. This depends, as already pointed out, on the degree to which the top gases can be oxidized by the ore, and this, in its turn, depends on the temperature of the gases. If they remain hot they will continue to react on the ore until they are discharged, but it would be as unreasonable to expect them to do this when chilled with water and diluted with steam as to expect a fire to burn as freely with a hose turned on it as without."

As a result of this investigation arrangements were made to dry 500 tons of ore for a trial run, and while this amount was sufficient for only two days the results bore out in the most striking manner the conclusions derived from the calculations. The fuel consumption was decreased about 12 per cent, and this threw the deficiency of heat into the hearth, with the result that the furnace responded to changes in blast temperature to an extent that was almost incredible, in view of previous experience, and everything indicated, as far as so short a trial could, the complete agreement of practice with this theory of two thermal equations instead of a single one, as in the older theory, and that both of these must be satisfied before the furnace would function, even though the satisfaction of one involved a great surplus of heat above the requirements for the other.

A second article on the thermal principles of the blast furnace will follow.

Electroplating with Cobalt.—The complete report on the work done on plating with cobalt by Dr. Herbert T. Kalmus, C. H. Harper and W. L. Savell has been issued by the Canadian Department of Mines as Bulletin No. 334. A description of this work was given in our issue of May, 1915.

The Mineral Resources of Texas, by William B. Phillips, is the title of Bulletin No. 365 of the University of Texas. The work is restricted to mineral products and undeveloped resources are not considered. It is a very complete account of the products of Texas and contains much valuable information.

Products and By-Products of Coal.—In Bulletin No. 323 of the Canadian Department of Mines, recently published, Messrs. Edgar Stansfield and F. E. Carter present a general outline of the products and by-products obtained from the utilization of fuels in Canada. The publication is of special interest in view of its connection with the dyestuff problem which has confronted Canada as well as the United States.

Potash from Wood and Plant Ashes

BY HARLOW BRADLEY

INTRODUCTION

Recently several companies have been formed for the extraction of potash from the enormous kelp beds along the Pacific Coast, but whether this method will be commercially successful or not remains to be seen.[1]

Considerable interest has been evinced, however, since the European war stopped imports from Germany, in the possibility of producing potash from wood ashes, and the present paper will attempt to deal with this phase of the subject.

HISTORICAL

The production of potassium carbonate, or potash, from wood ashes is one of the oldest of the purely chemical industries and was fairly extensive fifty years ago in Russia, the United States and Canada. Elm, birch, larch and maple were the woods most generally used, and the devastation of the forests in the vicinity of leaching plants was beginning to assume alarming proportions.

The rapid development of the well-known Stassfurt potash deposits after 1870, however, had an immediate effect on the production of potash from wood ashes. In twenty years the amount produced in this way was not even half of the world's production, as the figures for 1890, given in Table I, furnished by H. Grüneberg,[2] will show:

TABLE I—WORLD'S PRODUCTION OF POTASH IN 1890

	Tons
Wood ashes—Russia, Canada, United States, Hungary, Galicia	20,000
Beet sugar waste—France, Belgium, Germany	12,000
Mineral salts—Germany, France, England	15,000
Suint (wool scourings)—Germany, France, Belgium, Austria	1,000
World's production	48,000

"These conditions differ strikingly from those which existed thirty years ago (in 1860), when wood ash was in exclusive use, and Russia potash ruled the market."

The industry in America was slowly undermined until, at the present time, the amount of "pearl ash," or refined "potashes," made either in the United States or Canada, is insignificant. Ashes are still used for fertilizer to a small extent, and farmers often lixiviate them to produce a lye for soft soap; an industry still exists for making a commercial potash, but it is very small. Before the war practically all of our potash was coming from the Stassfurt mines, giving the German Kali Syndicate a virtual monopoly.

The Twelfth Census[3] gives some interesting figures on the extent of the potash industry in America fifteen years ago.

"Though returns for the census year 1900 were received from sixty-seven establishments, producing 3,864,766 lb. of potash, valued at $178,180, no pearl ash was reported manufactured. Of these sixty-seven establishments, twelve produced products valued at less than $500. Cognizance was taken of this industry in the reports of the United States as early as 1850, so that the data are at command for comparing the condition of the industry in this country for each decade since 1850, as set forth in Table II.

"This Table II shows that there was a constant decrease in the value of the product, though the quantity varied somewhat."

TABLE II—TOTAL PRODUCTION OF POTASHES, BY DECADES 1850 TO 1900

Year	Number of Establishments	Product: Pounds	Product: Dollars	Average Price per Pound Cents
1850	569		1,491,533	
1860	212		538,550	
1870	105		327,671	
1880	68	1,571,671	232,643	5 09
1890	75	5,106,939	197,507	3 86
1900	67	3,864,766	178,180	4 82

The establishments reported in 1900 were distributed as stated in Table III:

TABLE III—GEOGRAPHICAL DISTRIBUTION OF POTASH FACTORIES 1900

States	Number of Establishments	Average Number of Wage Earners	Capital	Value of Product	Per Cent of Total
United States	67		$70,899	$178,180	100 0
Michigan	44	52	25,851	79,642	44 7
Ohio	15	25	20,050	35,519	19 9
Indiana	3	4	2,275	6,560	3 7
Maine, Wisconsin, Illinois	5	11	22,723	56,459	31 7

"There were reported as having been used in this manufacture 812,399 bushels of wood ashes valued at $40,191. The yield of potash per bushel of ashes, as reported, varied from 2.4 to 7 lb. In the product given above there is included potash packed in cans, amounting to 820,000 lb., having a value of $53,349. Excluding this, as being in the nature of a duplication, it appears that the total production of potash for 1900 was 3,044,766 lb., and that, therefore, the average yield of potash per bushel of wood ashes, as shown by the extra returns, was 3.75 lb. Pelonze and Fremy[4] give the yield by weight as 10 per cent, and this appears in other textbooks; but all returns for ashes received at the census of 1900 were given in bushels.

"From the data for production given above it is evident that although the average price of potash for 1900 was higher than for 1890, the industry was not remunerative and consequently the total quantity and value of the product decreased.

"The cost of producing a barrel of 650 lb. of potash was stated by a Michigan manufacturer to be as given in Table IV:

TABLE IV

Ashes, 150 bushels, at 3c	$4.50
Hauling ashes	6.00
Fuel	2 00
Labor	3 00
Barrel, cost of	1.25
Repairs, interest, etc	1.50
Total	$18 25
Selling price at works	25 00
Gross profit, per bbl.	$6.75

"The ashes, therefore, yielded 4 1/3 lb. of potash per bushel, and the potash sold at 3.85 cents per pound. It will be noted that the weight of a barrel of potash is given above as 650 lb. From the returns it appears that the net weight of a barrel of this material varied from 650 to 740 lb., the average being about 700 lb."

USES OF POTASH

The chief use of potash is in the form of crude mineral salts for fertilizer purposes. Over $13,000,000 worth of these crude salts was imported in 1912. Large quantities of potassium in the form of the cyanide are used in the recovery of gold from tailings and low-grade

ores. The glass industries require potash for certain forms of glass, and some potash is used for the manufacture of soft soap. Previously most of the manufactured potassium salts were imported, but potash is now used in this country for the manufacture of the chromate, the hydrate (caustic potash) and several others.

MANUFACTURE OF POTASH FROM WOOD ASHES

Potash is prepared by dissolving out the soluble contents of wood ashes and evaporating the solution to dryness. The process as carried out formerly on a commercial scale is as follows:

The wood, often mixed with vine stalks and ferns, is incinerated in pits 3 or 4 ft. deep and sheltered from the wind. The material is thrown in in portions and burned until the pit is nearly full of ashes. The latter are then removed, spread on a floor and dampened. According to an old observation ash which has been stored a long time produces more potash. This is because the silicate of potassium is transformed to carbonate by the carbon dioxide and water in the air.

The ash should be spread in moderately thin layers and turned for several months. It is doubtful, however, whether the increased yield of potash pays for the large amount of floor space necessary. Should the silicate content of the ash be comparatively high, an artificial method could probably be introduced. Often (in American practice) a small amount of lime (5 per cent) is added.

The ash is now placed in tubs or vats, formed from tar barrels by cutting them in half. These are arranged in double rows, one above the other, to permit the weaker leachings to run from the upper vats to the lower. The vats are provided with two cross beams, which support a cullendered false bottom covered with straw, and below this is a cock for the removal of the lye. Water, preferably hot, is poured on the mass in the upper vats and emerges strong lye.

If it is 32 deg. Tw. strong (20 deg. Bé., 20 per cent to 25 per cent salt), it can be boiled down at once; the weaker liquors and washings, however, are run through several vats successively. Care should be taken to have the ash well tamped down in the vat. Using cold water would leave the potassium sulphate behind, but hot water is used to obtain more potash, and the sulphate can be separated out later. The latter is valuable to the manufacturers of alum.

The leached residue, which contains some potash and available phosphoric acid, makes a fair fertilizer. The lye is boiled down in shallow evaporating pans made of iron with corrugated bottoms to produce a greater heating surface. The boiling down is generally a rough process. The waste heat can be used to warm the feeder which supplies the pans. In lieu of pans possessing a large heating surface (pans fired from the top would be best), circular cast-iron pots are often employed.

Evaporation progresses rapidly at first and new supplies of strong liquor are poured in, the heat being continued until a sirupy consistence is attained, when the fire is gradually slackened, and the contents of the pan becoming solid (containing about 6 per cent moisture) are dug out and placed aside as crude potashes.

In spite of much stirring before the mass becomes quite dry, much of it burns fast to the pan, causing a great waste of fuel and a speedy destruction of the bottom.

In Russia the lye was concentrated in copper kettles to the point of crystallization and then discharged into wooden cisterns where potassium carbonate crystallized out. After draining, the carbonate was calcined and the mother liquor returned to the cistern.

In America the mass was heated nearly to redness and converted into greyish-pink compact potashes, which were assorted into firsts, seconds, thirds and unbrandables.

The brown crude potashes are calcined in a reverberatory furnace, which causes the carbonaceous and other organic matter to burn away, the hydrate being carbonated and the sulphide converted into sulphate. The loss in weight during this operation is from 10 to 20 per cent. Too great a heat is to be avoided because the mass would then fuse, leaving a mixture of fine charcoal, from the carbonaceous material, and salt which cannot be burned white.

Potassium carbonate is difficult of fusion, but when large amounts of chloride are present the mixture fuses at an incipient red heat. The resulting product is white with a bluish tinge, the latter due to small amounts of potassium permanganate, contains more carbonic acid than the crude product, and is called "pearlash." A purer material is obtained by dissolving this pearlash in water, separating the insoluble matter, evaporating the liquor, and calcining it again. This latter process was generally used in America.

The American practice used so much lime that the major portion of the potassium existed as hydrate. In this way some of the silicate, which would otherwise have been lost, was recovered as hydrate. Potash with a large quantity of lime in it must be even more carefully protected against attracting atmospheric moisture than ordinary commercial carbonate, although the latter is also deliquescent. Such semi-caustic potash was very much in demand by soap makers, as it took less lime to make their lye and caused less loss.

In purifying carbonate of potash either of two methods can be employed: The carbonate may be stirred up in an iron pot with 1½ or 2 times its weight of cold water, and the mixture, which gets hot, allowed to cool down before siphoning off the clear liquor. The sulphate and some chloride remain behind together with the insoluble matter; the residue is not washed (which would cause the sulphate to be redissolved), but only pressed. The liquor, containing mostly carbonate, but also chloride and silicate, is brought to dryness, stirring it up to the end.

The second method is to dissolve the material in hot water; the residue is exhausted in the same way. The liquors are boiled down to a specific gravity of 1.50 and allowed to cool, when the sulphate and some chloride crystallize out. This process is more expensive than the former.

In order to make still purer carbonate for flint glass, pearlashes are calcined with a little sawdust, lixiviated, and the clear liquor boiled down and calcined. This is repeated twice over, and the last product is dried down until it is converted into granular "crystallized" carbonate with 15 per cent to 18 per cent water (less deliquescent—$K_2CO_3 \cdot 2H_2O$).

Fig. 1 is a sketch of a typical calcining furnace. Air entering through *b* passes up through grate *a* and the flame plays over *t* upon the calcining hearth. The furnace should be warmed before charging and should be run continuously.

When the furnace is red hot 300 or 500 lb. of crude potash are broken up and spread over the calcining hearth. Water begins to come off, violently if too much is present, so that the heat must be raised gradually. It takes about one hour to drive off the moisture and constant agitation must be practised.

The heat is then increased to redness so that the combustible and coloring matter is consumed. At this period the potash takes fire, burning with a flame of slight intensity, becoming black from the carbonization

of the combustible material. It becomes clearer and clearer until at length a sample drawn off appears quite white. Some potash sticks to the hearth of the furnace, and the flame is allowed to play over it until it softens, when it can be removed. The white calcined ash is removed and allowed to cool, and should be packed in close casks before it has an opportunity to absorb moisture.

POSSIBLE IMPROVEMENTS IN THE METHOD OF MANUFACTURE

Assuming that a sufficient supply of wood ashes was available to supply a plant for operation at the present time, many improvements could be made in the leaching, evaporating and calcining apparatus over the old methods. Leaching vats with a greater capacity than the tar barrels, and provided with cullendered, metal, false bottoms and a more efficient filtering medium than

aa—grates. bb—ash pits. c—calcining hearth 3 to 4 ft. wide. tt—fire bridges, iron plates. e—not necessary, may be used for other purposes.

straw, could be arranged in batteries much after the fashion of beet sugar diffusion batteries. In place of the shallow evaporating pans, or the cast-iron pots, an evaporator of the Enderlein type provided with a rotary calcining furnace, could be used, such as is employed in the recovery of soda at the soda and sulphate pulp mills. Fuel being no object, since the ashes would be a source of potash, this arrangement could do without the vacuum evaporators used at pulp mills for the preliminary concentration of the weak spent liquor, thus saving a considerable investment. A brief description of the Enderlein evaporator follows.

This apparatus consists essentially of an open wrought-iron vessel about 16 ft. long, 7 ft. deep and 14 ft. wide, inclosed in a brick chamber. Two shafts, each mounted with thirty-two wrought-iron disks, 5 ft. 6 in. in diameter, set about 5 in. apart, run across the vessel. The shafts are mounted 7 ft. apart, center to center, and the disks are intended to dip into the liquor. About one-sixth of their surface is submerged in the lye, giving a total surface exposed to the hot gases of 3140 sq. ft. The shafts revolve at nine or ten revolutions per minute.

At the front of the evaporating chamber, and opening into it is the rotary calcining furnace or roaster. This is about 16 ft. long by 8 ft. in diameter, slightly inclined away from the evaporator, and revolves at a slow rate of speed dependent on the conditions of evaporation. The liquor, which runs continuously into the evaporator, runs out in concentrated form through a weir into the rotary roaster, where it is evaporated nearly to dryness, and drops out at the other end between the mouth of the roaster and the smelter.

The smelter as used at pulp mills is merely a firebrick lined chamber or dutch oven, but for recovering potash a calcining furnace of the hearth type might be used. As the black ash drops out at the end of the roaster it is shoveled into the calcining furnace where the organic matter burns, providing most of the heat for evaporation.

About 15,000 to 20,000 gallons of waste soda pulp liquor can be evaporated from 16 deg. Bé. to 37 deg. Bé. with this apparatus in twenty-four hours, or about 1.25 lb. of water per square foot of heating surface per hour. The operation of this apparatus would probably have to be modified somewhat in dealing with potash.

CHARACTERISTICS OF POTASH PRODUCED FROM WOOD ASHES

Calcined potash is a hard, light, porous, and granular saline mass—the white color merges into pearl grey or becomes yellowish or bluish. Single pieces often exhibit blue and red spots on the fractured surface. The red is caused by oxide of iron, grey by carbon particles, and blue by the action of the alkali on oxide of manganese, giving rise to small amounts of potassium permanganate. Insoluble matter in varying quantities is generally present in commercial potashes—partly due to imperfect filtration through the straw in the leaching vats and partly to ashes being carried over in the calcining furnace.

In the soluble portion potassium carbonate, potassium sulphate, potassium chloride, and potassium silicate are always present. Sodium carbonate, potassium phosphate, potassium bicarbonate, potassium hydrate, sulphide of potassium, manganate of potassium, and organic matter are sometimes present.

In the insoluble portion there is always silicic acid present, and sometimes silicate and phosphate of lime, calcium carbonate, magnesium carbonate, magnesium phosphate, oxide of iron, protoxide of manganese, alumina, and lastly sand and carbon.

The caustic potash present is due to the addition of slaked lime, as stated before, and is found only in American potash. Sulphide of potash is caused by the action of organic matters on the sulphate, while bicar-

bonate of potassium must be due to the action of carbon dioxide from the gases.

Table V shows the composition of various potashes produced in America.

THE PRACTICAL UTILIZATION OF ASHES

THE INORGANIC CONSTITUENTS OF PLANT AND WOOD ASHES

Plant ashes of all kinds, as well as wood ashes, contain varying quantities of potassium salts; in fact, many herbaceous plants contain much higher percentages of this material than trees do.

Sage brush (artemesia), for example, which grows in considerable quantity in the West, contains from 5 to 7 per cent of K_2O, based on the weight of the plant, or about 20 to 30 per cent on the weight of the ash.[5] The brush must be cleared from the land to enable plowing, and this is often done by dragging heavy railroad rails over the ground, the brush being collected in piles and burned. It would not be profitable to save the ashes for leaching in this case, although they can be thrown back on the land for fertilizer.

In this connection it might be well to note that when black sage is steam distilled, an oil is produced containing considerable camphor.[6] Should the distillation of this material prove commercially possible, the waste could be burned for its potash content. That the artemesias have been considered as a source of potash is shown by the following quotation from Knapp's Chemical Technology:

"Hermbstädt planned to plant wormwood (an artemesia) for the production of potash, as it grows on very poor soil. One Magdeburg acre (18,000 sq. ft.) affords in a summer three crops, or 20,000 lb. of the dry plant, which produces 2364 lb. of ash, or 936.6 lb. of potashes. The plan was forbidden by the German Government as wormwood takes the potash out faster than it is produced by disintegration of the soil."

This artemesia is not the same as our black sage, which is perennial and would require two or three years' growth between each harvesting.

In Java the stems and leaves of the indigo plant were used to produce potash after the extraction of the coloring matter, while the Russians produce a potash for soap making from the ash of the stalks, hulls and leaves of the sunflower.[7] About one-fifth of this should be thrown back on the land for fertilizer. The sunflower industry in Russia is a large one, the seed being pressed for its oil, or eaten as peanuts are in America.[8] Cottonseed hulls were burned extensively for fuel in the Southern States, and the ashes used for fertilizer or for making potash, but at present the hulls command a higher price as cattle food. An analysis of cottonseed hull ashes is given in Table X. The mangrove tree, growing in marshes where the water is soft, contains high percentages of potash, it is stated.

Potash occurs mainly in the stems and leaves of plants. The amount present varies greatly in different parts of the plant, and is dependent upon the season of the year and the nature of the soil. Two trees of the same species, growing side by side, generally show differences in the amount of potash taken up, so that the ashes found on the market were exceedingly variable in composition.

Tables VI and VII illustrate the above facts very well.

Bottinger showed that the soil may affect the constituents of the ash. A sickly fir tree growing in the neighborhood of a manganese mine contained 15 per cent of protoxide of manganese on the weight of the ash, while in healthy wood only 2.7 per cent was found. In a like manner, Saussure got 12 per cent ash from flowering vetch growing on arable land, while from the same plant grown in distilled water only 4 per cent was found.

Prof. E. Emmons, from 150 analyses of ashes of American woods, deduced the following:

1. Proportion of ash in limbs and branches greater than in inside wood, and greater also in outside than inside wood, though exceptions occur to latter inference.
2. Inorganic matter acquires maximum proportion in bark of trunk.
3. Alkalies acquire maximum proportion in fruits and envelopes.
4. Phosphates acquire maximum proportion in outside woods, fruits and envelopes.
5. Lime acquires maximum proportion in bark.
6. Phosphates and alkalies acquire maximum proportion in bark of trunk.

The potassium found in wood ashes is extracted from the soil by the plant during its growth, the presence of potassium compounds in the soil being essential to the growth of vegetation. Consequently, wood ashes are valuable fertilizing material. Ordinary soils contain from 3500 to 12,000 lb. of potash per acre to a depth of 1 ft.

The results of many analyses of plants and plant ashes, partly of European origin, are compiled in tabular form in Tables IX and X.

It is not intended that such materials as rye, straw, potato stems, thistle, and vine pith are to be considered as a practical source for potash. These analyses are merely included for the sake of completeness. The cost of collecting such materials or even their ashes would be prohibitive.

The potash in cottonseed hull ashes varied from 10 per cent to 42 per cent and the total phosphoric acid

from 3 per cent to 13.5 per cent. Some silicate of potassium was always present.

The analyses of woods and wood ashes in Tables XI and XII have been compiled from various sources.[11]

The two analyses given on the top of the right-hand column of this page show the effect of leaching on the composition of wood ashes.

	Per Cent					
	Moisture	Phosphoric Acid	Potash	$CaCO_3$	Insol.	Undeter.
Wood ashes, leached	30.00	1.40	1.1	51.00	13.00	3.5
Wood ashes, unleached	12.00	1.90	5.5	61.00	13.00	6.6

SOME SOURCES OF WOOD ASHES

As a possible source of wood for potash purposes we may turn to our far Western sawmills. Improved sawmill and logging machinery, together with the many more or less well-developed industries using wood waste as a raw material, are doing much to lessen the wastes in the lumber business, but at best a sawmill recovers a scant 40 per cent of the total weight of wood in lumber, lath and shingles. The sawdust, slabs, trimmings and edgings are sold for fuel where there is a market for the material and the rest is burned or used for filling in tide flats and marshes. Within a radius of one small town in the State of Washington there are at least twenty-five sawmills, each of which turns out an average of 150,000 ft. B. M. per ten hour day, and this is excluding the shingle mills.

The total annual output of lumber in this small area is then approximately 1,000,000,000 board feet, or

*Retabulated from Knapp's Chemical Technology.

roughly 1,500,000 tons, assuming the low figure of 3000 lb. per 1000 ft. as the average weight of green lumber. If the manufactured lumber represents even 50 per cent of the weight of the logs and half the waste is sold for fuel purposes there is 750,000 tons of actual waste produced in this locality annually, a possible source for 1000 tons of excellent potassium carbonate, worth $85,000 to $100,000 at ordinary market rates and over $400,000 at the present rate (August, 1915).

Undoubtedly there is plenty of wood being burned by the Western sawmills to produce several times this quantity of potash. As the burners are now operated a large share of the ash is lost, due to the draft. To recover all the ashes a downcomer, together with some means for separating the ashes from the swiftly moving gases, such as a dust catcher, would have to be provided. Difficulties of a like nature have been overcome with blast furnaces and smelters, so that no serious obstacles should be encountered.

The sensible heat of the waste gases could be used for preheating the liquor where the leaching and burning operations were carried on at the same place. With properly designed burners located at the various mills the ash could be collected and sent to a leaching plant without excessive transportation charges.

It might be possible to recover considerable ash in addition from the brush and slashings which are often piled and burned in the logging operations and in the clearing of logged-off land. Several lumber companies in Washington have estimated that there are 40 cords of wood in the average acre of stumps and waste after logging operations. The waste in this part of the country would consist essentially of Douglas fir, Western hemlock and Sitka spruce. Should water freight rates between southern California and Washington ports be sufficiently low it might be possible to combine wood ashes with those produced from kelp at the seashore, thus eliminating several leaching plants and permitting production on a larger scale.

Hardwood distillation plants use considerable quantities of wood and charcoal for fuel, the ash of which is available for potash manufacture in districts where a number of plants are in close proximity. Hardwood ashes are richer in potassium than those from softwood.

Where cottonseed hulls are burned for fuel or any quantity is thrown to waste, they should be considered as a source of potash. It is hardly necessary to state, however, that the demand for potash in this country could in no way be supplied from these sources.

Peat.—According to the U. S. Geological Survey the total production of peat in the United States was 47,093 short tons.

Barometric Condensers.—The Mesta Machine Co., Pittsburgh, Pa., has issued Bulletin R, describing its barometric condensers for vacuum installations.

The Dow Chemical Company, Midland, Mich., the American manufacturer producing indigo, has increased its capital stock from $1,500,000 to $3,000,000, the additional stock being distributed as a dividend.

Erecting Acid Plants.—One indication of the unusual activity in the sulphuric acid industry is the fact that the Chemical Construction Company, Charlotte, N. C., have contracts for the erection of several concentrating plants, six Glover towers and six Gay-Lussac towers. This equipment consists of acid-proof brick and cement with no lead casing around the towers.

Canadian Salt Industry.—In Bulletin No. 325 of the Canadian Department of Mines, Mr. L. Heber Cole describes the occurrences of salt in Canada and gives a very complete account of the technology of its manufacture. A chapter on the allied industries, such as caustic soda, chlorine, etc., is also included. The report contains many illustrations, maps and diagrams of salt beds, springs, and apparatus for commercial production and discusses the present status of commercial salt production in Canada.

New Portland Cement Plant.—The Fuller Engineering Company of Allentown, Pa., has just closed the contract for the new 2000-barrel-per-day Portland cement plant for the Consumers' Portland Cement Company of Chicago. This plant is to be built at Foreman, Ark., and will be modern in every respect and electrically driven throughout with individual motors. All the latest approved methods of manufacturing will be incorporated, including a complete installation of Fuller dreadnought mills.

Rail Tests.—The Titanium Alloy Manufacturing Co. has issued Rail Reports, Bulletin No. 8, describing examinations of open-hearth rails for the purpose of determining carbon segregations and merit comparison. The rails examined were Standard A and titanium-treated and the results are represented in diagrams. Sulphur prints are given of all test pieces, showing the segregation. The following summary shows the results of these segregation tests:

Segregation	Number of Pieces Standard	Titanium-treated
0-12 per cent	45	95
12-15 per cent	5	4
15-30 per cent	49	1
30-40 per cent	8	1
Over 40 per cent	4	0

A diagram representing merit percentages, calculated by the Wickhorst formula from analyses and tests made on the above samples, shows titanium treatment to have considerably increased the merit.

Flotation of Joplin-Galena Slim

BY GEORGE BELCHIC AND GLENN L. ALLEN

The Joplin-Galena slimes constitute the material that overflows from the settling tanks and deposits in slime ponds. It may be divided into two classes: (1) slimes formed from a free milling ore, and (2) slimes formed from a "chatty ore," the latter being an ore in which the minerals are finely disseminated in the gangue rock and consequently requires finer crushing. The following screen analysis will suffice to show the difference in fineness of the material, as well as the assay, of slimes formed from chatty and free-milling ores:

Table I.—Slimes formed from a chatty ore taken from a Joplin mill. This material assays 6.55 per cent metallic zinc, and 99 per cent of it passes through 150 mesh.

Table II.—Slimes made from a free milling ore, taken from a Galena, Kan., mill, and assaying 7.82 per cent metallic zinc.

Table III gives the analyses of six samples of slimes taken from various ponds in Galena, Kan., these samples covering the district geographically.

TABLE III

Sample	Per Cent Zinc	Per Cent Lead	Per Cent Iron	Per Cent Insoluble
1	3.77	0.69	4.58	85.87
2	7.82	1.09	4.46	70.75
3	5.57	0.37	10.78	78.81
4	3.69	0.41	3.08	88.87
5	7.43	0.45	7.81	81.23
6	4.20	0.26	4.18	81.27

The flotation tests were carried out with a laboratory experimental machine, and over a hundred tests were made, in order to establish the following factors:

1. Kind and amount of oil.
2. Effect of adding acid.
3. Effect of temperature.
4. Ratio of dilution of pulp.
5. Speed of agitation of propellers.
6. Time of agitation.

The oils used in the tests were pine oil, creosote oil, tar oil, crude petroleum, crude carbolic acid, cresylic acid, eucalyptus oil, rosin oil, oleic acid, rape seed oil and various combinations of the above. Tests were also made with mixtures of the above oils with carbon-bisulphide, benzine-sulphonic acid, kerosene, turpentine, etc. Summarizing the results of the numerous tests the following facts were established:

1. Good results may be obtained without the use of sulphuric acid, although a small quantity (0.5 per cent of the weight of dry slime) in many instances brought the extraction somewhat higher without, however, increasing the zinc tenor of the froth-concentrate. With Kansas crude oil the addition of sulphuric acid is detrimental to flotation. Better results may be obtained if benzine-sulphonic acid be used instead of sulphuric acid with both crude petroleum and tar oils.

2. Comparatively high temperature (60 deg. C.) gives better results with light pine oils and rape seed oil, while room temperature (25 deg. C.) is better suited for the heavy tar oils and crude petroleum.

3. Speed of agitation was found best between 1200 and 1500 r.p.m. Above 1500 r.p.m. gangue material is often thrown over with the froth. Excessive speed of rotation produces, in many instances, air bubbles as large as 2 in., which carry readily both gangue and sulphide particles.

4. Pulp dilution varies with the fineness of the slimes. With very fine slimes a 7:1 dilution was found to give the best results. With coarser slimes a 3:1 dilution worked satisfactorily. With those slimes, in which a large percentage of the particles is in colloidal form, greater dilution is necessary to suspend the particles and allow the oil to surround the sulphide grains. Mechanical adhesion of sulphide and gangue particles in the froth are readily visible in slimes of this character.

5. Time of agitation in these tests ranged from five to ten minutes. This, however, is not so important since on a commercial scale the operation may be continuous.

6. The oils that gave the best results were the following:

Pine oil (specific gravity 0.937) gave a froth-concentrate assaying 53 per cent metallic zinc, with an extraction of over 73 per cent; 2.5 lb. of oil and 10 lb. of sulphuric acid were used per ton of dry slime. The slime feed assayed 5.17 per cent metallic zinc with a trace of lead.

Rape seed oil (specific gravity 0.85) gave a froth-concentrate assaying 48 per cent metallic zinc, with an extraction a little over 55 per cent when used in quantity of 10 lb. of oil per ton of dry slime, and without the use of acid. The slime feed assayed 5.17 per cent metallic zinc with a trace of lead.

Benzine-sulphonic acid and tar oil (1:1 by weight) gave good results when used in the quantity of 8 to 10 lb. of the mixture to the ton of dry slime; a froth-concentrate assaying 56 per cent metallic zinc with an extraction of over 50 per cent was obtained. The slime feed assayed 3.69 per cent metallic zinc and 0.41 per cent metallic lead.

Carbon-bisulphide and rosin oil (1:1 by weight) gave a froth-concentrate assaying 40 per cent metallic zinc, with an extraction of 50 per cent when used in the quantity of 5 lb. of the mixture to the ton of dry slime. The feed assayed the same as the one above.

These preliminary results would indicate that the Joplin-Galena slimes, which at present are a waste product, might be treated on a commercial scale by flotation, and by this means the loss of zinc in milling in this district might be greatly reduced.

Division of State Chemical Research,
Department of Chemistry, University of Kansas,
Lawrence, Kansas.

The Driver-Harris Wire Co., Harrison, N. J., will erect a brass foundry, the contract having been let.

California Gold and Petroleum Yield.—The gold yield of 999,113 fine ounces in 1914, valued at $20,653,496, was, with the exception of 1883, the greatest of any year in California since 1864, according to the State Mining Bureau. California leads all States in this item, as well as petroleum, which is the largest single item, the 1914 figures for which were: 102,881,907 barrels, valued at $47,487,109.

Electrolytic Antimony Refining*

BY ANSON G. BETTS

It is already known that antimony may be electrolytically deposited in a very satisfactory mechanical condition from the fluoride solution, and that the deposit does not carry down antimony salt with it, as the deposit from the chloride solution is apt to do. I have shown that the fluoride solution, for an easy anode reaction, should not contain sulphates or other oxygen acids, or their equivalents, because the anode reaction tends to the formation primarily of antimony sulphate, for example, which quickly decomposes into an insoluble basic sulphate (Transact. Am. Electrochem. Soc., vol. 8, p. 187, 1905). This material insulates the anode surface, and by raising the electromotive force helps the solution of the less-readily attacked constituents of the anode. The fluorine anion is relatively sluggish, and in presence of the more easily transported sulphion, for example, forms at the anode a small proportion only of the directly soluble antimony fluoride. To achieve at once complete solution of the anode as fluoride, it is necessary to exclude all other anions from the solution.

It has not been known how the impurities of the antimony anodes will behave. Lead can be expected to form lead fluoride, which by reason of its insolubility may remain largely in the anode slime. Bismuth also makes an insoluble fluoride in the presence of free hydrofluoric acid, and in the absence of stronger acids, and may be expected to remain in the anode slime, if the solution is rightly proportioned.

Silver stands about 0.6 volt below antimony in the scale of electromotive forces of solution, and could only be expected to remain in the anode residue as metal; gold would, of course, act likewise, and for the same reason.

Copper is readily dissolved as anode in a fluoride solution, and stands so near antimony in the scale that it might seem unlikely that copper would remain undissolved if there is the usual polarization voltage at the anode surface of 0.1 to 0.2 volt, even with a pure fluoride solution. It will be shown by what follows that generally copper does not dissolve at the anode, and knowing the ready solubility of copper fluoride, we can be quite sure that the copper remains in the slime in the metallic condition.

Arsenic is also very near to antimony in the electrochemical scale, and is thought to have a higher deposition voltage than antimony. One would expect that arsenic would dissolve from the anode, and not depositing so rapidly as the antimony, would accumulate in the solution until by virtue of its increasing concentration it finally deposited in the cathode metal as fast as it dissolved from the anode. This expectation was not realized experimentally.

The first experiment was made in a paraffined wood cell holding about 1500 c.c., fitted with a stirrer which at times stopped working and detrimentally affected the experiment, but not seriously.

The anode was 1 x 4.25 x 6 in. (2.5 x 10.5 x 15 cm.) and weighed 3655 grams. Analysis showed it to contain 74.79 per cent antimony, 11.88 arsenic, 3.98 lead, 3.25 copper, 0.16 iron, 2.58 bismuth and 0.092 silver.

The solution was made up to contain in 100 c.c., 10 grams of antimony as trifluoride, besides potassium fluoride and hydrofluoric acid in the proportions given by the formula $SbF_3.KF.HF$. The mixture crystallized partly, so the solution was not as strong as was intended.

The cathodes were of copper, spaced about one inch (2.5 cm.) from the surfaces of the anode. The current used varied from two to three amperes, and mostly it was very near 2.1 amperes, corresponding to a current density of 6.6 amperes per square foot, or 73 amperes per square meter. The electromotive force was near 0.6 volt, but this increased after two or three days, as the slime layer grew thicker. The slime was removed occasionally, to prevent this undue voltage with the consequent increased solution of impurities from the anode that one would expect. The deposited metal was removed from the cathodes frequently, and the percentage of impurity it contained was determined. No appreciable quantity of impurity was found in any of it, except about 0.35 per cent of Pb, and some As. The principal results are shown graphically in Fig. 1. It was noted that the percentage of As in the metal deposited only varied a little, depending on the rate of circulation to a slight extent, but more on the current density and on the amount of slime on the anode.

The amount of arsenic in the solution at all times was small, the amount being plotted in Fig. 1. Com-

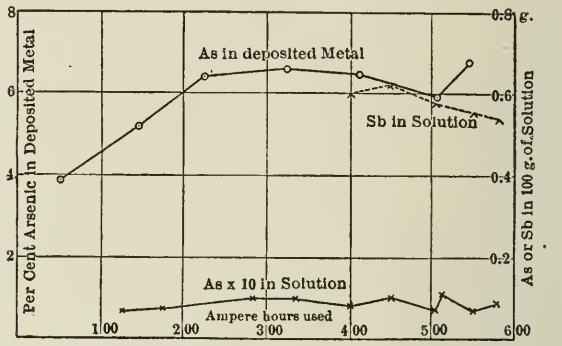

FIG. 1—AMOUNT OF ARSENIC IN SOLUTION AND IN CATHODE DEPOSIT

paratively, the As is far more concentrated in the cathode metal than in the solution, which shows it to be more readily precipitated than antimony. As/Sb in cathode metal approximated to 0.065, while As/Sb in solution approached 0.016.

The deposited metal was at all times hard, solid and non-projecting.

The principal conclusions to be drawn are: (1) there is no difficulty in eliminating lead, bismuth, and copper under these conditions, which are rather severe with so low a proportion of antimony in the anode metal; (2) the solution does not become contaminated with impurities; (3) the physical condition of the deposit is all that could be desired; (4) the required current density is less than is desired and generally used for other metals, and the voltage is a good deal higher; (5) only about half the arsenic could be kept in the anode slime.

The additional analyses which were made in connection with the experiment are given in Table I:

Samples of the cathode metal for analyses were fused under KCN, before the analyses. The weight of anode decomposed was 853 grams, and of metal deposited, about 675 grams. There was 199 grams of slime produced. Some metal was found in the bottom of the cell.

In the preceding experiment the anode contained a larger percentage of impurity than is usual in electrolytic refining of metals. As it was impossible to conclude that with an anode containing less impurity arsenic would remain entirely, or in larger proportion, in the anode residue, another experiment was necessary.

Part of the old anode was melted with an equal

*A paper presented at the San Francisco meeting of the American Electrochemical Society, September, 1915.

quantity of fresh antimony, and was cast into a new anode, which should have had about the following composition: 87.5 per cent antimony, 5.95 arsenic, 2.0 lead, 1.65 copper, 1.3 bismuth, and 0.16 iron. (It was not analyzed.)

The solution and cathodes were the same as were used in the former experiment. The current density was about 6 amperes per square foot, and electromotive force 0.6 to 0.65 volt. The electrolysis was continued for about 36 hr., and 250 grams of the anode was decomposed, while 221 grams was deposited on the cathodes. The anode slime was very soft and readily removed, and did not interfere with the solution of the metal underneath, as was the case in the first experiment.

The electrolyte was analyzed at intervals for As, which was found to amount to 0.06 gram As per 100 c.c. during the entire experiment. The first 143 grams deposited contained As, 4.23 per cent; Cu, Pb, Bi, none, and the 78 grams following contained 13.9 per cent As and 25.3 per cent Sb.

The conclusions are these: (1) With an anode of this composition the electrolysis goes smoothly, and there is no need of scraping the anode slime from the anodes; (2) a larger proportion of the arsenic goes into the cathodes, viz.: 60 per cent as against about 40 per cent of the total As in the first experiment. The deposit was physically good, perhaps a little better than before. Cu, Pb and Bi may be separated from antimony in this way.

When a solution of arsenious chloride is heated with metallic copper, a black arsenide of copper is precipitated on the copper. To learn whether the presence of copper would tend to retain arsenic in the anode slime as an arsenide of copper, thus yielding a purer antimony deposit at the cathode, an anode was made containing about 84.8 per cent antimony, 5.4 arsenic, 1.8 lead, 6.65 copper and 1.2 bismuth.

In refining this anode, the solution and conditions were the same as in the preceding experiment, except that the stirring was even more vigorous this time. At the end of 31 hr., the solution contained 0.045 per cent As and the deposited metal 3.15 per cent As, with only a trace of copper.

The result shows the effect of copper in holding back arsenic in the slime to be certainly small, if there is any such effect at all.

Following up the discovery that arsenic tends to deposit from the fluoride solution more rapidly than antimony, in proportion to the quantities present, it becomes important to know if in depositing antimony from the fluoride solution containing sulphuric acid, with an insoluble lead anode, as is sometimes done in treating Pb refinery anode slime, the arsenic present in the solution could not be collected with the first part of the antimony, thus producing the latter, and perhaps, greater part of the antimony in pure form.

One thousand four hundred cubic centimeters of solution was used containing about 124 grams of antimony and 5.3 grams of As as trifluorides, 1 or 2 grams HF, and 65 grams H_2SO_4; or per 100 c.c. Sb 8.85 grams, As 0.38 grams, HF about 0.1 gram, H_2SO_4 4 grams. The solution was electrolyzed at the ordinary temperature with two copper cathodes, having an active area of 24 sq. in. (150 sq. cm.), and with a lead anode, cotton-covered, having an active area of about 2.5 sq. in. (15.6 cq. cm.). The current was 1.2 amperes, or a cathode current density of 7.2 amp. per square foot (80 per sq. m.).

Analysis of the solution was made at intervals for antimony and arsenic, the difference between two consecutive analytical results showing the quantities deposited. The results are plotted as Fig. 2, in which the curves show grams of antimony, and twenty times the grams of arsenic per 100 c.c.

Only one analysis of deposited metal was made, that of the first 9 grams deposited, which contained 5.0 per

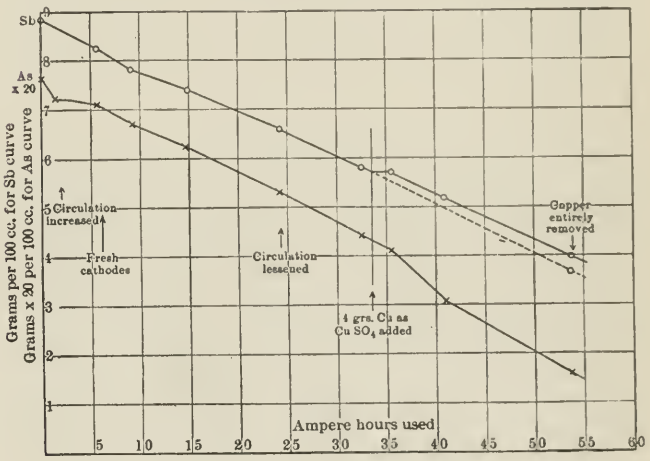

FIG. 2—ANTIMONY AND ARSENIC ANALYSES

cent As. The proportion of As to Sb at the start was 4.3 per cent.

Referring to the figure, the Sb and As curves, up to 34 amp. hr. show that the Sb and As are depositing out in very nearly the same proportion as they exist in the solution. If any separation of the two were practicable in this way, the favorable conditions of this experiment, low current density, and very good circulation, should show it. During the experiment the rate of circulation was changed to see if it made any difference, but none was detected.

After about 34 amp. hr. of current passed, and it was seen that no practicable separation of As and Sb was indicated with this solution, copper sulphate was added to the solution, to see if copper in depositing would have any tendency to carry As out with it. Furthermore, copper is usually present to some extent in the antimony fluoride solutions resulting from the treatment of lead-refining slimes by hydrofluoric acid, and in removing that copper by electrolysis with a very low density, arsenic might be found to separate with it.

The conclusion of the experiment showed that copper has a tendency to do this, but the effect is too small to be of any use.

The continuation of the Sb curve in a dotted line is derived by subtracting from the antimony found by analysis, the antimony equivalent of the copper added.

Calculating the ratios of antimony and arsenic in the deposited metals and in the solution, in the beginning of this experiment they are respectively about 19.1 and

23.1, so that the relative speed of deposition of antimony and arsenic in proportion to the amounts present, is about 1: 1.2.

With the solution used in the antimony refining experiments, the principal difference being that the refining solution contained no sulphuric acid, the corresponding ratio is about 1: 4.2. The presence of sulphuric acid interferes to a large extent with the tendency toward separation of the two elements.

With such a refining solution as that used in the first experiment described, there is sufficient difference in the behavior of arsenic and antimony to make possible a differentiation of the deposited metal into two parts, one a good deal lower in arsenic and the other higher, by alternately causing the refining solution to circulate rapidly and remain at rest. If the solution were electrolyzed quietly, keeping the anode away from the cathode, and removing a large proportion of the metal from the solution in contact with the cathodes, the deposited metal should contain only about 1 per cent of As instead of 6 per cent, as the total quantity of As present in the solution is so small. If the solution is then rapidly circulated so that the As brought into solution from the anode could be quickly brought to the cathodes, the proportion of As deposited should be much greater than 6 per cent, perhaps as high as 25 per cent.

The simplest way in which to carry out this idea of producing two quantities of antimony, one very high and one very low in arsenic, is to cause the solution to pass in turn through a cell with strong agitation, and one with as little agitation as possible, preferably arranged so that the heavy solution running down the anode surface could be collected in the bottom of the quiet cell, and siphoned out into the agitated cell.

The apparatus used consisted of one main wooden cell 38 cm. deep by 12.75 cm. by 20.3 cm., with a capacity of about 10 liters, and a series of four auxiliary cells 12.9 cm. deep by 7.75 cm. by 7.75 cm., with a total capacity of about 3 liters.

The main anode, about 1.8 cm. thick by 15 cm. by 30 cm. was suspended in the middle of the main tank, between two copper cathodes.

The first of the small cells, through which the solution from the main tank passed, contained one anode of the same composition as the main anode, and a copper cathode, the active anode or cathode area being about 6.8 cm. by 10 cm.

In the other three tanks anodes of pure Sb, and Cu cathodes were used, of the same size as those in the first of the small tanks. The alloy to be refined contained 84.0 per cent antimony, 5.4 arsenic, 3.6 copper, 3.7 lead and 1.1 bismuth.

The solution was made to conform to the formula SbF_3.NaF.KF.HF, and should have contained 4.4 grams Sb, 1 gram Na, 1.4 grams K, and 0.8 gram HF per 100 c.c. A small quantity of salts crystallized out and a very little solution was spilled, so the solution was undoubtedly somewhat weaker and contained at the end of the experiments only 1.8 per cent Sb. This lowering would, of course, result from the conversion of the lead in the anode to lead fluoride with the reduction of the corresponding amount of antimony.

Some difficulty was experienced in regulating the flow of solution through the tanks, and the stirrers sometimes stopped during the night.

With an electromotive force of 1.35 volts the large tank used (at about 17 deg. C.) 8.5 amp., and the four small tanks in multiple about 15 amp., or current densities of respectively 1.2 and 0.4 amp. per square decimeter (12 and 4 per square foot).

The large tank was fitted with a distributer, so that the heavy solution flowing in from the four small purifying tanks should mix with the light solution at the top of the large refining cell.

The heavy solution running down the anode collected in the bottom of the tank and was continuously removed to the purifying tanks through a rubber tube.

During the first experiment the heavy solution at the bottom of the refining cell and in the purifying cells contained about 6.2 per cent Sb, and the solution at the top of the refining cell 3.3 per cent Sb.

The character of the deposit in the four purifying cells was different, that in the first cell especially being darker, duller and less crystalline, and containing more As, as was expected.

After three days the solution in the first three of the purifying cells contained:

No. 1	0.148 per cent arsenic
No. 2	0.133 per cent arsenic
No. 3	0.122 per cent arsenic

The purification was evidently less complete than could be inferred from the fact that the solution in the first refining experiment contained only about 0.05 per cent As.

After five days the upper three-quarters of the main cathode was collected and melted separately from the bottom quarter. The upper 660 grams contained 3.0 per cent As and the lower 210 grams contained 3.4 per cent As. To the solution was then added enough NaF to correspond to the formula SbF_3.2NaF.KH.HF. The solution crystallized a little, so it was taken out, filtered, mixed and analyzed, showing it to contain 0.07 per cent As, and put back.

After five days more 1060 grams of cathode metal was found to contain 3.18 per cent As.

The analyses of Table II are of the slime produced in the first five days, the second five days, and that taken from the first small cell.

Table II

	First Slime, per Cent	Second Slime, per Cent	Slime in Small Cell, per Cent
Arsenic	8.2	8.17	8.5
Antimony	7.16	7.94	16.7
Lead	26.9	28.1	
Copper	30.1	26.2	
Bismuth	6.53	5.4	

Thinking that a diaphragm might keep the impure anode solution in the refining cell away from the cathodes, a muslin diaphragm was used, reaching nearly to the bottom of the cell. The diaphragm was of two or three thicknesses, spaced ½ in. (1.25 cm.) in the clear from the anode surface. The current was reduced to 5.5 amp. for the large cell and 1.5 amp. for the four small cells in multiple. After six days electrolysis the figures of Table III were obtained by analysis of the products:

Table III

	Grams	Per Cent Arsenic
Upper third	240	3.4
Middle third	275	3.3
Lower third	260	3.3
Small tank No. 1	59	4.6
Small tank No. 2	87	3.9
Small tank No. 3	75	3.9
Small tank No. 4	100	3.9

The absence of a diaphragm was evidently not the weak point in the first part of the experiment, as the result was practically the same either way. The percentage of As in the metal deposited in the four small tanks was evidently much less than indicated from the

ratio of 1: 4.2 for As in metal found in the first experiment. The difference must be due to a difference in the temperature, current density, or composition of the solution.

Another run of four days with the addition of four grams HF per liter yielded products analyzing as stated in Table IV.

TABLE IV

	Grams	Per Cent Arsenic
Main cathode metal	430	3.6
Small tank No. 1	17	6 6
Small tank No. 2	23	6.3
Small tank No. 3	20	6.1
Small tank No. 4	20	5.8
Total of small tanks	80	6 05

The improved, but still unsatisfactroy result, is believed to be due to the presence of more HF in the solution.

The solution (now thrown away) contained 1.8 per cent Sb and 0.06 per cent As, giving a ratio calculated as before of 1:2 since

$$\frac{\text{As in solution}}{\text{Sb in solution}} = 0.033 \text{ and } \frac{\text{As in metal}}{\text{Sb in metal}} = 0.066.$$ Ratio is 1:2

It was concluded that a study of the ratio

$$\frac{\text{As in solution}}{\text{Sb in solution}} : \frac{\text{As in metal}}{\text{Sb in metal}}$$

with varying solution composition, temperature, current density, and perhaps other factors is necessary for successful refining by this method.

Experiments were then made to determine the effect of temperature on the amount of As passing over into the cathodes. As there is a counter e.m.f. even with the fluoride solution, sometimes as high as 0.2 volt, it might be possible by raising the temperature to reduce the anode e.m.f. to a point where antimony but not arsenic could be dissolved.

The solution used contained, in 100 c.c., 3 grams NaF, 11 grams SbF_3 and 1 gram HF. Three small rubber jars were arranged as electrolytic cells at temperatures of 30 deg., 40 deg., and 50 deg., respectively. The current varied from 1 to 1.4 amp., corresponding to a current density per square foot of 14 to 20 amp., with an e.m.f. per cell of about 0.9 volt. After 43 hr. electrolysis the experiment was discontinued with these results:

Thirty degree cell short circuited, 35 grams deposited, in smooth condition at the bottom and rough and flaky on top.

Forty degree cell, 54 grams deposited, rather smooth and even throughout.

Fifty degree cell, 45 grams deposited, in still smoother condition.

The deposits were melted and analyzed for As, with these results:

Temperature, Degrees	Arsenic, per Cent
30	3.5
40	3.6
50	3.9

I tried the purification of antimony from arsenic by crystallizing the melted metal analogously to the purification of lead and bismuth by crystallization. Numerous experiments with antimony-arsenic alloys containing from 3 to 8 per cent of arsenic gave in all cases crystals and liquid portions containing the same percentages of arsenic.

The alkaline sulphide solution of antimony was tried as a refining medium. The solution was made by dissolving 30 grams of SbF_3 in 500 c.c. sodium sulphide solution of specific gravity 1.19. The solution was electrolyzed warm with the same composition of anode as used in the last preceding refining experiments.

After 24 hours' run the cathode deposit averaged 1.0 per cent As and after 48 hours 2.1 per cent As.

Returning to the original idea of refining in the usual way, with the fluoride solution, some of the refined antimony containing about 3 to 3.5 per cent arsenic was cast in the anode and again refined in the same way. About half of the arsenic remained in the anode slime. By several refinings the arsenic may probably be eliminated.

The most positive reaction noted in these experiments is that due to the composition of the solution. An increase in HF is highly beneficial and the presence of sulphates or sulphuric acid is shown to be objectionable. It is likely that the hydrofluoric acid may have contained traces of sulphuric or fluosilicic acid, and the negative results might have been traced to that cause. The effect of alkaline fluorides and ammounium fluoride should be studied, also.

A successful method of electrolytic refining of antimony should receive technical application, inasmuch as present methods do not save the gold frequently present and are incapable of making a product of a high and uniform grade at all comparable to the copper, lead and silver on the market.

Gas Analysis

Technical paper 104 of the Bureau of Mines deals with the "Analysis of Natural Gas and Illuminating Gas by Fractional Distillation at Low Temperatures and Pressures," the authors being G. A. BURRELL, F. M. SEIBERT and I. W. ROBERTSON.

"This publication, which is one of a series dealing with the increase of efficiency in the production and utilization of fuels, describes in detail the results of experiments, made by the Bureau of Mines, with a method of separating and determining the hydrocarbons in gaseous fuels. The method employs fractional distillation in a vacuum at low temperatures. The gas is liquefied, the different constituents separated by proper adjustment of temperatures, the various fractions removed with a mercury pump, and these fractions analyzed by ordinary slow-combustion methods. The method was successfully applied to the separation of hydrocarbons in natural gas and in artificial illuminating gas, and is the only known method applicable to the separation of some hydrocarbons."

The first part of this report describes the results of experiments by which the natural gas used in Pittsburgh, Pa., was separated into its individual paraffin hydrocarbons. The second part describes experiments in which the separation of the illuminants in artificial illuminating gas, that used in Pittsburgh, Pa., and that used in New York City, was effected. Some experiments to determine the practicability of separating gases whose boiling points lie close together, such as ethane and ethylene, are included.

"Each year much experimental work is done in the destructive distillation of different fuels, liquid, gaseous and solid, which yield complex mixtures of different hydrocarbon gases. In reports on these tests some of the gases are not separated, but are invariably lumped together as illuminants (determined by absorption in fuming sulphuric acid, or bromine water) or calculated in the combustion analysis as methane and ethane. By the methods described in this publication the gases can be separated into the individual constituents. Hence a wide field of investigation is opened up, in that a much more exact study of combustion processes can be made and chemical changes more closely followed and better understood."

The Electrolytic Precipitation of Gold, Silver and Copper from Cyanide Solutions*

BY G. H. CLEVENGER

(*Concluded from page* 806)

Practice at San Sebastian, Salvador

The original electrolytic precipitation plant installed at Butters' Salvador Mines, San Sebastian, was similar to the Minas Prietas plant.

However, after being placed in operation it was found necessary to modify the practice in several important particulars. The two wooden containing boxes used were 30 ft. (9 m.) long, 10 ft. (3 m.) wide, and 4 ft. 8 in. (1.4 m.) in depth. The bottom was given a slope to one side at the rate of 1 in. per foot (8 cm. per m.). Each box was divided into twelve compartments, ten of which were used for precipitation, the last two merely serving as settlers. Each compartment contained 25 anodes and 24 cathodes.

The anodes were rolled lead plates $\frac{1}{8}$ in. (0.3 cm.) thick, 22 in. (55 cm.) wide and 48 in. (120 cm.) long. For some time the anodes were peroxidized in a special cell using an electrolyte consisting of 1 per cent of potassium permanganate and 2 per cent sulphuric acid; but later untreated lead plates were used.

At first tinplate cathodes similar to those used at Minas Prietas were tried, but certain difficulties arose which made it necessary to abandon the tinplate cathode. The original intention was to deposit the gold and copper as a non-adherent slime, as at Minas Prietas, but despite the fact that a higher current density was used the gold and copper were deposited upon the cathodes as a quite firmly adherent coating.

*A paper read at the San Francisco meeting of the American Electrochemical Society, September, 1915.

The predominating metal in the solution at Minas Prietas was silver, but at San Sebastian it was copper. The well-known fact that silver is very prone to give non-coherent coatings, while copper has a strong tendency to give adherent coatings, seems to offer a ready explanation of this difference.

The removal of the strongly adherent copper-gold plating from the tin cathodes presented a most difficult problem. Various expedients for removing it were tried, such as heating the cathodes with a gasoline torch, scraping and pounding them, etc. After these various heroic measures had proved ineffective, it was decided to return to the lead-foil cathode cut into strips, as used in the Siemens-Halske process. When it was desired to "clean up," the lead-foil strips were removed, ground and shipped to smelters for the separation of the metals.

The current was supplied by a belt-driven Siemens-Halske dynamo giving 450 amp. at 30 to 35 volts. The current density was 10 amp. per square foot (110 per sq. m.) of anode surface, and the voltage across anodes and cathodes was 4 to $4\frac{1}{2}$.

This general practice was continued until C. P. Richmond modified it so that the metals could be separated locally. The lead-foil cathodes were replaced by sheet-lead cathodes 1/16 in. (0.15 cm.) thick, 22 in. (55 cm.) wide and 48 in. (120 cm.) long, so arranged that they could be readily removed from the containing box. To this end, the connecting wires for the cathodes, instead of being soldered to the copper bus bars, were clamped by wing-nuts in split studs screwed into the bus bars.

The general arrangement of the preciptation box is shown in Fig. 3. The wires from five anodes and cathodes of opposite compartments were laid in each

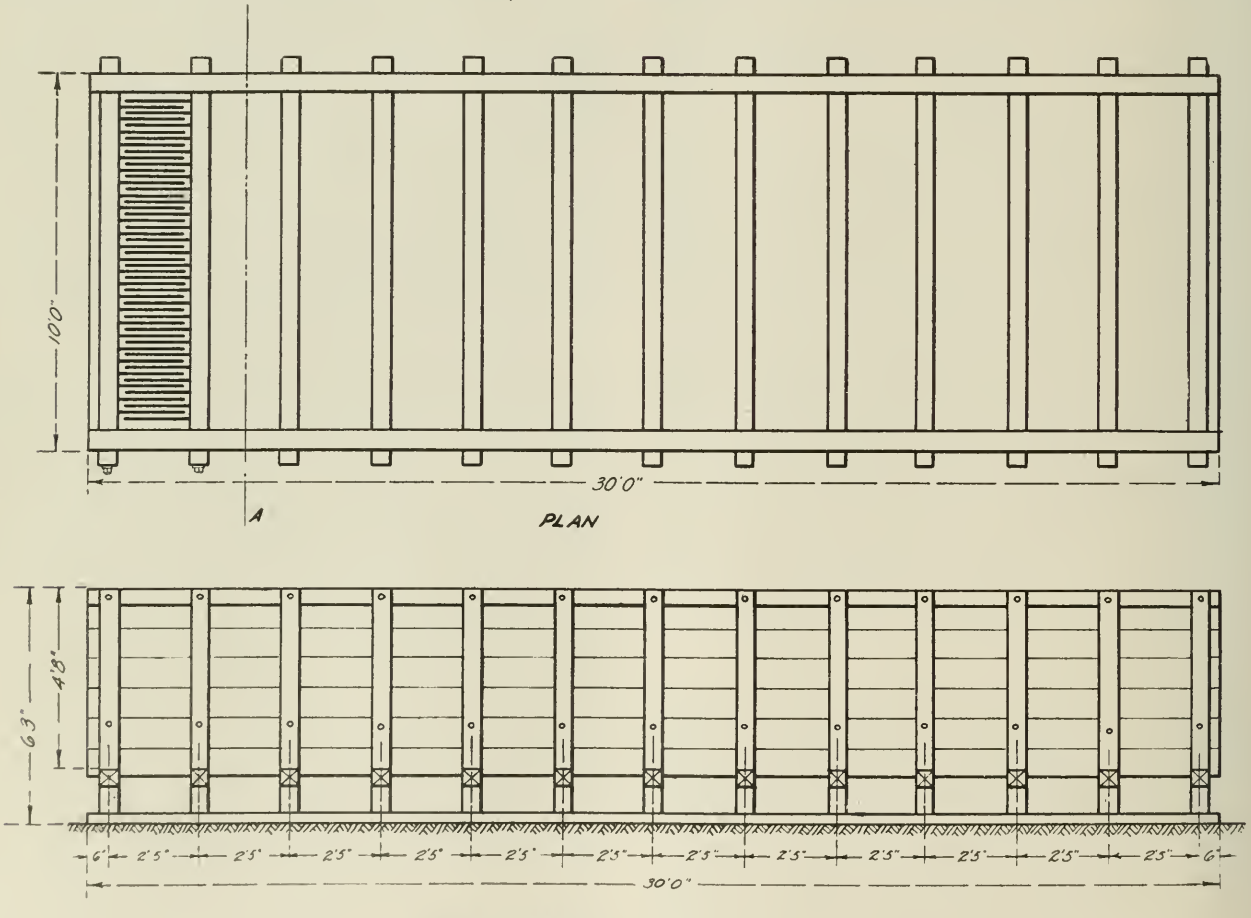

FIG. 3—ELECTRIC PRECIPITATION BOX, SAN SEBASTIAN, SALVADOR

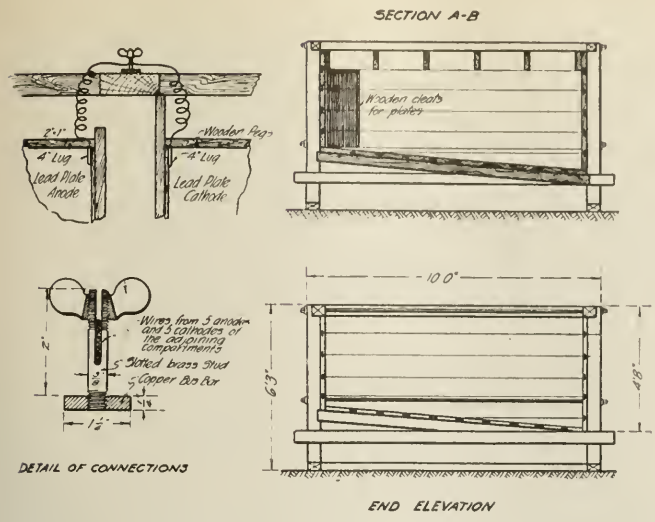

FIG. 3A—DETAILS OF FIG. 3 (ELECTRIC PRECIPITATION BOX)

slot and a tight connection secured by screwing down the wing-nut. The studs were spaced 19 in. apart and six of them connected the cathodes of one compartment to the anodes of the adjoining compartment. By this arrangement it was possible to remove any of the cathodes without interrupting the flow of current or solution.

At San Sebastian it was found advantageous to operate so as to keep the concentration of the copper down to a point where it did not interfere with gold extraction, and precipitate the remaining gold by zinc shaving. This was done despite the fact that zinc was said to interfere with electrolytic precipitation in South Africa.

The solution leaving the electrolytic boxes was divided between two zinc boxes, each 22 ft. (6.6 m.) in length and having 14 compartments, 2 ft. (60 cm.) by 1 ft. (30 cm.) and 2 ft. (60 cm.) deep, filled with zinc shaving. The ore treated was a high-grade gold ore containing considerable pyrite and sufficient copper left in the soluble form after the roasting which preceded cyanide treatment, to occasion trouble in cyanidation unless electrolytic precipitation were used.

The average gold content varied, but at the time that electrolytic precipitation was in use ranged from 2 to 4 oz. (58 to 117 g.) per ton. The soluble copper varied from ½ to 2½ lb. (0.23 to 1.14 kg.) per ton. The ratio of gold to copper in the electrolytic deposit ranged from 1 to 7 up to as high as 1 to 25, but generally was between the limits of 1 to 9 and 1 to 14.

The average results of two months, taken at random, will give a general idea of the performance. During this period there was treated 45 tons of ore daily, averaging 2.27 oz. (66.2 g.) gold per ton. Approximately 150 tons of solution was precipitated daily. The average content of the head solution was: Gold, 0.79 oz. (13.0 g.) per ton; copper, 0.075 per cent; cyanide, 0.118 per cent. The average content of the tail solution from the foot of the zinc box was: Gold, 0.004 oz. (0.117 g.) per ton; copper, 0.048 per cent; cyanide, 0.154 per cent. The percentage of gold in the deposit at the head of the electrolytic box was about 7; at the foot of the box it was about 3. The current density was 1.0 amp. per square foot (11 per sq. m.) of cathode surface. The voltage across the anodes and cathodes of each compartment was 4 to 4½.

During the treatment of the ore there was consumed 7.2 lb. (3.27 kg.) of sodium cyanide per ton. There was precipitated in the electrolytic boxes 1.5 lb. (0.68 kg.) of copper and apparently there was regenerated 1.92 lb. (0.87 kg.) of cyanide, in terms of potassium cyanide, per ton of ore treated. Eighty to 90 per cent of the gold and most of the copper was precipitated in the electrolytic boxes. Passage through the zinc boxes brought the total percentage of gold precipitated up to 99.5.

The zinc boxes precipitated little copper, despite the fact that the solution invariably contained copper at this point. Under normal conditions the percentage of copper in solution remained more or less constant, any increase through contact with the ore being precipitated by the electrolytic boxes. When the copper built up in the solution, as was sometimes the case through treating ore containing an unusually high percentage of copper, the bad effect was at once noted upon the gold extraction.

ELECTROLYTIC REFINING OF THE CATHODE DEPOSIT

After the cathodes had remained in the precipitation boxes 20 to 30 days, during which time they had increased in weight from 8 to 12 lb. (3.5 to 5.5 kg.), they were removed and, after draining, were connected as anodes in a special electrolyzing cell shown in detail in Fig. 4, containing an electrolyte of 2 to 3 per cent sulphuric acid, which was thrown away when its strength was reduced to 1 per cent.

They were here enclosed in compartments so constructed as not to interfere with the free passage of the current, and which served to collect the gold slime freed by solution of the copper of the deposit. The compartments consisted of a wooden frame having a pocket at the bottom somewhat larger than the cathode plate, covered on both open sides with cotton twill held in place by tacking. The cathodes used in the refining boxes were lead plates 1/16 in. (0.16 cm.) thick, 22 in.

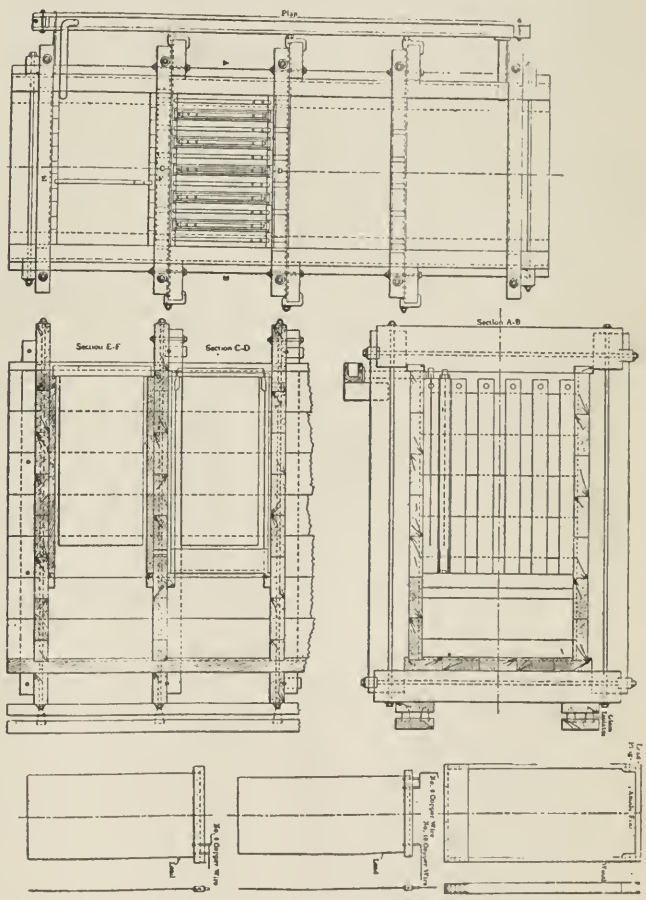

FIG. 4—ACID REFINING TANK, WITH DETAILS OF ANODE AND CATHODE

(55 cm.) wide and 48 in. (120 cm.) long. The refining box contained four compartments, each holding 5 anodes and 6 cathodes. The spacing between the plates was 4 in. (10 cm.). The compartments were connected in series and received a total current of 450 amp.

The average voltage across the electrodes of each compartment was 8. The current density was approximately 5 amp. per square foot (55 per sq. m.) of anode surface.

The copper was deposited at the cathode as a flocculent non-adherent precipitate, which collected in the bottom of the main cell, while the gold slime remained inside of the cloth-sided compartments surrounding the anodes. When the operation had proceeded to the point where all of the copper of the copper-gold deposit was dissolved, the anode plates were removed, washed and replaced again in the regular precipitation box as cathodes. The time required for dissolving the deposit on a plate was from 48 to 72 hr.

Two electrical connections were provided for each cathode; one, a No. 10 copper wire, used when the plate functions as cathode in the regular precipitation box, and the other a No. 6 wire, which is used for carrying the heavier current employed in the refining cell. Both wires are permanently soldered to the lead lugs cast on the plate.

Beginning at the head of the precipitation box the cathodes were removed and, as refined, replaced, thus gradually working down toward the foot of the precipitation box. By the time that the foot of the box was reached, the cathodes at the head were again ready for refining. The total time of "cleaning up" a precipitation box was from 25 to 30 days. Consequently the operations of cleaning up and refining were going on almost continually.

The solution in the acid refining box was circulated by a lead air-lift. The interval between "clean-ups" of the refining box varied from 15 to 25 days, depending upon the quantity of copper which accumulated at the bottom of the cell.

The copper capacity bore a definite ratio to that of the anode compartments, so that when the former was full the latter was about three-quarters filled. By this time the twill sides of the receptacle were so weakened by the acid that they required replacement.

When it was desired to "clean up" the refining box, the acid electrolyte was siphoned into a storage tank and the anode receptacles were raised and allowed to drain over the refining box. They were then placed in an upright position upon a washing board supported above a tank provided with a filter bottom, the twill was cut down the sides, removed, and the gold slime washed into the tank. The wooden frames were well scrubbed and the twill washed over the same tank, after which it was burned in a dryer. When thoroughly drained, the gold slime was removed from the tank, dried and united with the ashes from the twill.

After mixture with the proper fluxes it was melted in graphite crucibles heated in an oil-fired furnace. The buttons resulting from the preliminary melts were combined, remelted and cast into bars 700 to 800 fine for shipment.

The copper slime was flushed through 1½ in. (4 cm.) holes bored in the side of each compartment 1 in. (2.5 cm.) above the bottom into a cement launder in the floor which conveyed the slime to a tank outside the building provided with a filter bottom. After draining and drying it was sampled and boxed for shipment. The dried copper precipitate contained 84 to 87 per cent metallic copper and 1.82 to 3.72 oz. (53 to 108.5 g) gold per ton. The total time required for a clean-up was 7 hr. A number of years ago, when this system of refining was in operation, the net returns from the copper more than paid all the expense of refining, melting the gold and shipping the copper.

Practice at Virginia City, Nevada

In the installation of the electrolytic precipitation plant at Virginia City, Nevada, Messrs. Charles Butters & Co., Ltd., had the benefit of the experience gained at the plants previously installed on the Rand, South Africa, at Minas Prietas, Mexico, and at San Sebastian, Salvador. This resulted in several quite important improvements.

Originally there were nine boxes, similar to that shown in detail in Fig. 5, the plan being to use three of these boxes for precipitating copper from a preliminary wash by sulphurous acid, which, when the plant first began operations, was intended to precede cyanide treatment. The other six boxes were to be used for precipitating gold and silver, together with any remaining copper from the cyanide solutions.

The preliminary treatment with sulphurous acid was finally abandoned and direct cyanidation practiced.

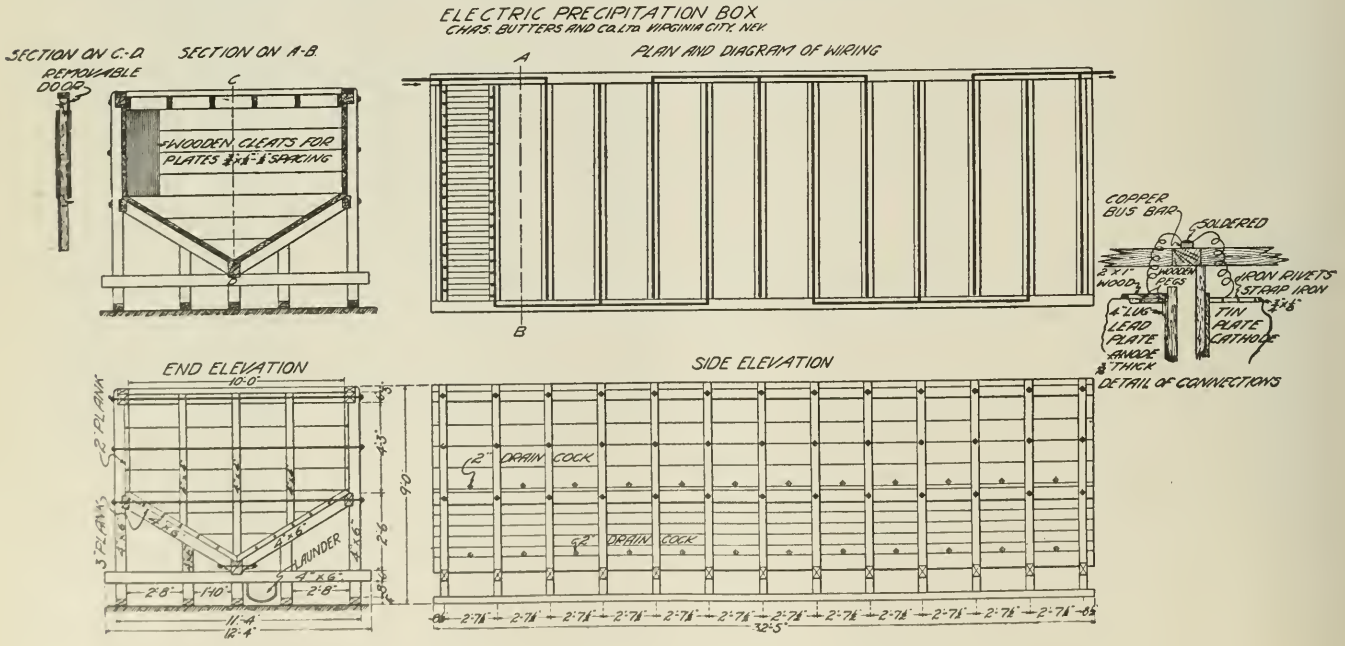

FIG. 5—PRACTICE AT VIRGINIA CITY, NEVADA

The precipitation practice finally evolved for the cyanide solution was to use four of the boxes in pairs of two arranged in tandem, the solution issuing from the first set of boxes passing through the second set. As at San Sebastian, electrolytic precipitation was followed by zinc shaving. The zinc box was improvised by placing screens in the bottoms of a number of the compartments of two of the discarded electrolytic boxes.

At Minas Prietas the method of handling the precipitate was rather crude, as a part of the cathodes and anodes had to be removed to give access to the bottom of the boxes during the "clean-up." At Virginia City this feature of the process was greatly improved by constructing the precipitating boxes with hopper bottoms. In each compartment where one of the sloping sides of the hopper joined the vertical side of the box was located a valve through which the bulk of the solution contained in the box could be drawn prior to sluicing out the precipitate. At the apex of the hopper in each compartment was located another valve through which the slime could be sluiced to a launder which conveyed it to a small concrete tank equipped with a mechanical agitator, whence it was pumped by a centrifugal pump into an ordinary distance-frame and plate type of filter press. After drying, the precipitate was sampled and shipped to the Selby Smelting Company. Later a refinery was built.

The precipitate, after retorting to recover mercury, and after the addition of the proper admixture of fluxes, was melted in graphite crucibles heated in specially designed tilting furnaces.

With the arrangement described above it was not necessary to disturb the anodes or cathodes when cleaning up.

Each box had twelve large compartments, in which were suspended 18 peroxidized sheet-lead anodes ⅛ in. (0.32 cm.) thick, 25 in. (63 cm.) wide and 48 in. (120 cm.) long, and 18 tin-plate cathodes of the same size. Sheet aluminum cathodes were also tried.

Later, an anode composed of lead rods, detail drawing of which is shown in Fig. 6, was used. The advantage of this anode was that it could be made locally from scrap lead or old anodes. The Wood dynamos, each giving 500 amp. at 50 volts, and direct connected to an induction motor, furnished the current.

The character of the ore treated at this plant varied greatly. Originally it was built to treat a large accumulation of tailing which had resulted from the treatment of Comstock ores by pan-amalgamation. Later Comstock ore and concentrator tailing, and ore from the Tonopah district of Nevada, were treated. The treatment of outside ore began before the exhaustion of the tailing, so that at times there was a varying mixture of tailing and ore treated.

The pan-amalgamation tailing had been re-treated a number of times by the same process and was, therefore, very low grade. It contained copper, mercury and chlorides as a result of the chemicals added during pan-amalgamation.

The tonnage and metal content of the solution varied considerably, but the following is an average of the results obtained over a considerable period when treating pan-amalgamation tailing exclusively, and precipitating 474 to 668 tons of solution daily. There was no distinction made between the solution originating from the sand and slime treatment, the two being combined for precipitation.

The average content of the head solution per ton was: Gold, 0.033 oz. (0.97 g.); silver, 0.78 oz. (22.7 g.); no record of copper determinations; cyanide, 0.046 per cent; protective alkali, 6 points. The tail solution from the electrolytic box contained: Gold, 0.01 oz. (0.29 g.); silver, 0.22 oz. (6.4 g.); cyanide, 0.066 per cent; protective alkali, 4 points. The zinc-box tails contained: Gold, 0.003 oz. (0.09 g.); silver, 0.03 oz. (0.88 g.).

The current density was 0.245 amp. per square foot (2.7 per sq. m.) of anode surface. The voltage across the anodes and cathodes in each compartment was 3.1.

The average content of the head solution when treating a mixture of Tonopah ore and pan-amalgamation tailing was: Gold, 0.055 oz. (1.61 g.); silver, 3.15 oz. (91.9 g.); cyanide, 0.18 per cent; protective alkali, 10 points. The tail solution from the electrolytic boxes, when precipitating 432 tons per 24 hr., contained: Gold, 0.02 oz. (0.58 g.); silver, 0.60 oz. (17.5 g.); cyanide, 0.18 per cent; protective alkali, 10 points.

The current density was 0.245 amp. per square foot (2.7 per sq. m.) of anode surface. The voltage across the anodes and cathodes in each compartment was between 3.1 and 3.2. Four lots of precipitate contained

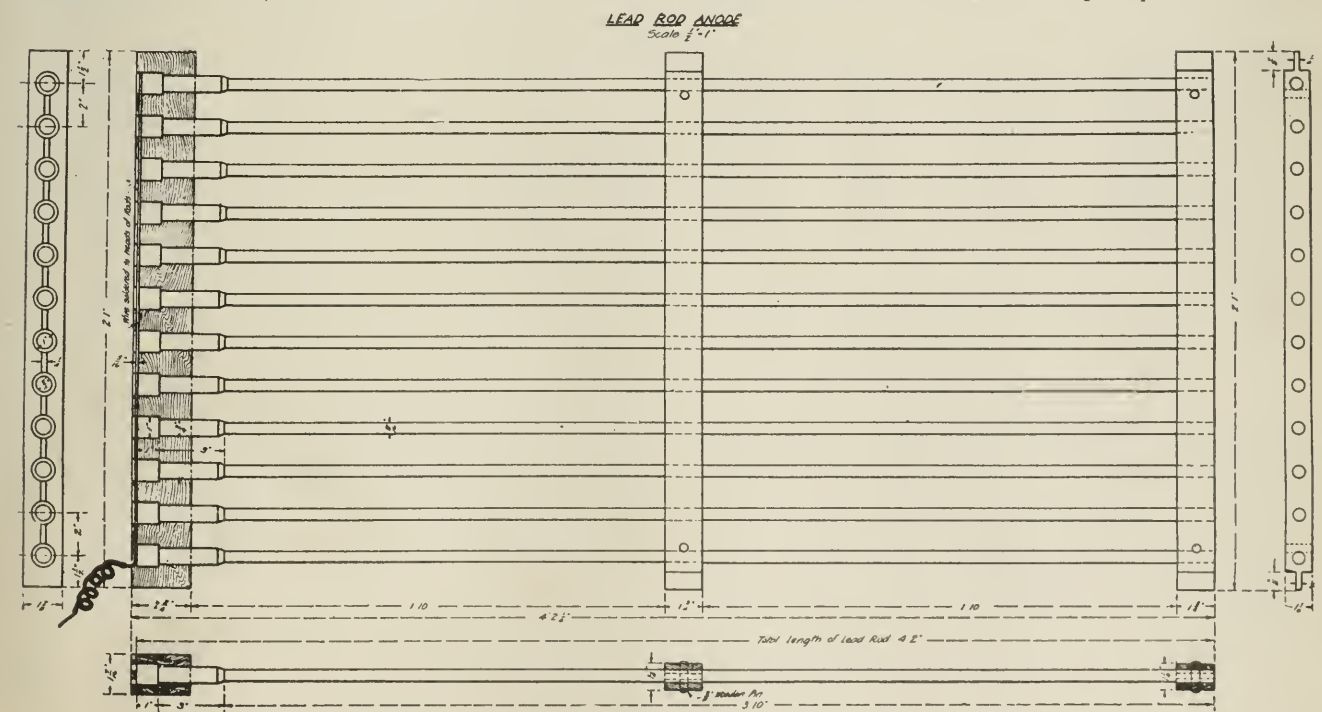

FIG. 6—LEAD ROD ANODE

the percentages of gold, silver and copper, given in Table I.

Table I

	Per Cent		
	Gold	Silver	Copper
A	0.23	9.60	26.60
B	0.23	8.49	29.25
C	0.29	9.99	31.40
D	0.27	7.97	20.10

Table II shows the results obtained in one of the boxes when the conditions of tonnage precipitated, current density, voltage, etc., were the same as those given above.

2d zinc compartment	46.20	1 03	52.77

In the case of the electrolytic box, each sample was taken directly from the surface of the cathode.

Practice at El Rayo, Mexico

The equipment installed at El Rayo followed rather closely the lines of that used at San Sebastian, Salvador, and consisted of one wooden box 10 ft. (3 m.) wide by 20 ft. (6 m.) long, 4 ft. (1.2 m.) deep on one side and 5 ft. (1.5 m.) deep on the other, with the usual arrangement of wide and narrow compartments. In each of the seven wide compartments were installed 25 sheet-lead anodes, 20 in. (50 cm.) by 40 in. (100 cm.) and 1/8 in. (0.37 cm.) thick. Alternating with the sheet-lead anodes, there were 24 sheet-copper cathodes, 20 in. (50 cm.) by 40 in. (100 cm.) and 1/32 in. (0.16 cm.) thick. Electrical connection of the anodes and cathodes to the bus bars was made by means of lead plugs cast onto the plates, to which were soldered copper connecting wires. The current was supplied by a Crocker-Wheeler generator giving 500 amp. to 50 volts.

At the time that this installation was made zinc-dust precipitation of the gold and silver was giving satisfactory results. A change in the character of the ore indicated that trouble might arise through a greatly increased proportion of copper. It was, therefore, planned to continue to precipitate the gold and silver by zinc and depend upon electrolytic precipitation to keep the copper in solution down to a concentration which would not interfere with cyanide treatment. To this end 200 tons of solution, the total flow from the zinc precipitation equipment, was passed through the one electrolytic unit. The intention was to deposit the copper in as pure a state as possible so that it could be marketed directly. Certain difficulties arose in accomplishing this end, and before they were overcome, the proportion of copper in the ore had decreased to a point where it was no longer necessary to use electrolytic precipitation.

The equipment was not dismantled and stood as originally installed until the exigencies of the Mexican revolution caused the management to turn to it in an effort to conserve both cyanide and zinc. In this case the original practice was reversed. The cyanide solution was passed directly from the treatment tanks to the electrolytic precipitation box and from thence to the zinc-dust precipitation equipment. There was an average of 200 tons per day of solution precipitated. The average content of this solution was as stated in Table IV.

Table IV

Simple alkaline cyanide	0.15 per cent
Total cyanide	0.38 per cent
Alkalinity	100 points
Copper	0.12 per cent
Zinc	0.05 per cent
Gold	0.30 oz. (8.8 g.) per ton
Silver	5.00 oz. (146 g.) per ton

Approximately 65 per cent of the gold and silver, 20 per cent of the copper, and a small amount of zinc were precipitated by electrolysis. There was a gain in cyanide strength of about 0.075 per cent, with a considerable decrease in the alkalinity. The current density used was 1.2 amp. per square foot (13.2 per sq. m.) of anode surface. Under these conditions of operation the lead anodes disintegrated very rapidly.

Practice at Nelson, British Columbia

In 1907, Douglas Lay described a modified Siemens-Halske installation in use at the Reliance mill, Nelson, British Columbia. The three wooden containing tanks were 35 ft. (10.5 m.) long, 5 ft. (1.5 m.) wide, and 3 ft. (0.9 m.) deep, inside dimensions. The anodes were No. 10 sheet iron (0.35 cm. thick), 5 ft. 1 in. (153 cm.) by 2 ft. 8 in. (80 cm.), set in saw cuts three inches (7.5 cm.) apart, made in the sides and bottom of the containing tank.

The alternate downward and upward flow of the solution, by which means it was caused to pass uniformly by the anode and cathode surfaces, was attained by setting each alternate anode 1½ in. (4 cm.) off the bottom of the box, the solution passing under these anodes and over those set into the bottom of the box.

The anodes were enclosed in cheesecloth to prevent short circuiting. Connections to the main positive wire, which rested in a groove in the top of one side of the box, was made by means of lead plugs cast in holes bored downward to intersect the top edge of the anodes where they rested in the saw cuts in the side of the box.

The cathodes were sheet lead about 1/40 in. (0.6 mm.) thick, made by a special casting process at the Trail smelter, and of approximately the same area as

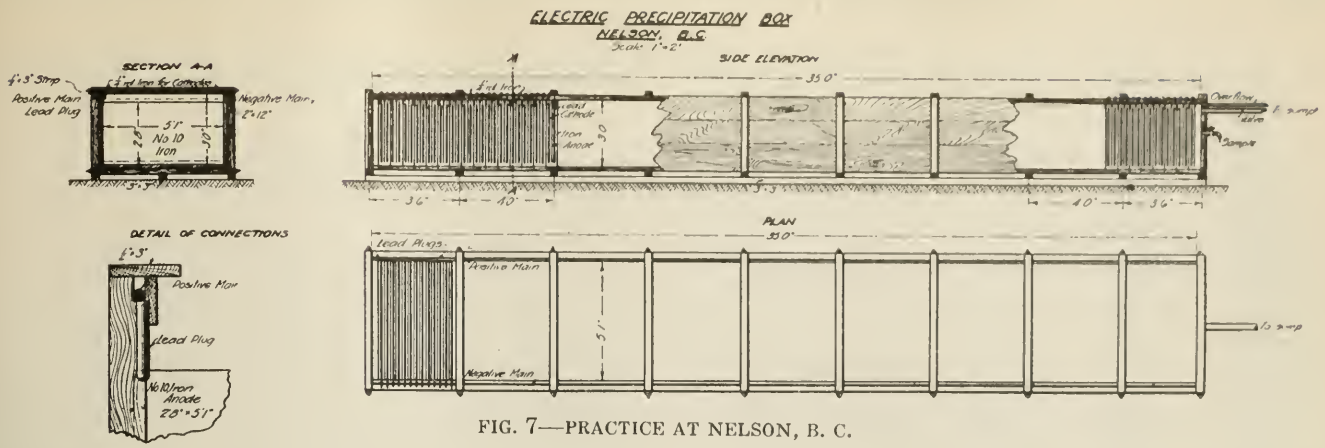

FIG. 7—PRACTICE AT NELSON, B. C.

the anodes. For convenience in handling, each cathode was made up of three sheets, each weighing about 7 lb. (3 kg.), attached to a ¼-in. (0.6 cm.) round iron cross-bar by two strips of roofing tin.

The cathodes previous to being used were dipped momentarily in a slightly acidic solution of zinc chloride to clean them thoroughly. Connection of the cathodes to the main negative wire, which rested on top of the opposite side of the box from the positive main, was made by direct contact of the cross-bar at one end with the negative wire upon which it rested. The other end of the cross-bar rested upon a strip of wood which insulated it from the positive main.

The distance between the anodes and cathodes was therefore 1½ in. (4 cm.). Each box contained approximately a total of 3500 sq. ft. (320 sq. m.) each of anode and cathode surface. A detailed drawing of the whole arrangement is shown in Fig. 7.

The three boxes precipitated 150 tons of solution per 24 hr., resulting from the treatment of 50 tons per day of low-grade gold ore containing 0.20 oz. (5.8 g.) gold ($4.00) per ton. The solutions precipitated were kept at 70 deg. Fahr. (21 deg. C.). A low current density of 0.02 to 0.03 amp. per square foot (0.22 to 0.33 per sq. m.) of cathode surface was used. The voltage across the anodes and cathodes was 4 to 5.

Accurate figures are not available for the composition of the head solution precipitated, but the following are reasonably accurate estimates: Gold, 0.06 oz. (1.75 g.) ($1.20) per ton; cyanide, 0.01 to 0.05 per cent, and protective alkalinity, 0.03 per cent lime. The tail solution contained from a trace to a few cents in gold per ton.

When protective alkali was present there was no loss of cyanide in passing through the precipitation box, but when there was no protective alkali about 30 per cent of the cyanide was decomposed by the current. Presence of sufficient alkali also caused the iron dissolved at the anode to separate as ferric hydroxide, instead of the Prussian blue formed when there is insufficient alkali.

In this installation a special arrangement was made to run off the ferric hydroxide which collected on the surface of the solution, by shutting off the regular outflow and allowing the solution to rise above the tops of the high anodes and overflow momentarily from an auxiliary outflow carrying with it the ferric hydroxide. This operation required but two or three minutes upon each shift.

Anodes

Iron anodes were used with the Siemens-Halske process in South Africa, but lead, with a few exceptions, has been used in American practice. Various other anode materials have been tried but, everything considered, lead is the most satisfactory. One important advantage that lead has over many other anode materials is that it has a certain salvage value after it has served its useful life as an anode. It has been used both plain and peroxidized, but in general the peroxidized anodes have had the longest life.

Many investigators have reported certain anodes as being satisfactory when used in cyanide solutions, but these tests carried on in a small way have always covered entirely too short a period of time. The fact that an anode will stand up for two or three days of continuous operation in no way signifies that it will be satisfactory for a period of operation sufficiently long to make its use commercially economical.

Experiments with Acheson graphite have been most disappointing, notwithstanding the favorable reports made by other investigators who have tried out this material in a small way for short periods of time. The graphite anodes gradually become mushy and soft, and finally are useless. The reason for the failure of the graphite anode is not clear, but at one time I thought that it was due to the disintegration of the binding material used in the original carbon plates from which the graphite plates were made. In other words, the graphite resulting from the carbonaceous binding material of the original carbon plate does not appear to form a strong union with that resulting from the carbon proper of the plate.

The sheet-lead anodes are made up as shown in Fig. 8. The sheets of lead, after cutting to the desired size, are thoroughly cleaned and in one corner or on the two opposite corners of the short dimension of the sheet is cast a special connecting lug, ½ in. (1.3 cm.) in diameter by 4 in. (10 cm.) long, by means of a special iron mold which firmly clasps the plate at the point where the lug is to be attached. The lugs are cast from lead to which has been added a small amount of tin, to lower its melting point. The temperature of the lead used in casting the lug should be such that does not melt through the lead sheet, but still is sufficiently hot to form a thorough union with the lead sheet. A tongued wooden supporting strip is attached to the top of the plate by means of wooden pins.

The lead-rod anodes are made up as shown in Fig. 6. Lead rods of the form shown in the drawing are cast in special iron molds, observing the usual precautions for preventing the oxidation of lead during melting and the obtaining of a clean, smooth casting free from holes or spongy spots. Twelve of these rods supported in strips of pine drilled to receive them at the bottom, at the center and at the top, comprise an anode.

The bottom and center strips are 1.75 in. (4.4 cm.) by 1.25 in. (3.2 cm.), and are kept from shifting by means of wooden pins which engage the two outside rods. These also serve to prevent short-circuiting of the tinplate cathodes, which have a strong tendency to buckle.

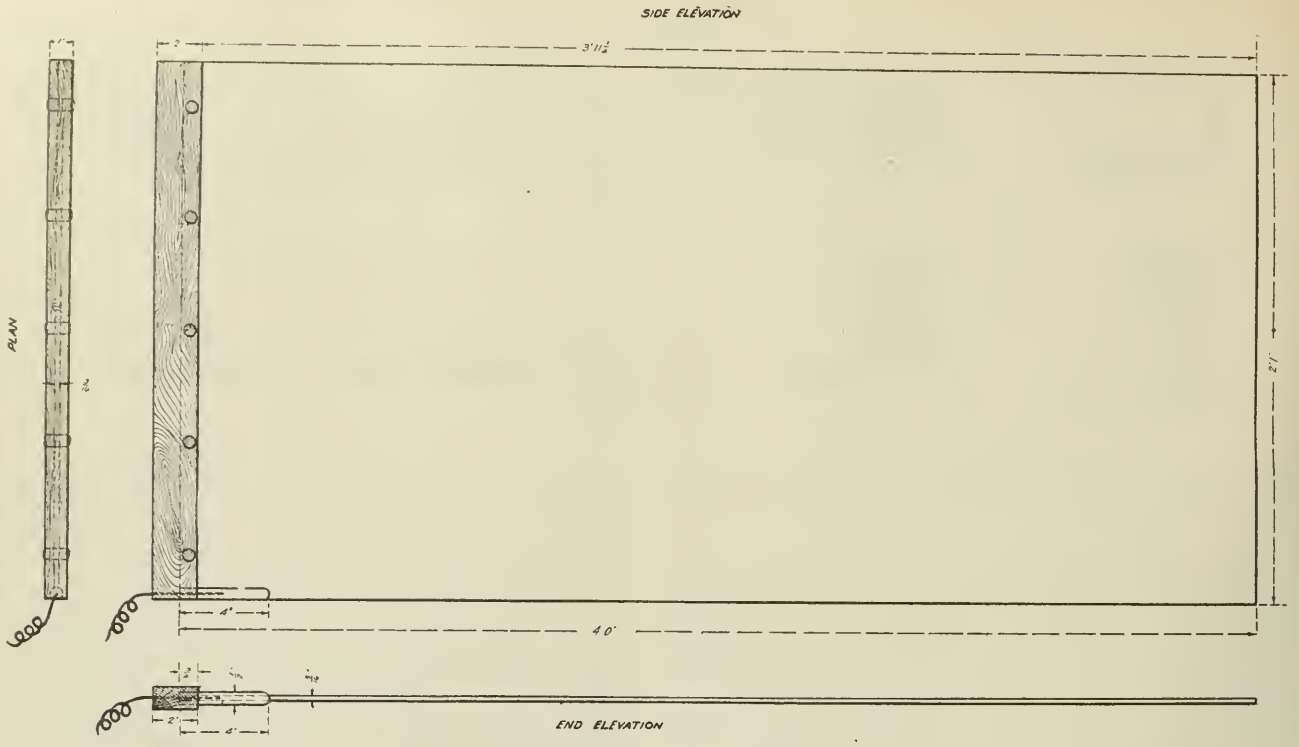

FIG. 8—LEAD PLATE ANODE

The top strip, 2¾ x 1⅞ in. (7 x 4.7 cm.), is counterbored to receive the large ends of the rods and supports the whole weight of the anode.

Electrical connection to the individual rods is made by soldering to them a No. 10 (2.5 mm. diameter) copper wire, which rests in a groove at the top of the strip. The continuation of this wire serves as the means of connecting the anode to the bus-bar.

The method of peroxidizing the anodes varied somewhat at the different plants. This operation was performed in a separate cell where a few anodes at a time were treated. The first step was to clean and brighten thoroughly the surface of the lead with a scratch brush.

At Minas Prietas a 1 per cent potassium permanganate solution was used and a current density of 1 amp. per square foot (11 per sq. m.). The time was 1 hr. or longer. During the operation the strength of the solution was frequently tested with a standard solution of ferrous sulphate, fresh permanganate being added to keep the solution as near 1 per cent as possible.

At San Sebastian various combinations were tried, but the practice that met with the most favor was to use an electrolyte containing 1 per cent of potassium permanganate, 2 per cent of sulphuric acid and a current density of 2½ amp. per square foot (27.5 per sq. m.). The time of treatment was 6 hr.

In passing, it is well to mention that it has been found in certain of the electrochemical industries that a denser and more satisfactory coating of the peroxide is formed if the operation is performed in an alkaline solution.

At Virginia City the peroxidized lead anodes had a life of about one year. At San Sebastian, on account of the higher current density the life was 8 to 12 months. At Minas Prietas the life was in some cases considerably over a year.

Cathodes

The lead-plate cathodes used at San Sebastian were constructed similar to the anodes, except that the sheet lead used was thinner.

An interesting feature of the lead cathodes used at the Reliance mill was that they were not ordinary rolled sheet lead, as had been previously used elsewhere for both anodes and cathodes, but were plates cast upon an inclined machine at the Trail smelter. The simplicity of the arrangement will be apparent from the drawing shown in Fig. 11. It was said that one man could make 500 cathodes in a shift.

The tin-plate cathode was made from medium-weight tin-plate, as shown in detail in Fig. 9. A piece of strap iron ¾ x ⅛ in. (1.9 x 0.3 cm.), whose length was the same as the width of the plate, was riveted to the top. The connecting wire was introduced between the plate and strap iron in such a manner that one of the rivets clamped it firmly in place.

Fig. 10 shows the tools used in removing the portion of the deposited metals which adhered to the cathodes. The double brush was used at intervals for removing the slightly adherent deposit. The manner of using was to set it over the cathode so that a brush was bearing on either side of the cathode, when the whole tool was pressed downward until the brushes had reached the bottom of the plate; this operation was repeated until the whole surface of the plate had been covered. When it was desired to make a complete clean-up, especially if the plates were old, it was necessary to remove them entirely from the box and scrape them with the triangular scraper, shown in Fig. 10.

By-Products of Electrolytic Precipitation

The by-products which appear to be inevitably produced during electrolytic precipitation and which are particularly troublesome when treating gold ores on account of the greater value of the metal involved, have always formed a most serious problem.

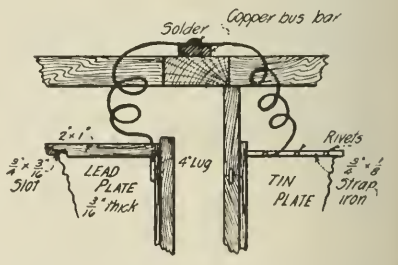

FIG. 8A—DETAIL OF CONNECTIONS (SEE FIG. 8)

In the Siemens-Halske process the Prussian blue, formed as a re-

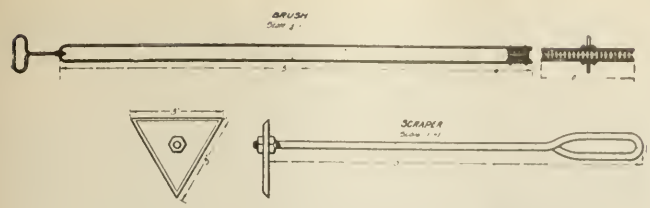

FIG. 10—TOOLS FOR CLEANING CATHODES

sult of the attack on the iron anodes, had to be subjected to special treatment for the recovery of the cyanide and gold which it contained. The disadvantages arising through the separation of calcium salts, which deposited upon the anodes and cathodes and in the bottom of the box, was early noted in the application of the process. It has been variously estimated that from 0.6 to 25 per cent of the gold had to be recovered from the by-products in the Siemens-Halske process.

At Minas Prietas, the precipitation of calcium salts was especially troublesome, and owing to the method of operating in which the non-coherent deposit of the metals was collected in the bottoms of the boxes, all of this eventually became intermingled with the precipitate. At this time the calcium salts, chiefly the carbonate, formed a large proportion of the precipitate.

TABLE V.—ANALYSIS OF LIME DEPOSIT

	Per Cent
Moisture	0.275
Loss upon ignition	6.060
Calcium oxide	41.580
Carbonic acid	31.120
Lead metallic	13.530
Iron oxide	0.540
Copper metallic	0.750
Sulphuric acid	4.400
Chlorine	0.670
Vanadium	0.095
Silver	0 126
Gold	0.003
	99.149

This made the precipitate more difficult and costly to smelt. In Table V is given a typical analysis of the lime deposit at the plant.

Lowered current density lessens the formation of the lime precipitate. In the course of time the lead anodes disintegrated to the extent that they had to be discarded. At first these were shipped to lead smelters, but later they were remelted locally, and after the separation of the dross, which had to be shipped to the smelter, were cast into slabs which were rolled by a special set of rolls into sheets which were used in making new anodes.

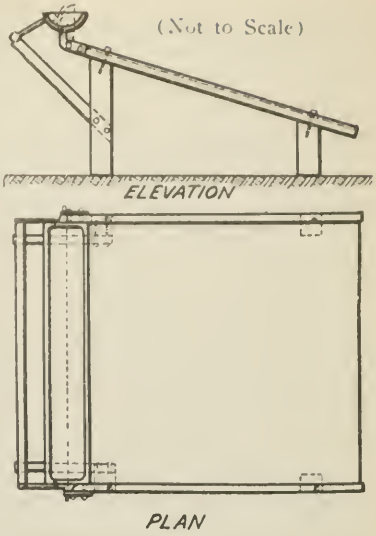

FIG. 11—CASTING MACHINE FOR LEAD PLATE CATHODES, TRAIL SMELTER, B. C.

At San Sebastian, where the gold and copper formed a coherent deposit upon the cathodes, it was possible to keep the deposit which accumulated at the bottom of the box separate from the deposited metals. However, the gold contained in this material was considerable, and at one time, when a considerable amount of it had been allowed to accumulate, it represented a great deal of value. The material more directly resulting from the disintegration of the anodes contained:

Lead	53 7 to 57.1 per cent
Copper	3.1 to 4.7 per cent
Gold	0 031 to 0.154 per cent

The fine material, or "lime" as it was termed, contained:

Silica	8 to 10 per cent
Alumina	22 to 28 per cent
Calcium oxide	15 to 21 per cent
Lead	Not determined
Copper	5.9 to 6.9 per cent
Gold	0.322 to 0.363 per cent

A small blast furnace and other refining equipment was installed for treating the by-products, but on ac-

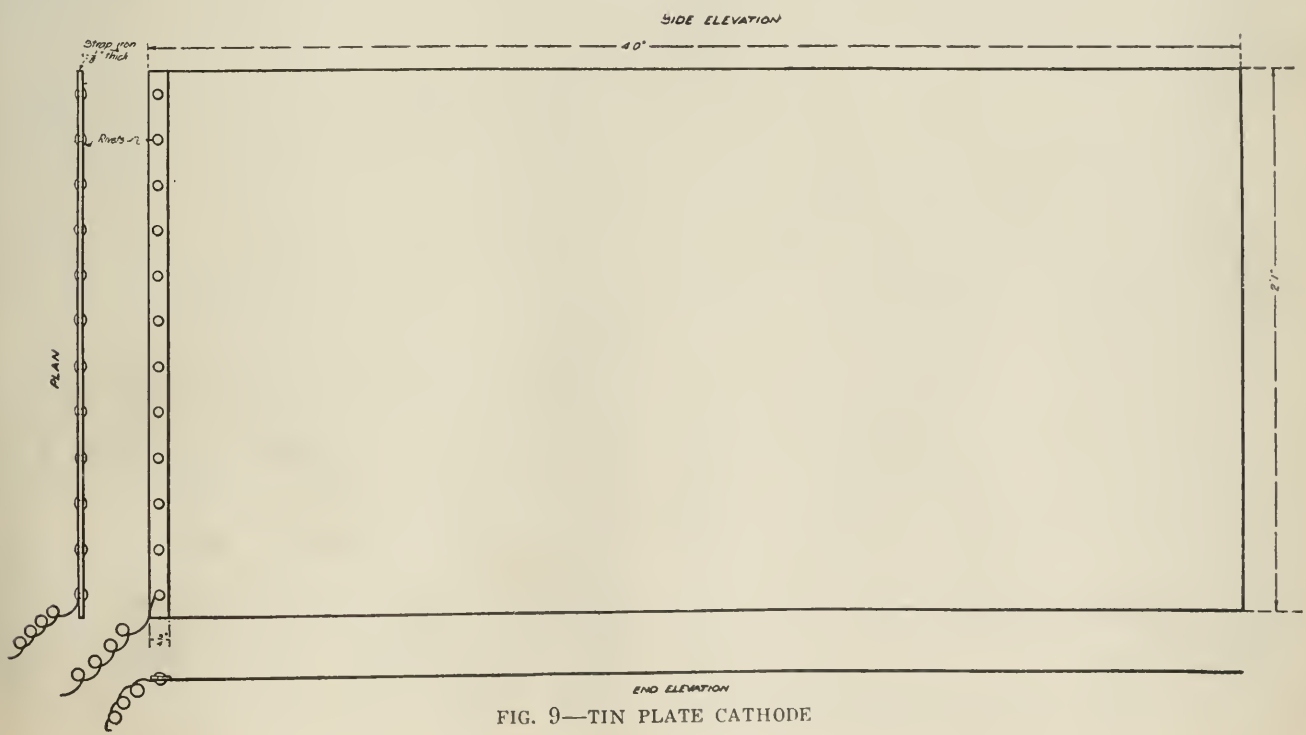

FIG. 9—TIN PLATE CATHODE

count of the high cost of coke and other supplies and the lack of skilled labor, it was generally found more economical to ship this material to smelters in the United States. No attempt was made at this plant to reclaim the anodes.

At Virginia City the conditions were much the same as at Minas Prietas. A much lower grade precipitate was invariably obtained from the electrolytic boxes than from the zinc boxes on account of the calcium precipitate. At one time, as the result of careful sampling and assaying, it was estimated that the anodes contained about 10,000 ounces of silver. This came about by reason of the fact that the solutions contained chlorine. The source of this in the tailing was the salt which had been added during pan-amalgamation and, in the Tonopah ore, was due to the occurrence of part of the silver as chloride. The presence of the silver as chloride in the anodes was proved by solution in ammonia and the regular qualitative tests. In the earlier operation the disintegrated anodes were shipped to the smelter; but later it was found that by careful heating in suitable pots the greater part of the metallic lead could be liquated, leaving most of the gold and silver in the dross. The dross was shipped to the smelter and the lead cast into rods which were mounted in wooden supports and used as anodes.

Cost of Installation and Operation of Electrolytic Precipitation Plants

The cost of the six electrolytic precipitation boxes at Minas Prietas, Mex., was as stated in Table VI.

Table VI.—Cost at Minas Prietas

Box construction	$10,000.00
Dynamos	3,000.00
Lead anodes	4,455.00
Tin plate cathodes	300.00
Wiring, switchboards and instruments	1,000.00
Labor	1,000.00
Incidentals	250.00
Total for six boxes	$20,005.00

At Virginia City, Nev., U. S. A., the cost of six standard boxes was as stated in Table VII.

Table VII.—Cost at Virginia City

Box construction	$6,000.00
Dynamos	4,075.00
Lead anodes	4,080.00
Aluminum cathodes	*1,598.00
Wiring, switchboards and instruments	1,000.00
Labor	1,500.00
Incidentals	250.00
Total for six boxes	$18,503.00

*N. B.—Tin plate cathodes also used.

W. H. Wood, in 1899, compiled comparative figures of the cost of installation on the Rand, South Africa, of precipitation equipment for operating the Siemens-Halske electrolytic and the zinc-shaving lead-couple processes for a plant crushing 500 tons of ore per day. These are given in Table VIII.

Table VIII.—Comparative Costs

	Zinc Lead Precipitation	Electrolytic Precipitation
Extractor house space	$792.18	$2,551.50
Concrete floor	296.46	928.26
Wooden containing boxes	558.90	3,159.00
Platforms	.....	703.00
Piping	109.35	257.58
Zinc (Cut.)?	299.62	.....
Dynamo	.....	1,083.78
Lead cathodes	.....	414.32
Frames for cathodes	.....	218.70
Iron anodes	.....	1,603.80
Anode bags	.....	148.23
Wiring and proportion of power	.....	1,044.90
Proportion of general charges	71.93	424.04
	$2128.44	$12,537.11

The only costs available for electrolytic precipitation are those given in Table IX, which are the average for six years' operation of the Minas Prietas plant.

Table IX.—Electrolytic Precipitation Costs at Minas Prietas

Power	$0.083
Labor	0.037
Supplies	0.031
Depreciation	0.04
Total per ton of ore	$0.191

It will be noted that both the cost of installation and operation of electrolytic precipitation is higher than zinc precipitation.

In the preparation of this paper I am indebted to the following gentlemen: Mr. Charles Butters for information upon electrolytic precipitation obtained through visits to his plants during the time that they were in operation, as well as through personal communications; E. M. Hamilton for information contained in his paper upon the practice at Minas Prietas, also personal communications; Charles P. Richmond for information contained in his paper upon the practice at San Sebastian, also personal communications; James Colbath for the details of the El Rayo practice; Richard Snell, H. Bulmer and Robert Wisnom for certain details of Virginia City practice; Douglas Lay for information contained in his paper upon the practice at the Reliance mill, and M. F. Perry for the detailed costs of installation and operation of the Minas Prietas plant. I have freely used the information contained in von Gernet's first paper upon the Siemens-Halske process, as well as that contained in other papers upon the subject which have been published at various times in the Proceedings of the Chemical and Metallurgical Society of South Africa. I also wish to acknowledge the faithful and painstaking work of my assistant, Mr. K. Pyle, in the preparation of the drawings.

Palo Alto, Cal.

Potash.—The American Potash Company of Long Beach, Cal., has been purchased by the American Produce Company, who will operate the plant for producing potash and cellulose from kelp on a large scale.

Stamp Mills.—The Allis-Chalmers Co. of Milwaukee, Wis., have issued Bulletin 1432-A describing their stamp mills and accessory machinery for free-milling gold ores. This includes specifications for complete ten-stamp and two-stamp mills.

Abrasive Grinding Wheels.—The Abrasive Material Co., Philadelphia, Pa., has sent us its catalog of abrasive grinding wheels, and also pamphlet describing Boro-Carbone, a new abrasive which it has recently placed on the market.

Precious Metals in Colorado.—The total value of the output of gold, silver, copper, lead and zinc in Colorado in 1914 was $33,460,126, according to the annual statement of the U. S. Geological Survey. Of the total, 59 per cent represented gold.

Resistance and Inductance of Wires.—A paper dealing with experimental determinations of the electrical properties of iron and bi-metallic wires used in telephone and transmission work has been issued by the Bureau of Standards as Scientific Paper No. 252. The author is Mr. John M. Miller.

The Johnson Engineering Co., Chicago, Ill., has just shipped to the Detroit Copper Mining Company, Morenci, Ariz., two of its largest diameter Marathon mills, which will do all of the regrinding in a plant of 1800 tons daily capacity. Five of the largest diameter mills were also shipped to the Burro Mountain Copper Company, Tyrone, N. M., for regrinding in the new plant of 3000 tons daily capacity.

Manufacture and Tests of Silica Brick for the Byproduct Coke Oven*

BY KENNETH SEAVER

It is rather gratifying that in the field of the manufacture of refractories, in which, as a whole, foreign practice has surpassed us, the United States stands pre-eminent in the making of silica brick. In some instances European manufacturers have refused point-blank to credit the possibility of making to such specifications as are common with us, until the actual completed shapes were shipped for inspection. But both the manufacturer and consumer in foreign lands are now frankly learning from us, and benefiting by our advanced practice in this field, as is evidenced by the orders placed here and the efforts put forth abroad to come up to the standard of American-made material.

In no metallurgical operation has the employment of silica brick spread with such leaps and bounds as in the building of plants for the carbonization of coal, particularly in the byproduct coke oven. To-day, in practically all types of oven, the structure above the floor level (except the facings) is of silica, while in the recuperative and in some regenerative types, its use is extended to that portion of the oven below the floor as well.

By reason of the fact that there are a number of classes of refractories of higher silica content than the usual so-called fire-clay brick, there is sometimes a misunderstanding as to the class of material referred to as "silica" brick. We here refer only to a brick having a silica content of 94 per cent or more and made usually from quartzite rock with a small percentage of lime as a binder. The term "silica" brick is sometimes rather loosely applied to brick from highly siliceous clays, or to a quartzite refractory of mingled fire-clay and quartz rock; but such products are not considered in this discussion.

Materials

The rock from which practically all high-grade silica brick are made is a true quartzite or metamorphosed sandstone, variously known as ganister, quartz, quartzite, sandstone, silica rock, etc.—the fields of major importance being in the order of their relative importance, those of Pa., Wis., Ala., and Col.

PENNSYLVANIA QUARTZITE

Pennsylvania probably manufacturers from 75 to 85 per cent of all the silica brick made in the United States, almost entirely from the quartzite found in the Medina and Oneida formation. While this formation extends across the State of Pennsylvania reaching into New York State on the north, and Maryland, Virginia and still farther toward the South, the quarries are practically all in Huntingdon and Blair counties, Pennsylvania. It is in this restricted area that the quartzite is at its best. Toward the north and toward the south it becomes softer, is no longer a true quartzite, or is too much impregnated with iron. The rock is also comparatively easily accessible in the counties mentioned, enormous quantities lying loose upon the surface. The particular occurrence of this loose rock has here been brought about by the Juniata River and its tributaries, as they have cut across the formation, wearing away the softer formations beneath, and leaving the Medina overhanging and exposed. In the course of time it has been weathered and broken up by the elements into the bodies of loose rock or "floes," as they are called, which may cover an area of a thousand acres or more. The depth usually varies from three or four to as much as 20 ft. Smaller floes formed in the same way may be found along the flanks of the mountains; but they nowhere compare in size with those formed where the measures have been cut transversely.

This rock is sometimes quarried out of the solid measures; but by far the largest amount used is that taken from the bodies of loose rock, as the latter is not only cheaper to work but is of more uniform quality. The white Medina formation is not composed entirely of quartzite, but is made up principally of sandstone with intermingled strata of quartzite. Thus where the formation has been broken up, the softer sandstones unsuitable for the manufacture of silica brick have tended to weather away and disintegrate, and have left the larger portion of the floes to consist of quartzite. When sandstone is mixed with the quartzite in the floes it is readily detected by its appearance, as it tends to become much more rounded and worn in weathering than does the quartzite, which maintains its sharp, angular edges.

The individual pieces in these floes range in size from those of fist-size to boulders weighing many tons. Probably 50 per cent of the rock occurs in pieces weighing more than 500 lb. The largest floes are found at the gorges of the Juniata River near the towns of Mount Union, Mapleton, Point View, Lewiston, etc.

It is interesting to note that the Oriskany sandstone, extensively used as glass sand, is found in close proximity to the Medina and that although exceedingly pure in its composition, its softness renders it unsuitable for high-grade silica brick. It consists of a mass of minute quartz grains loosely held together, and often so friable that it can be easily worn away by the hands. On the other hand, the Medina quartzite consists of quartz crystals cemented in a mixture of the same composition and of equal hardness with the crystals. The difference in the two types of rock when ground to sufficient fineness for the manufacture of brick is obvious. The harder stone gives splintery, angular fragments; the other, rounded grains. Experience shows that a hard rock like the Medina is required for a physically strong silica brick.

The white Medina which occurs in southern Pennsylvania near the town of Hyndman is there prominent and of a pure variety, but by no means as hard as the quartzite of Huntingdon County.

A representative analysis of the Pennsylvania quartzite is as follows:

	Per Cent
Silica (SiO_2)	97.80
Alumina (Al_2O_3)	0.90
Iron peroxide (Fe_2O_3)	0.85
Lime (CaO)	0.10
Magnesia (MgO)	0.15
Alkalies	0.40
	100.00

WISCONSIN QUARTZITE

This rock, much used in the manufacture of silica brick in the vicinity of Chicago, is known as the Baraboo quartzite from the town of that name where these measures appear, and near which are the quarries. The rock occurs in high cliffs throughout this region and is especially prominent around Devil's Lake. Here glacial action has excavated a deep, broad valley in the quartzite formation bounded on each side by cliffs several hundred feet in height. Their bases are covered with the loose rock split from the parent ledges. While the fragments are much larger as a whole than the weathered Medina of Pennsylvania, the quality by no means compares with the latter. Practically all the stone used in brick making is here quarried from the solid measures.

The marked peculiarity of this rock, as compared with the Pennsylvania quartzite, is its reddish color, which ranges from a light pink through a dark purplish red

*A paper read before the San Francisco meeting of the American Institute of Mining Engineers, September, 1915.

almost to black. It is often as red as the red Medina of Pennsylvania, a sandstone wholly unsuited for brick making. While the coloring of the Baraboo quartzite is due to iron, it is yet an exceedingly pure rock. The quartzite often becomes lighter in color as the quarry works in from the face of the cliff; but it is the exception to find white rock.

This Baraboo quartzite, estimated as some 4000 to 5000 ft. in thickness, is a metamorphosed sandstone, the sedimentary origin of which is indicated by its parallel bedding planes, by ripple marks, etc. Layers of quartzite are often separated by beds of quartz schist varying from a few inches to several feet in thickness. This schistose structure is due to the admixture during deposition of clayey material, which in the subsequent folding and bending of the rock has developed a slablike or schistose structure.

The United States Geological Survey explains the formation of the quartzite as due to the enlargement of the original quartz grains and to the deposition of interstitial quartz. It was the latter that carried the iron oxide, giving the characteristic color to the rock. Regardless of its color, the formation throughout shows the physical characteristics of hardness and strength, and the splintered and angular fracture in crushing, identical with the Medina quartzite of Pennsylvania. A typical analysis follows:

	Per Cent
Silica (SiO_2)	97.15
Alumina (Al_2O_3)	1.00
Iron peroxide (Fe_2O_3)	1.05
Lime (CaO)	0.10
Magnesia (MgO)	0.25
Alkalies	0.10
	99.65

ALABAMA QUARTZITE

The material used in silica brick manufactured in Birmingham, Ala., is found in the eastern part of that State. It is bluish white, and as hard and crystalline as the Wisconsin quartzite; average analyses show it to be equally pure. It occurs in lenses of varying size, in a sandstone formation. It is probably a quartzite formed by a leaching out of impurities from the parent rock followed by a crystal growth and additional deposit of silica from circulating waters. A typical analysis follows:

	Per Cent
Silica (SiO_2)	97.70
Alumina (Al_2O_3)	0.96
Iron oxide (Fe_2O_3)	0.80
Lime (CaO)	0.05
Magnesia (MgO)	0.30
Alkalies	0.31
	100.12

In Colorado and Montana both quartzite and sandstone are used to some extent in the manufacture of silica brick.

Method of Manufacture

QUARRYING

The methods of quarrying as necessitated by the mode of occurrence of the quartzite are so obvious as to need no description. The only point which is of importance is that of adequate supervision in the selection of the rock, whether it be from floes or from the solid measures. Whatever the location or occurrence of the rock, such care is essential; the easiest way to keep bad rock out of the brick is never to let it reach the plant.

GRINDING

After the rock broken to one-man size is received at the rear of the brick plant, it is put through some of the familiar types of crusher, which reduces it to practically the size of a 1- to 2-in. ring. It is then elevated to storage bins from which it may be fed direct

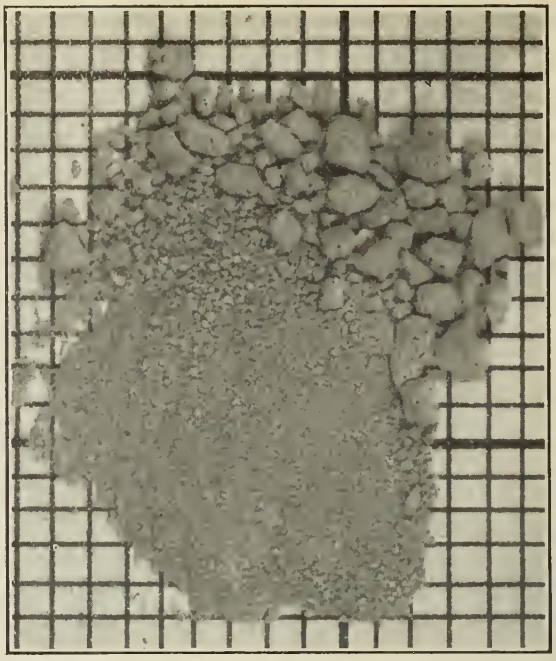

FIG. 1—MATERIAL FROM UNBURNED AVERAGE STANDARD 9-IN. BRICK

in definitely weighed quantities to the wet pans for grinding.

Into the wet pans, as the grinding proceeds, 2 per cent of lime, by weight, is introduced as milk of lime. When the brick is burned, the lime in combination with the other elements in the mass serves to give the necessary bond or physical strength. The quality of the lime has no small effect upon the resulting characteristics of the brick. The effect of an increase in lime from 2 to 3 per cent is not marked; but such as it is, renders the brick less able to withstand abrasion, as is indicated by rattler tests. The decrease in strength on further additions of lime up to 7 per cent is progressive, and becomes more and more evident with each addition. There is, on the other hand, a decrease in strength at 1.5 per cent of lime, and a marked weakness and friability as the amount of lime is still further diminished. As regards ultimate refractoriness, no marked effect is noticeable upon increasing the lime addition up to 3 per cent. From that point on the effect is clear in a lowering of the fusing point.

The fineness to which the charge in the wet pan is to be ground depends upon the nature of the brick to be made from it and is, of course, controlled by the time during which the charge is allowed to remain in the pan. In general, one charge, containing material for 200 brick, will be ground by approximately four pans per hour for standard 9-in. brick, while to obtain the fineness requisite for the intricate and difficult shape-work necessary in byproduct coke-oven construction, but two pans per hour may be possible. The rock is exceedingly hard, and a comparatively slight increase in the fineness of grind is accompanied by a seemingly disproportionate lowering of grinding capacity, and increase in wear on the pans.

The actual differences in grind, however, are much smaller than is often imagined. Figs. 1 and 2 are photomicrographs with a magnification of 2 diameters, the ground material showing on a background of cross-section paper with 0.1-in. spacing. The specimens are from pieces of green or unburned silica brick, crushed down after drying. Fig. 2 indicates typical fine-ground shape-work, while Fig. 1 is that of average standard

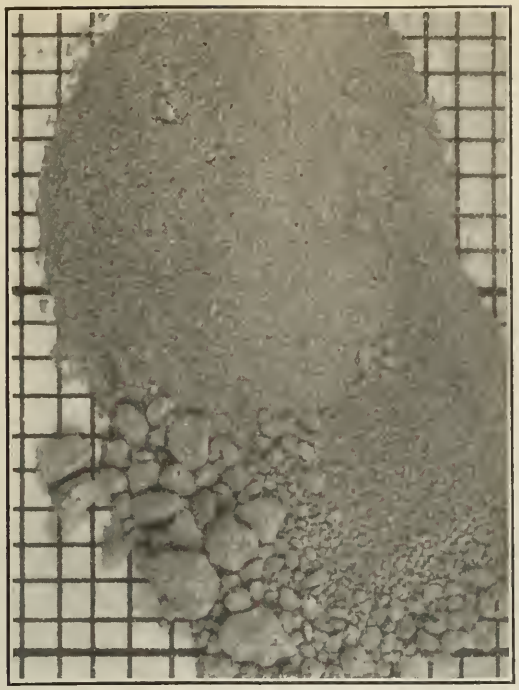

FIG. 2—SAMPLE SHOWING MATERIAL USED IN TYPICAL FINE-GROUND SHAPE WORK

9-in. brick. The difference between these is also shown in the screen analysis of the two.

It will be plainly apparent from the photomicrographs that the difference lies not so much in the actual size of either the coarse or the fine grains as in the relative proportion of fines. In the finer-ground brick the larger proportion of these is clearly evident. There can be no question that the general effect of increasing the fineness of grind is to improve the abrasive resistance of the brick, if it is properly burned. In general, the requirements as to grind contained in typical coke-oven specifications have worked no hardship upon the manufacturer; for the present-day standard of workmanship on byproduct oven shapes is such as to "carry its own grind with it," if the expression may be used. To secure the accurate filling out of the shapes, and the clean-cut accuracy everywhere essential, the grind is actually much finer than is requisite to satisfy the usual specifications as to that particular feature.

MOLDING

The ground silica material as ready to mold is of about the consistency of damp sand, but (possibly because of the extreme angularity of its grains) has less flow as it is manipulated. As a consequence, the molds must be filled by pounding with heavy plank beaters covered with metal, and all corners and shapes of irregular outline must be rammed in by hand, much as sand molds are made, but with much heavier blows. Unequal ramming, leaving too great a variation in the density of the green brick, will give unequal expansion in the kiln. It is by no means uncommon to lose hundreds of a new and difficult shape through such fire-cracking. To get proper molding and ramming requires the strictest supervision.

FIG. 3—TYPICAL SECTION OF HOT FLOOR SHOWING COKE-OVEN "GUN" BRICK SHAPES IN PROCESS OF DRYING

The wear on the molds due both to the attrition of the grains and the pounding is exceptionally severe. In view of the extreme accuracy required, steel molds are used exclusively for all high-grade coke-oven work. These molds are often decidedly complicated, and always expensive, as "loose sides" must be used throughout. Ground silica has, as molded, almost no physical strength, and can be taken from the mold only by allowing the sides to come with it, after which the sides are stripped.

After molding, the shapes are placed on pallets, on which the brick are dried either on the steam-heated hot floor or on rack cars in some form of tunnel dryer (Fig. 3). The brick are then ready to be set in the kilns. Although setting is a most important feature in the manufacture will not attempt to discuss it here.

BURNING

The vast majority of silica brick are burned with soft coal in the familiar type of round, down-draft kiln, varying in diameter from 30 ft. upward. Although practice may vary somewhat, and much depends on the size of the kiln, the following schedule of burning may be considered as fairly normal. Assume that the setting is complete and the doors are sealed. Fire is immediately started, and continued slowly and with slight acceleration for from nine to twelve days, during the last two or three of which the final temperature should be practically maintained. The kiln is then held at the required temperature, say a 26 cone (1650 deg. C., or 3002 deg. Fahr.) directly in front of the firebox, for another day, after which the fireboxes may be sealed and allowed to remain thus for approximately 24 hr. more. Cooling will require about as long as the burning proper; but this varies somewhat with atmospheric conditions.

It is obviously difficult to take temperatures in the interior portions of the kiln except by cones; but there are often most perplexing variations in this method. There are apparently certain conditions in the atmosphere of a burning silica kiln which alter the readings of standard cones to no small degree. Cones which give concordant results, week in and week out, in clay kilns are often decidedly erratic in registering the temperatures of silica kilns. It is by no means uncommon to witness cones of higher number go down, while next to them those lower in the series are either but slightly bent or apparently unaffected.

EFFECT OF BURNING ON COMPOSITION AND EXPANSION

In any discussion of the desirable qualities of silica brick there is frequently expressed the necessity that "all the expansion shall be burned out of them." This brings out the questions: to what is the expansion due; how may it be completely effected if that be possible; and by what means can that result be ascertained.

That the terms used in the discussion may be clear, let it be premised that all silica brick are of course made in molds smaller than the proposed size of the finished or burned brick, and that under the influence of heat a permanent expansion occurs, swelling the

brick from the mold or "green" brick size to the required or "burned" size. It is this expansion occurring during burning that it is desired to accomplish so completely as to preclude further expansion in subsequent use.

Now, in every burned silica brick expansion will occur on heating—a true thermal expansion, identical in its general character with that incident to the heating of practically all bodies. Such thermal or temporary expansion will disappear upon cooling, and being the expression of the coefficient of expansion of the silica it is unavoidable. But it is argued that, if a silica brick is not properly burned, then, upon reheating in actual coke-oven practice, there will be not only a normal thermal expansion but an additional expansion of indeterminate amount which will be permanent. It is essential in the construction of the coke ovens that the expansion, whatever its nature, be as small as possible, and that, whatever it is to be, it be known and adequately cared for.

It will be recalled that the silica brick under consideration is made merely by adding 2 per cent by weight of milk of lime to quartzite rock of the following composition, say:

	Per Cent
Silica (SiO_2)	97.80
Alumina (Al_2O_3)	0.90
Iron peroxide (Fe_2O_3)	0.85
Lime (CaO)	0.10
Magnesia (MgO)	0.15
Alkalies	0.40
	100.20

The representative silica brick produced may be assumed to have the following composition:

	Per Cent
Silica (SiO_2)	96.25
Alumina (Al_2O_3)	0.88
Iron peroxide (Fe_2O_3)	0.79
Lime (CaO)	1.80
Magnesia (MgO)	0.14
Alkalies	0.39
	100.25

What are the changes which occur as the siliceous mass is burned?

Certain of these are obvious, such for instance as the formation of a bond of one or more of the lime-silica compounds such as the meta-silicate CaO, SiO_2 or the ortho-silicate 2CaO, SiO_2. With the exception of the lime present, the peroxide of iron and the alumina, though small in quantity, are the preponderating impurities and there is undoubtedly formed a certain amount of silicate of iron as well as compounds of the lime-alumina series. Whereas the lowest melting point incident to any eutectic of the lime-silica system is 1436 deg. C. (2617 deg. Fahr.) and of the alumina-silica series is 1610 deg. C. (2930 deg. Fahr.), while that of the lime-alumina system is 1400 deg. C. (2552 deg. Fahr.), some of the eutectics of the ternary system CaO, Al_2O_3, SiO_2 melt at approximately 1170 deg. C. (2138 deg. Fahr.) and are thus among the first of the flux compounds resulting.

No less important, though less recognized, changes are occurring in the brick as it is heated. The evidence of the change, regardless of its reason, is easily indicated by the most casual measurement when brick are drawn from the kiln from time to time, as higher temperatures are reached. The final expansion will be very close to 38 in. per foot.

The valuable work done by Day, Shepherd and particularly by Fenner, on the Stability Relations of the Silica Minerals (*American Journal of Science*) give the results in a large field of laboratory experiment, which make possible a fair understanding of what occurs in the actual burning of the silica brick. Fenner's work was to establish among other things the relations between the minerals quartz, tridymite, and cristobalite, all silica minerals and any of which could be converted into any other by appropriate heat treatment. For the purposes of this discussion it is unnecessary to touch upon the alpha and beta phases of these minerals. In substance, the results under the conditions imposed by the experiments were that powdered quartz, if heated, remains quartz until a temperature of 870 deg. C. (1598 deg. Fahr) is reached, at which inversion point there begins a slow change to tridymite. If heat is still applied, there is no further change from tridymite until 1470 deg. C. (2678 deg. Fahr.) is reached, when inversion to the form of cristobalite has its beginning. There is no further change until the cristobalite may melt into a glass. Thus the stable phase of quartz (quartzite rock as applied to silica-brick manufacture) extends to 870 deg. C. (1598 deg. Fahr.). Between 870 deg. C. (1598 deg. Fahr.) and 1470 deg. C. (2678 deg. Fahr.) the stable phase is tridymite, while above 1470 deg. C. (2678 deg. Fahr.) cristobalite is stable.

As a whole it must be carefully noted that the changes from one mineral to another were exceedingly slow, particularly near the inversion points. So slow in fact were the alterations, that the melts were made in a flux of a large excess of sodium tungstate which acted as a flux or catalyzer. The powdered quartz or whatever might be the silica mineral under study was stirred into the molten bath of flux and the platinum container was then treated in a suitable furnace. This flux in no way entered into chemical combination with the silica but only aided and quickened its action, apparently furnishing a fluid medium through which the molecular rearrangement was facilitated. In spite of this, the slowness of the inversion, often requiring many hours, will bear emphasis in drawing conclusions regarding any parallelism between these experiments and the burning of brick.

A particularly noteworthy fact is that in the absence of a flux or catalyzer, the inversion from quartz to tridymite does not occur, but the inversion is direct to cristobalite, and there is a shift in the inversion point to as low as 1000 deg. C. (1832 deg. Fahr.) while at 1300 deg. C. (2372 deg. Fahr.) the change is very rapid.

This entire absence of tridymite in quartz heated well above 870 deg. C. (1598 deg. Fahr.) the quartz-tridymite inversion point, although difficult of explanation, is apparently proved. As indicative of the time element requisite for such an inversion, in one experiment fine-ground quartz heated 108 hr. at 1250 deg. C. (2282 deg. Fahr.) without flux gave but a small percentage of inversion while with 90 hr. at 1360 deg. C. (2570 deg. Fahr.) approximately two-thirds became cristobalite.

In considering these changes in the crystalline form of silica, some of the characteristic properties of the three will not only make clearer the method of distinguishing them, but also throw some light on the reasons for the effects these inversions exhibit.

Quartz has a specific gravity of 2.65, tridymite of 2.27, and cristobalite of 2.33. Each has its characteristic crystal form, the quartz being usually in the familiar pyramids, prisms or combinations of these. Tridymite often occurs in thin tablets or plates hexagonal in shape. Cristobalite is exceedingly irregular in the development of its crystal form but often develops octahedral caps along the closely interlacing axes of elongation.

It is the difference between the indices of refraction of these minerals, however, that furnishes the greatest aid in distinguishing the one from the other.

Tests.—As a starting point from which to work in determining the effect of burning, a set of sample silica brick were taken from one kiln, all from the same zone

and from a kiln of absolutely normal burn. In this instance they were first burned at a point about 8 ft. from the wall and 6 ft. from the bottom. This sample was divided into three parts, one to be kept unaltered, one to be reburned under the same conditions, and a third to have two reburns. In addition to this, pieces of quartz rock received one and two burns respectively, with the view of obtaining the same data.

The primary object was to determine, if possible, how far the inversion from quartz to cristobalite had progressed under the successive conditions. Each burn was made as nearly uniform as practicable, and in each succeeding burn the effort was made to maintain identical conditions. At that part of the kiln where these brick were burned the temperature reached 1540 deg. C. (2804 deg. Fahr.), and they were subjected to that heat for approximately 40 hr.*

In general, the chief optical constant serving to distinguish cristobalite on the one hand from quartzite and calcium silicate on the other was the index of refraction. The slow ray of quartz has a refractive index of 1.544 while the index of the fast ray of cristobalite is about 1.485. The immersion method was used to determine the indices of the grains, the powdered brick being immersed in a liquid of index 1.51. By this method it was possible to distinguish between the higher-refracting quartz and calcium silicate and the lower-refracting cristobalite.

With the aid of a *camera lucida*, the fields were sketched on very thin tracing paper. The grains, as represented on the paper, were then cut out and weighed for each constitutent. Aside from the fact that the composition of different fields may vary, other errors are entailed in the sketching, cutting out and weighing so that a variation of 5 per cent is justifiable. In these determinations the fields of the same specimen checked to within 5 per cent maximum and 1 per cent minimum error.

Results.—The tabulated data are as follows:

Specimen	Field	Quartz and Calcium Silicate, Per Cent	Average, Per Cent	Cristobalite, Per Cent	Average, Per Cent
Lot 1	1	24.87	.....	75.13	.....
(1st burn)....	2	20.42	22.65	79.58	77.35
Lot 2	1	14.31	.....	85.69	.....
(2d burn)	2	19.96	17.13	80.04	82.87
Lot 3	1	17.44	.....	82.56	.....
(3d burn)	2	14.60	16.02	85.40	83.98
Quartz rock	1	50.08	.....	49.92	.....
(1st burn)	2	51.05	50.57	48.95	48.95
Quartz rock	1	32.70	.....	67.30	.....
(2d burn) 2		30.06	31.38	69.94	68.62

A number of interesting deductions may be made even from these preliminary tests. The maximum change takes place at the first burning, followed by a further appreciable inversion at the second, and practically no change at the third.

The grain structure of the reburned silica brick may throw some light on this subject. Here the grains may be seen to be essentially cristobalite, with the quartz occurring as an inclusion. The last stages of the inversion are apparently exceedingly slow within the protecting envelope.

The smaller percentage of inversion in the case of the quartz rock as compared with the brick is very noticeable, and is undoubtedly due to the grinding of the quartz in the manufacture of the brick. This is wholly in line with Fenner's laboratory experiments, in which he found the influence of comparative grinds to be slight if the silica mineral were heated with a flux, but to be marked if the material were heated without a flux. Fine grinding greatly hastened the inversion. The greater freedom of movement in expansion as compared with the exceedingly dense quartz body is probably the controlling factor, rather than any difference in the penetration of the heat.

The part played in the inversion (if any part is played) by the lime and its compounds present, is of much interest. It appears logical that the greater fluidity conferred by the fluxes present should have an influence; but it must be borne in mind that, as compared with previous experimental work on silica minerals, the amount of flux present in the brick is exceedingly small, and that definite chemical compounds are formed in combination with the brick body. In Fenner's work the sodic tungstate formed no such chemical compounds, and remained unchanged at the conclusion.

The fact moreover that no tridymite was determinable in either the burned brick or the calcined quartz indicates that the burning of silica brick is closely comparable to heating the quartz without a true flux or catalyzer; for did the impurities of the rock and the added lime act in that manner, tridymite would undoubtedly be distinguishable.

Thus far, we have assumed the changes in crystal form to be desirable, because of their effect on the expansion of the material.

EFFECT OF BURNING ON PHYSICAL STRENGTH

It is also of interest to note the effect of the reburning on the physical strength of the brick. To determine this, the following tests were run:

CROSS-BREAKING OR MODULUS OF RUPTURE TEST

Number of Burns	Mark	Breadth of Brick, Inches	Depth of Brick, Inches	Weight Causing Fracture of Brick, Pounds	Length Between Supports, Inches	Rupture, Pounds	Average, Pounds
1	9 A	2.46	4.40	3,550	6	671	.....
1	9 A	2.42	4.40	3,000	6	567	624
2	9 B	2.50	4.50	4,140	6	730	.....
2	9 B	2.50	4.50	5,000	6	889	809
3	9 C	2.06	4.50	4,500	6	971	.....
3	9 C	1.96	4.50	4,550	6	1,031	1,001

CRUSHING TEST; WHOLE BRICK CRUSHED FLAT

Number of Burns	Mark	Dimensions, Inches	Area, Square Inches	Load, Inches	Crushing Strength Per Sq. Inch, Pounds	Average, Pounds
1	9 A 2	9.00 by 4.40 by 1.96	39.60	176,800	4,465	.....
1	9 A 2	9.04 by 4.44 by 2.04	40.14	167,000	4,161	4,313
2	9 B 2	9.10 by 4.46 by 2.02	40.58	186,500	4,596	.....
2	9 B 2	9.10 by 4.40 by 2.06	40.04	168,000	4,196	4,396
3	9 C 2	9.06 by 4.42 by 2.00	40.04	195,000	4,870	.....
3	9 C 2	9.12 by 4.46 by 2.06	40.68	168,000	4,130	4,500

The increased strength of the brick is evident.

Conclusions

In considering whether or not all the expansion possible is burned out of the brick, it is necessary to determine first the limits and then how closely they are approached.

Day, Sosman and Hostetter say that the true specific volume of cristobalite as compared with quartz at 20 deg. C. is 13.4 per cent greater. Assuming a green brick to be wholly pure quartz (100 per cent SiO_2), and the brick burned from it wholly cristobalite, the volume increase would then be 13.4 per cent. This theoretically possible expansion is diminished by the effect of the impurities present in the actual brick, and by the resulting compounds formed. For instance, 4 per cent of impurities would produce a much larger proportion of compounds to which this expansion formula does not apply.

An expansion of, say 3/8 to 7/16 in. per foot, to which byproduct coke-oven silica is burned, thus provides for somewhat more than 13 per cent increase in volume.

It must be borne in mind, however, that by quick burning the brick may be easily expanded by double or

*The heartiest appreciation is here expressed to A. A. Klein, Petrographer in the U. S. Bureau of Standards at Pittsburgh, for his courtesy in making these determinations that they might be concluded in time for presentation here. The quality of Mr. Klein's work needs no comment.

treble the normal amount; but sound brick do not result. This excessive expansion is due to minute fissures opened up in the body of the brick by a too sudden rise in temperature during burning. In the early stages of firing the heat must be raised very slowly. In general the conclusion is justified that the present good commercial practice carries the results of the quartz-cristobalite inversion to the greatest degree economically possible and that the measure of the expansion of the brick affords a closely approximate measure of the inversion—providing only that the brick are sound.

The short series of tests outlined above are given with full realization that, while indicative, they are by no means conclusive. They were but the preliminary runs, necessarily made somewhat in haste, but giving data which permit intelligent plans to be made for the more comprehensive tests now under way. There is much to be learned as to the effect of both time and temperature as well as the influence of pressure, which may produce a shifting of some of the inversion points. Judging from the work thus far done, it is impossible to expect the full inversion of quartz to cristobalite under any practical operating conditions of manufacture.

Unstable States in Arc and Glow*

BY W. G. CADY

In solid and liquid conductors, in which Ohm's law is applicable, unstable states, where a small variation in voltage produces a large change in current, are almost unknown. Exceptions occur only when a critical state in the conductor is reached, as, for example, in an iron wire at a certain temperature, or in an aluminium valve cell at break-down voltage.

Characteristics of the gas discharge.—When an electric current passes through a gas, the number of available carriers of the discharge increases with increasing current at a very rapid rate. In a popular sense, an ionized gas is a most "unstable" conductor, having a resistance by no means amenable to Ohm's law. In the language of dynamics, however, a gas discharge is normally stable in the sense that there is a restoring force to damp out small disturbances. The nature of this force, as well as the criterion for stability of any discharge, can be understood best by reference to the characteristic curve of the discharge, Fig. 1.

This curve shows qualitatively the relation between current and voltage in the discharge between two fixed electrodes. The nature and pressure of the surrounding gas are supposed constant, except as modified by conditions at the electrodes themselves. All of the common types of discharge are represented on this diagram. With a sufficiently high emf. it is theoretically possible, by decreasing the external resistance, to pass through all the stages in succession. Practically certain portions are unattainable, and different sources of supply are necessary for different forms of discharge. In any case, however, the curve is characteristic of the discharge apparatus and not of the supply.

The first part of the curve, *OA*, represents the saturation current, which soon assumes a value that is practically constant over a great range of voltage. This current is carried by the few free ions that are always present. As the voltage increases, the charged particles are sufficiently accelerated to form new ions by impact. At this point the current begins to increase, and a faint glow appears. The point *A* represents the sparking potential. In the present case the external resistance is supposed to be too high to admit of sparking.

AB is the glow discharge proper, in which the rate of ionization is so great that the voltage across the gap begins to drop. If the cathode is small, the curve may rise again before *B* is reached, owing to the abnormally high cathode drop.

Since the drop at the cathode is much larger than that at the anode, the cathode becomes relatively hot. As *B* is approached, the expenditure of energy at the cathode becomes so high that the cathode rapidly becomes incandescent. Here a new phenomenon appears, namely, the emission of electrons from the hot cathode, according to Richardson's law. These greatly increase the

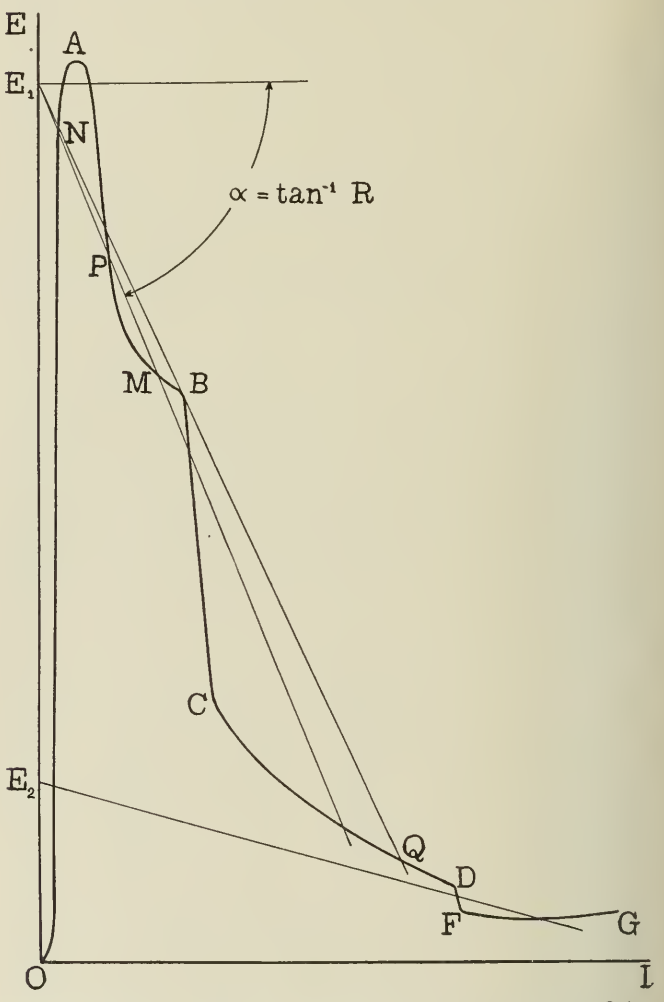

FIG. 1—CHARACTERISTIC CURVES OF GAS DISCHARGE. *OA*, SATURATION CURRENT; *AB*, GLOW; *CD*, ARC, FIRST STAGE; *FG*, ARC, SECOND STAGE

ionization close to the cathode, and the positive ions thus produced heat the cathode by impact still more. If the cathode metal is volatile enough, it begins to vaporize, thus lowering the cathode drop as well as the resistance of the gas.

The discharge quickly resolves itself into an arc, in which the negative base is concentrated to an intensely bright spot, the current is carried chiefly by the vapor from the cathode, but in which the mechanism of the discharge is essentially as before. The portion *BC* of the curve cannot be observed. Over *CD* the discharge is an arc as far as the cathode is concerned, but since less energy is being expended at the anode, at the latter we may still have a glow discharge. The positive base of the discharge is still diffuse and faintly luminous. This is the *first stage* of the arc.

*A paper read before the New York Section of the American Electrochemical Society on November 11 in joint session with the Illuminating Engineering Society.

With increasing current the anode is brought to the boiling point. This causes a decrease in the anode drop and a further increase in conductivity of the gas, so that the portion *DF* is quickly passed over. *FG* is then a full arc, or *second stage* arc. Exceptions to this typical sequence of events will be described below.

Quantitatively it is impossible to make the diagram give a correct idea of the voltage and current relations, since the current at *G* is in reality many thousands of times greater than at *A*.

Stability of the discharge.—While theoretically it is possible to maintain a steady discharge at any point of the entire curve, practically the transition from one portion to the next is always discontinuous. As the voltage or the external resistance is varied, a critical point is always reached where the discharge is absolutely unstable, changing abruptly to a stable region on another part of the curve. Still, with any given supply emf. and external resistance, it is always possible to predict between which two points the discharge must change. The method of procedure is largely due to Kaufmann.[1]

Let us suppose that the supply emf. is measured by OE_1 in the figure. If *M* is the point on the curve at which the discharge takes place, then since the ordinate of *M* is the voltage consumed by the discharge, it is evident that the external resistance *R* is equal to tan α. If *R* is decreased, α must decrease and *M* will move to the right along the curve.

Kaufmann showed analytically that a stable discharge is only possible when the line through E_1, or the "resistance line" as it is called, *slopes more steeply than the charactertistic curve* at the point in question. Thus the discharge is stable at *M*, and, starting with zero current, it would also be stable at *N* with the same external resistance, but not at *P*. A glow at *P* could only be obtained with an enormously high emf. At *B* the discharge is unstable; this is the first of the unstable states to which attention is directed. As soon as the point of tangency is reached, the discharge changes abruptly to a first-stage arc at *Q*. If now the external resistance is increased, the discharge does not change back to a glow along *QB*, but owing to the vaporization of the cathode it remains an arc until the point of tangency at C is reached. Then if, as is usually the case, the discharge cannot change to a stable glow, it goes out.

Similar points of instability exist at *D* and *F*. If the supply emf. is low, as at E_2, not even the first stage of the arc is possible, but only the second. This is the case with most arcs, operating with low emf. and small external resistance, and lighted by touching the electrodes together.

The physical significance of Kaufmann's criterion may be seen from the following considerations: If the resistance line slopes more steeply than the characteristic curve, then if through any chance the discharge at a given instant happens to take place at an abnormally high current, it cannot persist at this current, since the voltage available for the discharge is limited by the external resistance, and the steep slope of the resistance line brings the operating point too low for the discharge to be maintained; hence the current settles back to its normal value. Similar reasoning will show that if the resistance line slopes less steeply than the characteristic curve, then any slight disturbance will grow until the discharge goes out or becomes stable at another part of the curve.

In a general way this sort of stability is, of course, analogous to the mechanical stability of a pyramid, which is stable or unstable according to whether it stands on its base or is balanced on its point. A more exact analogy would be furnished by a hydraulic model, in which the discharge tube was represented by a valve so contrived as to open wider the greater the flow of water through it. This would provide the "falling characteristic." If then the water were supplied from a vessel of variable height, and regulated by a valve at the supply, it is evident that at high pressure and with supply valve nearly closed any given flow of water would be maintained more stably than if the pressure were low and the supply valve wide open, for in the latter case a much greater percentage of the total "resistance" would be in the valve of "falling characteristic."

Kaufmann applied his criterion of stability with great success not only to glow and arc, but to the point discharge, to a discharge gap ionized by an external source and, most remarkable of all, to the case of a discharge having a capacity in parallel with it. This came pretty near being the discovery of the singing arc, which, by a coincidence, was discovered experimentally by Duddell in the same year.

The carbon arc.—I have obtained a glow discharge and both stages of the arc between carbon terminals, using an emf. of 460 volts, in nitrogen at reduced pressure. Air was then admitted and the current increased until the hissing state was also reached, making four forms of discharge with the same electrodes. On the characteristic curve for carbon electrodes the hissing point would be represented by a kink similar to that at *DF* in Fig. 1, but situated between *F* and *G*. The laws governing the current-voltage relations on transition between normal and hissing carbon arcs are the same as those discussed above.

First and second stages of arc. Effect of impurities.—The unstable state occurring between the first and second stages of the arc has been investigated by Arnold and the writer. It is on the first stage that the ordinary mercury arc burns, having an anode of iron or graphite. The change from first to second stage has now been observed with anodes of a large number of metals, though in some cases reduced gas pressure or exclusion of oxygen was necessary.

An instability in the discharge is sometimes occasioned by traces of impurities on the surfaces of the electrodes. It is well known that the glow tends to change to an arc more readily if the metallic cathode is contaminated with traces of oxide. This is related, of course, to the emission of electrons from hot oxides. At the anode in a glow or a first stage arc, traces of impurities serve as nuclei around which the discharge tends to become concentrated, though it is still a glow. This effect may become so pronounced as to be taken for a new type of dischage,[2] especially since the voltage suffers a sudden drop when the concentration sets in.

An unusual type of arc.—A very unusual type of discharge is that in which, as the current increases, an arc appears at the anode while there is still a glow at the cathode. Those who define the arc as essentially a cathode phenomenon will not be disposed to admit that this is an arc at all, yet it has every characteristic of an arc at the anode, and the appearance here does not alter further when the arc phase sets in at the cathode. The writer has encountered this form of discharge with anodes of C, Ag, Cu and Hg, the cathode in most cases being of silver. The condition is decidedly unstable.

Is an arc possible from a pure metal?—The writer observed some years ago that a cathode of pure silver may become heated by the glow discharge in nitrogen nearly to the boiling point without the formation of an arc. At currents as high as 1.3 amp. the

[1] Kaufmann, Annalen d. Phys. 2. p. 158, 1900.

[2] Hagenbach, Phys. Zeitschr. 12, p. 1015, 1911.

discharge is still a glow, though the molten metal is white hot and vaporizes so intensely that clouds of silver "steam" fill the discharge tube. This is important evidence that incandescence and vaporization of the cathode are not enough of themselves to cause the formation of an arc. Whether even at the boiling point of silver the glow would still persist if no impurities were present cannot be stated. In the present tests, at the highest currents the cathode mantle always grew so large as to encroach upon the fringe of impurities that inevitably surrounded the molten mass, and then an arc immediately formed. The admission of a small quantity of oxygen also precipitated an arc.

Intermittent discharge. Corona.—Both glow and metallic arc, as well as the discharge from points, are sometimes found to be intermittent. For this to be the case, the current must be relatively small and the capacity of the external circuit considerable. There is usually a certain critical external resistance at which the intermittence vanishes, as shown by the cessation of sound in a telephone connected to the circuit. The phenomenon is closely related to the use of the arc as a generator of electric oscillations. The Cooper-Hewitt mercury interrupter is a notable example of intermittent arc.

In a strong magnetic field an arc can also be made intermittent. In this case the instability is due to the lengthening of the column of vapor by the magnet, causing the voltage to rise above the point where the discharge can be maintained. Owing to the incandescence of the cathode, the discharge quickly relights and the operation repeats itself.

The corona discharge from high voltage transmission lines is similar to a glow discharge, and is said to be often intermittent. It exhibits the characteristic cathode and anode phenomena, as well as the tendency to concentrate at certain points which was mentioned above. Since the air serves as one electrode, the corona has in some respects more in common with the discharge from points than with the typical glow.

Rotations at the anode.—Two effects will now be described, illustrating the instability of gas discharges as certain currents. The first of these has to do with the anode, the second with the cathode.

In the iron arc in free air the discharge normally takes place between globules of molten oxide. The second stage sets in at a little over an ampere. A close examination shows that the bright spot at the positive end of the arc is in rapid rotation, describing a minute ring. As the current increases this form of rotation suddenly changes to one in which the ring is still smaller, then at about 1.8 amp. a large ring takes its place, which presently yields the stage to a smaller ring again.

Each of the four types of rotation has its characteristic diameter and speed, and produces a faint note of a certain pitch. Oscillograph records show that the current and voltage undergo corresponding changes. Reasons have been given elsewhere[3] for believing that these movements are due to a reduction of the oxide at the positive base of the discharge, causing the base to wander to regions richer in oxygen. The changes from one type to the next are probably due to modifications in the composition of the oxide, brought about by increasing temperature. I have found similar effects to a slight extent in nickel and cobalt. These results have a bearing on the use of the iron arc as a wave-length standard in spectroscopy.

Glow-arc oscillations.—The effect at the cathode to which reference has been made is of the nature of a rapid pulsation back and forth between glow and arc. To obtain it, the supply emf. must be high, and the gas should be hydrogen at atmospheric pressure, mixed with a little hydrocarbon vapor. The electrodes may be of any metal, placed very close together, the discharge current being of the order of 1/10 amp.

When the discharge is a glow, a spot on the cathode becomes heated to such a degree that a small arc forms, but the voltage then drops so much and the current increases so little, owing to the shape of the characteristic curve, that the energy is too slight to maintain the arc, and immediately the glow sets in again. Such pulsations between arc and glow are of a frequency anywhere between 1 and 250,000, depending on various conditions. I have succeeded in converting 66 per cent of the power applied to the discharge into high frequency oscillations of this type. Unfortunately, the nature of the discharge is such that the conversion of large amounts of power by this means is impossible.

In these experiments no capacity was connected in parallel to the discharge, though the adjacent parts of the circuit acted as capacities for the high frequency currents.

The singing arc.—In the singing arc, including the Poulsen arc used in radio-telegraphy, a capacity and self-inductance in series are placed in parallel with the arc. The effect of the capacity is to drain energy from the arc when the current in the condenser circuit is in one direction, and to strengthen the arc current when in the other direction. Continuous oscillations are thus maintained, the condenser circuit receiving energy and timing its own impulses in a manner analogous to the balance wheel or pendulum of a clock.

The point of chief interest here is that, as Kaufmann, Simon and other have shown, such oscillations are possible only when the arc (or glow) possesses a falling characteristic. Simon has found that the alternating-current, or "dynamic," characteristic differs from the direct-current, or "static," characteristic, the difference being due to a sort of hysteresis, and that the result of this is that at high frequency the dynamic characteristic tends to change from a falling to a rising type. This limits the attainable frequency, but by reducing the hysteresis and choosing such conditions as will make the characteristic fall as steeply as possible, frequencies of over a million are easily reached.

If the oscillations are weak, the direct current through the arc simply fluctuates. This can occur with the carbon arc. If the oscillations are stronger, they put the arc out at each cycle, and before the arc relights the condenser becomes charged. The oscillating arc used in radio-telegraphy is of this type. A third type, in which the oscillations are powerful enough to make the arc relight in the opposite direction, produce a coarse tone and are not much used.

Effect of second harmonic.—When the oscillations are of the second type, extinguishing the arc at each cycle, the wave form is very complex. The second harmonic is especially prominent. As an example of oscillations of this type of audible frequency, the following experiment may be described.

A carbon arc is made to sing by connecting a large capacity and a self-inductance coil of low resistance in parallel with it. A second coil is connected to a capacity such that the natural period of the secondary circuit is nearly the same as that of the circuit connected to the arc. When the two coils are brought near together, the pitch of the arc changes, owing to the effect of close coupling. If the pitch falls, it can be made to reach an unstable value from which it suddenly jumps up a whole octave, the discharge remaining stable at this higher pitch.

The explanation of this is, that when any two oscillating circuits are closely coupled there are two possible frequencies, one higher and one lower, in either of which

[3] Phys. Rev. 2, p. 249, 1913.

oscillations may take place. At a certain stage of coupling the higher frequency is just an octave above the lower. If now the arc is on the lower frequency and has a very strong second harmonic, then if resonance is also possible at the octave above, the harmonic may be reinforced to such an extent as to assume the rôle of fundamental frequency itself. The pitch then rises to the higher octave.

It is hoped that the phenomena that have been described may serve to illustrate the unstable nature of some forms of gas discharge, as well as the very diverse ways in which the instability asserts itself.

With respect to practical conclusions, the following may be said: for stability, an arc should be operated with supply emf., external resistance, and current all large. Or if the discharge is to be a glow, a region on the characteristic should be chosen at a safe distance from a critical point, having due regard to the supply emf. For oscillations, a steeply falling characteristic, small current, large emf. and artificial cooling of the electrodes are important factors.

Notes on Chemistry and Metallurgy in Great Britain

(From our London Correspondent)

The General Situation in Great Britain

When a patient is in the throes of fever, when all normal functions are interrupted, and when several organs overstrained perform new functions, comparative standards by which to mark progress are not easily chosen. The world has had biggish wars before this, but none so big or so complex in economic and industrial aspects. Reckoned against all previous prophesies it was never considered possible that European civilization could have fought for so long or maintained such huge armies without utter collapse. Yet the collapse is far off when one or other group will throw up the sponge.

You, on your side should be seeing most of the game, but as you only see it through the filtering medium of censorships it is possible that the little we do see here of our own condition is of more utility to us as a combatant than the wider survey of a neutral.

Despite casualty lists, despite increasing indebtedness, despite the increasing conversions of factories and foundries to make munitions for our armies, the general outlook is one of confidence. Of course, there is the masked anxiety of those whose relatives are in the trenches, but it is well masked.

Blunders, of course, there are, but administratively we are much more likely to suffer because those in authority are honest fools than because they are clever rogues. With free ports and open seas raw materials and foodstuffs cause us no anxiety. The harvest season being almost over, recruits from the industrial class which can best spare them, will come forward. Despite the ill-advised advertisement given by the press to certain cranks the labor situation has greatly improved.

But in one respect there is cause for alarm, an alarm as to the consequences of the present high wages, good employment, and resultant present extravagance. To a certain extent the latest budget will check the tendency to extravagance, and for the rest, stern necessity will in due course intervene, and forcibly deal with the fruits of an unhealthy and abnormal activity.

The British Association Meeting

Among the many papers and sectional presidential addresses that by Dr. H. S. HELE-SHAW to the Engineering Section stands out with much prominence. Dr. Hele-Shaw is among those, who, while giving full attention to present needs is also giving careful consideration to the problems which will follow the end of the war. He says, "I do not believe the Germans despise us for our want *per se* of the application of science to industry. I do not think they have much reason to; but what they do despise us for is the want of co-ordination, which, I venture to say, amounts to positive slackness, which they are keen enough to observe permeating the whole of this country. They see different sections, instead of being united for a common end, quarreling with each other, filled with mutual suspicion and distrust, with apparently no common bond of union, and whereas the German is proud of the Fatherland, he sees in this country large numbers who seem, either through self-consciousness or ignorance, to be ashamed to mention the subject of the British Empire, or, what is worse, to acknowledge that any love of their country is or could be a mainspring and incentive to strenuous effort. . . .

"When peace is concluded, it will only be a prelude to another war, and a war which will recommence with a far greater energy on the part of our enemy than before, viz., the war of commerce—and the latter will be almost as serious for us as the more sanguinary one. This will be so even if we are victors, for 'after a long war the difficulties of the victors are often greater than those of the conquered. The conquered have their attention directed to the reparation of losses and are inspired by a patriotic desire to submit to losses for the sake of their country. The victors are in the frame of mind which expects everything to be easy.'

"Remembering how swiftly we relapsed into national ease at the end of the Boer War, it behooves every man who can do so to take his share in making ready for the terrific struggle Germany is certain to put up in the arts and manufactures. We shall better appreciate what this competition will mean if we consider the marvelous stride made by Germany during the last half-century in the arts and manufactures. It is undoubtedly in the matter of scientific organization even more than the organization of science that Germany has achieved such wonderful results, and it is, therefore, in this direction that we must leave no stone unturned if we wish to have any chance of holding our own in the future."

Also of importance was Prof. W. R. SCOTT'S presidential address to the Economic Science Section—speaking of the probable situation at the end of the war, Professor Scott pointed out that there may be a short trade boom (arising out of an attempt to restore some of the material ravages of war), but the joint demand from it and from the trades reopened is likely to be considerably less than the huge present expenditure of manufacturers for war. Thus the unemployment occasioned by dislocation of industry through hostilities is likely to be carried forward as a species of suspense account which must be liquidated not very long after peace. Moreover, international credit is likely to re-act on the situation in a prejudicial manner. Even already the financial system of Germany is more strained than appears on the surface. The fact is advantageous to us as belligerents, but it will probably be prejudicial to us not long after the re-establishment of peace. At present much of the inconvertible paper circulating on the continent does not affect us here. When the inflation has to be squeezed out after the war, a disturbance of credit is not unlikely.

"A special aspect of the problems under discussion is the provision of capital for re-starting of trades contracted by the war, and for the restoration of Belgium and other regions desolated during the progress of hos-

tilities. Chalmers, writing a hundred years ago, supposed that in cases of this kind 'in a very few years the recovery both of population and labor would be completed.'

"The explanation which he gave was far from satisfactory even for the time at which it was written, and it is still more deficient as applied to the present circumstances, when in industrial countries, fixed capital is much more important than in Chalmers' day. In the last quarter of a century, any great catastrophe, such, for instance, as the partial destruction of San Francisco by earthquake and fire, has been repaired with comparative ease by bringing capital from outside. But the waste of war renders capital exceedingly scarce; in fact, a famine of capital after the war has been predicted. Such an anticipation is over-pessimistic, but capital is likely to be obtainable for a time only with some difficulty. It is to be feared that after the war Europe will experience very considerable straits for several years to come. Not only must the waste of war be made good, but its evil legacy in inflated funded and floating debts must be gradually dealt with, lessening by reason of increased taxation the normal margin for new savings. Increased work and greater economy are the only remedies, aided by improved methods of production.

"It is to be hoped that some of the inevitable loss will be repaired in time by better methods of organization and by an accelerated rate of invention. The waging of a just war results in quickening of the national spirit. It forces a nation out of the easy and well worn paths of custom and convention. Thus out of all the suffering and all the loss, some good will come. The large proportion of our young manhood, which has gone to serve the country on the seas or in the field, and which returns having looked death in the face without being afraid, will not take up life where it was left. The noble qualities that have been evoked by the stress of battle will remain and will influence civil life during the next generation. The outlook will be both broader and also more simple."

Your correspondent has quoted somewhat extensively but not wholly prematurely from two important pronouncements. It must, of course, be recognized that the end is not yet, much water must first flow under London Bridge, many corpses choke the ditches in Flanders, and much blood trickle down to the waves of the Aegean before we can ever think the end is in sight. But just as the longest and weariest route march is cheered by the thought of rest and refreshment at *billets,* so in the months or years of a war, seemingly long drawn, it will do no harm to consider what fresh arrangements will be made when the time for that change of occupation which amounts to rest comes, so long as that consideration is of the serious order and takes full account of new difficulties to be faced.

The National Physical Laboratory

PROGRAM OF RESEARCH WORK FOR 1915-16

The following statement of work proposed for the current year in the Department of Metallurgy and Metallurgical Chemistry has been adopted by the General Board.

1. METALLURGY

Alloys Research.—The work outlined in the report for 1913-14 will be continued. The forging and rolling of a considerable number of light alloys will constitute a large part of the work for the year. The theoretical study of the aluminium-zinc-copper system, and the investigation into the permanence of light alloys will also be continued.

The work on the Effects of Stress on Steel at High Temperatures, on the Intercrystalline Cohesion of Metals, and on the Melting Point of Iron in Vacuo, will be continued with the new apparatus which has been obtained and set up for that purpose.

Acetylene Welding.—An investigation of acetylene welds will be carried out in conjunction with the Engineering Department.

Magnet Steels.—The research on magnet steels will be continued in co-operation with the Physics Department.

Volume Changes in Metals and Alloys on Fusing.—This research, which has been delayed owing to serious experimental obstacles, will be resumed, when circumstances permit, by means of new methods which have recently been devised.

Systematic Study of Steels.—The developments in the apparatus for taking thermal curves and for carrying out quenching and annealing which have taken place during the past few years, now render it eminently desirable that these new and more accurate methods should be utilized for a re-investigation of the thermal curves and micro-structures both of the fundamental carbon steels and of the more important special alloy steels derived from them. The latter study is particularly important in view of the increasing rôle which these special steels play in the investigatory test work of the department, particularly in connection with aeronautics. The systematic study indicated is, however, a large matter, involving a very considerable amount of work, and it is, moreover, correlated with the progress of two other researches, viz.: that on the melting point of iron in vacuo, and that on the effects of stress on steel at high temperatures. The present staff, and to some extent the equipment, of the department, do not permit of such an extensive investigation being taken up vigorously or with any hope of early completion. It is, however, so important that it is hoped to make a beginning as soon as circumstances permit.

II. METALLURGICAL CHEMISTRY

The study of analytical methods, and the further improvement of the methods in use in the Department, will be continued. Questions arising out of these matters will be investigated.

Investigations in conjunction with various industrial developments and problems arising out of war conditions will be undertaken.

With regard to electrotechnics and photometry, in regard to the latter the development of suitable substandards for use in the testing of gas-filled electric lamps is becoming an urgent matter. Experimental standards have already been made up for the laboratory by the Osram Lamp Works, and are being thoroughly tested before duplication into complete sets of standards. The cascade method adopted at the laboratory for the realization of candle-power in white light will be eminently suited for extension to these sources of light of still higher efficiency. Four sets of gas-filled standards are required to bridge the color interval between the present high temperature standards operating at 1.5 watts per candle and those which are required in the testing of nitrogen-filled lamps, and their preparation and standardization will be pushed forward during the year.

The experiments on the coefficient of reflection of the white cards used in photometry will be continued and extended to some other materials, a knowledge of whose characteristics in this respect will be of practical value.

If opportunity permits, it is hoped to repeat to a greater accuracy and to extend the scope of the experiments on the method of color identity for the estimation of the temperature of glowing bodies.

Measurements are being made at the instigation of the British National Committee of Illumination to determine the correct flame height of the Hefner lamp to give one British candle.

In regard to electrotechnics, some investigations on micanite are in hand and nearing completion, while the main research work of the year will be a continuation of the research work on buried cables.

Market Prices

SEPTEMBER, 1915

Copper opened £67.17.6 and was 68.5.0 on the 2nd, it then fell to £66 on the 6th, but recovered and continued to increase to 70.7.6 on the 21st and after a drop to 69.12.6 (23rd) rose to £71 on the 28th and closes £72.

Tin opened £151.10 and went better to £154.10 on the 3rd, then steady at 152.10.0 till the 10th, when it improved slightly to £154.10 on the 13th; since slightly lower, recovering to £154 on the 21st, then dropping to £150 on the 23rd, and subsequently recovering to £153.5 on the 28th, and closes weaker, £152.

Iron, Haematite opened 95/— and remained at this price throughout the month.

Iron, Scotch opened 70/9, and, after a rise to 70/10½ on the 3rd became easier till the 9th when 70/10½ again was reached. It was lowered on 15th and 16th to 70/—, but recovered to 70/9 on the 17th, dropping then to 70/3 on the 21st, and 70/— on the 27th; settlement, 70/9.

Cleveland opened 64/9 and went to 64/10½ on the 3rd, then falling to 64/4½ (7th) and recovering to 64/10½ on the 10th. On the 13th it was again 64/9 and 65/— on the 13th. It subsequently went lower to 64/3 on the 21st and 64/— by the 24th; settlement, 64/9.

Lead opened £23.5.0 and reached £23.15.0 by the 3rd and £24 by the 10th. It remained at this till the 21st when appreciated to £24.5 and was £25 on the 24th and closes £25.5.0.

Aluminium, 98-99 per cent	£190	0	0

Recent Chemical and Metallurgical Patents

Gold and Silver

Continuous Agitation.—Apparatus for continuous agitation of ore slime, as in the cyanide process, is shown in Fig. 1, being the patented invention of CYRUS ROBINSON of Mount Vernon, N. Y. It consists of a

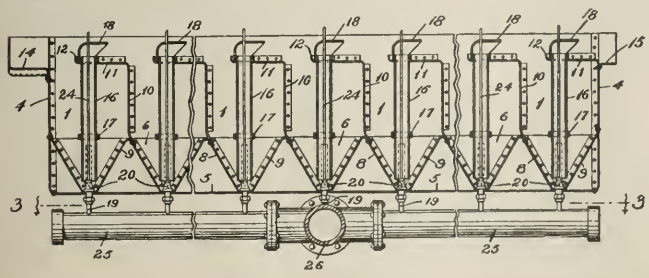

FIG. 1—AGITATOR

series of chambers connected, as shown. Extending beneath the chambers is a compressed air manifold with connections 19 to the bottom of each agitator. The latter has a central air-lift that is hooded in such a way that the discharged pulp is directed across an apron into the next agitator, and so on through the system, the pulp entering at 14 and issuing at 15. Regulation of the air used for agitation is accomplished by means of a nozzle 20 which has a beveled valve seat on which a conoidal valve closure rests. The closure has a depending finger that serves to protect it against lateral displacement and a vertical stem 24 which acts as a weight to hold the valve closed. (1,156,372, Oct. 12, 1915.)

Process of Cyaniding.—The diagram in Fig. 2 shows in considerable detail a patented procedure in cyaniding, by ROBERT S. TOWNE of New York City, and CYRUS ROBINSON of Mount Vernon, N. Y. The scheme

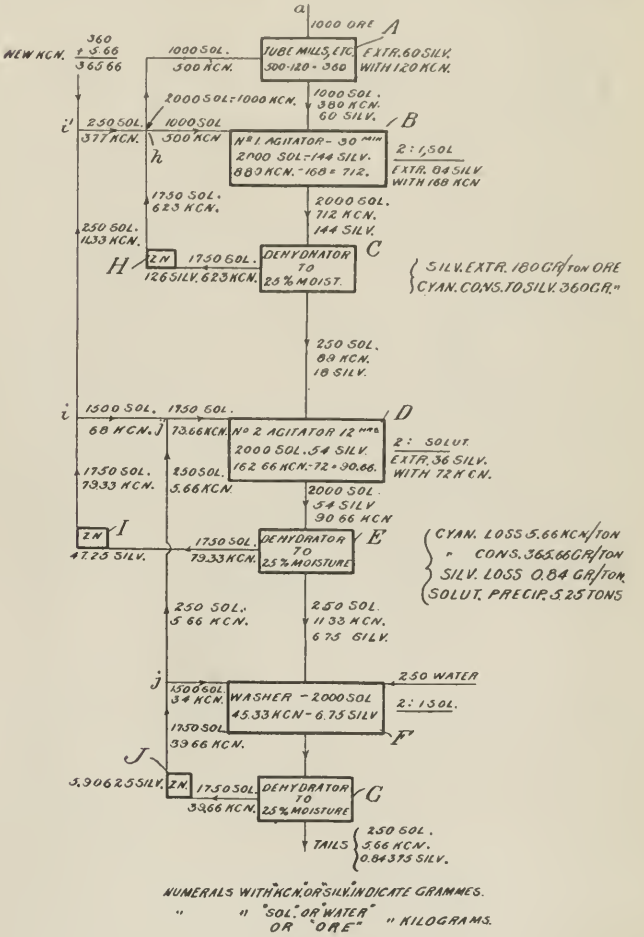

FIG. 2—PROCESS OF CYANIDING

is a multiple cycle process, the several cycles being successive in order and to a certain extent independent of each other. An object of the method is to effect extraction rapidly in a continuous process. It involves the use of a primary, relatively violent agitator and relatively strong solution, in combination with a secondary, relatively slow agitator and weak solution. The pulp is filtered between each step of the cycle so that the only solution flowing from one cycle to another is the amount carried with the dewatered ore. The quantity and strength of solution at various points can be regulated in accordance with the quantity and value of the ore, and the entire system maintained in equilibrium by the addition at an appropriate point of the proper quantity of fresh liquid and solvent. The diagram in Fig. 2 refers to the treatment of 1000 kilograms of ore containing 180 grams of silver per ton, for the extraction of which 360 grams of cyanide is required. (1,156,382, Oct. 12, 1915.)

Precipitating Metals from Solution.—A method of precipitating metals from solution, as, for example, gold and silver from cyanide solution by means of zinc dust, is patented by ROBERT S. TOWNE of New York

City, and Cyrus Robinson of Mount Vernon, N. Y. Previous methods of precipitating with zinc dust have made use of filter presses for the collection of the precipitant, but in this instance the inventors provide a settling or V-shaped receptacle, as shown in Fig. 3. The pregnant solution is mixed with zinc dust in any appropriate way and the mixture conducted through a pipe of considerable length before it reaches the separator, so that ample time for precipitation is allowed. The mixture is finally discharged from the pipe near the bottom of the receptacle 5, where the precipitate settles and is removed from the bottom. The solution freed from its precipitate flows upward and out of the tank by way of the launder 8. In order to prevent the upward flow and possible discharge of precipitate with the solution, a screen or grating 9 is placed across the tank, and on this screen is placed a layer of zinc in relatively finely divided form. This screen not only prevents the loss of precipitate, but also serves to obviate loss by re-dissolution of the precipitate while in the tank. (1,156,383, Oct. 12, 1915.)

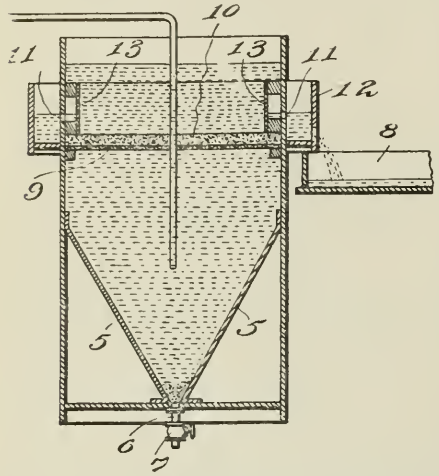

FIG. 3—DEVICE FOR PRECIPITATING AND SEPARATING METALS

Copper and Nickel

A process of separation of iron and nickel from copper in certain ores and metallurgical products is patented by Wilhelm Borchers and Eduard Thilges of Aachen, Germany. Experiments made by Lehmer at Aachen in 1906 showed that very pure metals could be produced by smelting sulphide ores with carbon and lime or limestone. According to this it would be easy to produce copper-nickel alloys by enriching a copper-nickel matte to a sufficient degree. But the market for copper-nickel alloy is not as good as for ferro-nickel, and since most copper-nickel ores and mattes contain iron sulphide in considerable quantity, it would be desirable to treat them for the production of ferro-nickel rather than copper-nickel. A high percentage of copper in the ferro-nickel, however, would be a disadvantage. The inventors have, therefore, discovered that copper can be separated from the greater part of the nickel and iron by melting copper-nickel matte with larger quantities of lime and smaller quantities of carbon than those used by Lehmer. In order to prevent the copper from separating in metallic form the matte is melted on a carbon-lined hearth of an electric furnace. Then an excess of lime is added, whereupon the iron and nickel sulphides are reduced and calcium sulphide is formed. The latter combines chiefly with the copper sulphide and prevents its decomposition. In this way it is possible by smelting comparatively poor copper-nickel mattes, to produce ferro-nickel, which is poor in copper and contains 15 to 20 per cent of nickel. (1,152,699, Sept. 7, 1915.)

Copper Hydrometallurgy.—The precipitation of copper from sulphate or chloride solutions by means of hydrogen sulphide and the reduction of cupric to cuprous sulphide with simultaneous generation of hydrogen sulphide for further use, form the basis of patents recently granted to Raymond F. Bacon of Pittsburgh, Pa. The preliminary treatment of the ore to put copper in solution can be carried out in any well-known manner. The resulting solution is treated with hydrogen sulphide, with the precipitation of cupric sulphide and regeneration of the solvent. To the precipitate is added elemental sulphur in quantity equal to one-half the sulphur in the sulphide, and the mixture

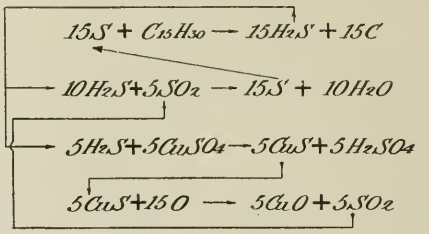

FIG. 4—COPPER HYDROMETALLURGY

is treated with a hydrocarbon body in a still at a temperature of about 300 to 360 deg. C., whereupon hydrogen sulphide is generated as a result of the reaction. Cuprous sulphide is formed and can be reduced by treatment in a converter or in any desired manner.

A related invention by the same patentee involves, first, the production of hydrogen sulphide by reaction between sulphur and a hydrocarbon; second, the use of a portion of the hydrogen sulphide to precipitate copper from a solution, and a portion to react with sulphur dioxide from roasting operations for the purpose of forming sulphur for utilization in the first step; third, roasting the cupric sulphide to oxide and treating the resulting sulphur dioxide as in the second step. The final products are carbon from the hydrocarbon treatment of sulphur and copper oxide from the roasting of cupric sulphide. These two products can be combined for the production of metallic copper. The relation of the different steps of the scheme are shown in Fig. 4. (1,151,234-5-6, Aug. 24, 1915.)

Electric Furnaces

Tapping Device for Electric Furnaces.—A simple method of tapping is patented by James G. Marshall of Niagara Falls (assigned to the Union Carbide Company). When the tapping spout is made of metal and exposed to the molten material it usually melts out.

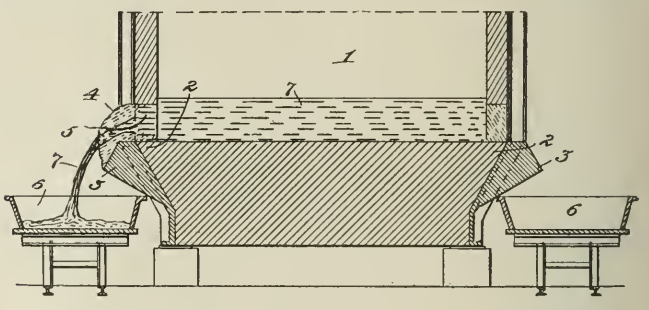

FIG. 5—TAPPING DEVICE FOR CARBIDE FURNACE

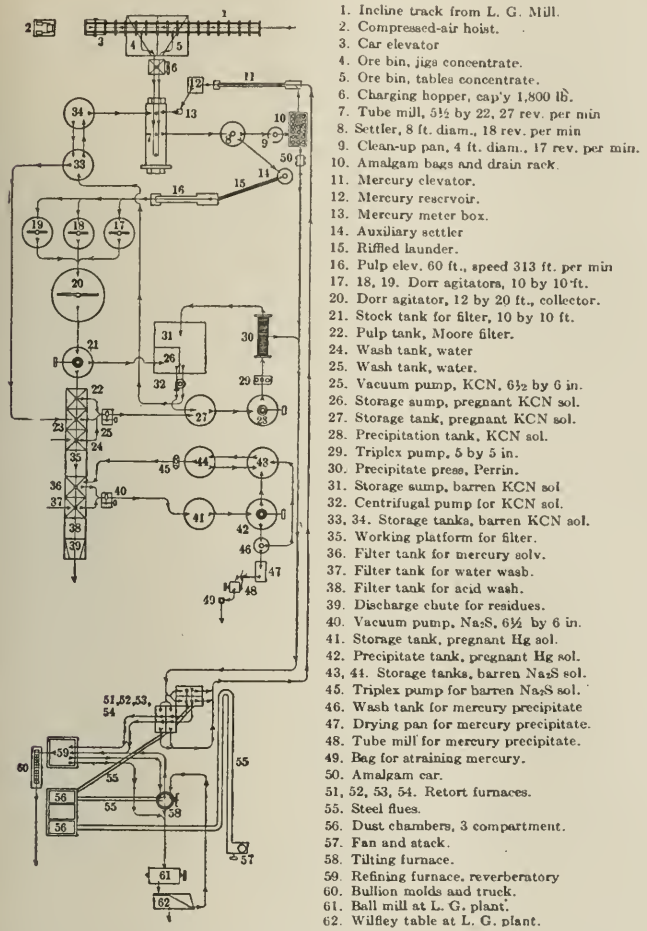
Repairs and renewals are inconvenient and costly. In the present method which is especially applicable to carbide manufacture, the furnace is made with an overhung hearth as shown at 2, Fig. 5. This allows the receptacle or chill 6, for the molten product to project under the furnace, and permits the tapping spout 3, to be merely a projection, so placed that it is not exposed to the direct heat of the molten material, but is protected by a layer of chilled material 4. In a carbide furnace the carbide chills rapidly on leaving the furnace, and an accumulation occurs at 4, thus preserving the spout. (1,149,203, Aug. 10, 1915.)

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Recovery of Mercury from Amalgamation Tailing, Buffalo Mines, Cobalt.—A paper by E. B. THORNHILL, metallurgical engineer for the Buffalo Mines at Cobalt, Canada, was presented at the San Francisco meeting of the American Institute of Mining Engineers, describing the process of recovering mercury from residues left

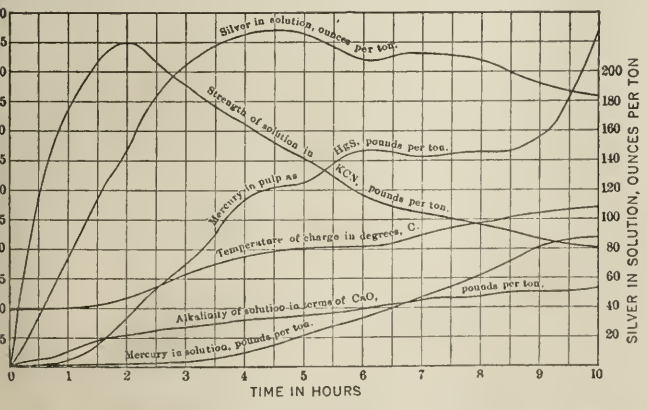


1. Incline track from L. G. Mill.
2. Compressed-air hoist.
3. Car elevator
4. Ore bin, jigs concentrate.
5. Ore bin, tables concentrate.
6. Charging hopper, cap'y 1,800 lb.
7. Tube mill, 5½ by 22, 27 rev. per min
8. Settler, 8 ft. diam., 18 rev. per min
9. Clean-up pan, 4 ft. diam., 17 rev. per min.
10. Amalgam bags and drain rack.
11. Mercury elevator.
12. Mercury reservoir.
13. Mercury meter box.
14. Auxiliary settler
15. Riffled launder.
16. Pulp elev. 60 ft., speed 313 ft. per min
17. 18, 19. Dorr agitators, 10 by 10 ft.
20. Dorr agitator, 12 by 20 ft., collector.
21. Stock tank for filter, 10 by 10 ft.
22. Pulp tank, Moore filter.
24. Wash tank, water
25. Wash tank, water.
25. Vacuum pump, KCN, 6½ by 6 in.
26. Storage sump, pregnant KCN sol.
27. Storage tank, pregnant KCN sol.
28. Precipitation tank, KCN sol.
29. Triplex pump, 5 by 5 in.
30. Precipitate press, Perrin.
31. Storage sump, barren KCN sol
32. Centrifugal pump for KCN sol.
33, 34. Storage tanks, barren KCN sol.
35. Working platform for filter.
36. Filter tank for mercury solv.
37. Filter tank for water wash.
38. Filter tank for acid wash.
39. Discharge chute for residues.
40. Vacuum pump, Na_2S, 6½ by 6 in.
41. Storage tank, pregnant Hg sol.
42. Precipitate tank, pregnant Hg sol.
43, 44. Storage tanks, barren Na_2S sol.
45. Triplex pump for barren Na_2S sol.
46. Wash tank for mercury precipitate
47. Drying pan for mercury precipitate.
48. Tube mill for mercury precipitate.
49. Bag for straining mercury.
50. Amalgam car.
51, 52, 53, 54. Retort furnaces.
55. Steel flues.
56. Dust chambers, 3 compartment.
57. Fan and stack.
58. Tilting furnace.
59. Refining furnace, reverberatory
60. Bullion molds and truck.
61. Ball mill at L. G. plant.
62. Wilfley table at L. G. plant.

FIG. 1—FLOW SHEET OF THE HIGH-GRADE AND MERCURY EXTRACTION PLANT

after amalgamating high-grade silver ore. A flow-sheet of the high-grade mill is shown in Fig. 1 and a chart of an amalgamation-barrel charge in Fig. 2.

In the amalgamation of high-grade ore in the Cobalt district considerable mercury is left in a residue, the metal being largely in the form of mercuric sulphide.



Silver in solution, ounces per ton.
Strength of solution in H2S, pounds per ton.
KCN, pounds per ton.
Mercury in pulp as
Temperature of charge in degrees, C.
Alkalinity of solution in terms of CaO, pounds per ton.
Mercury in solution, pounds per ton.
SILVER IN SOLUTION, OUNCES PER TON
TIME IN HOURS

FIG. 2—CHART OF AMALGAMATION BARREL CHARGE

The process of mercury recovery consists in leaching the mercuric sulphide from the residue by means of a caustic alkaline sulphide solution, and then precipitating mercury with aluminium.

The residue is caked on a Moore filter and washed free from silver solution with water. The filter is then lowered into a vat containing caustic alkaline sulphide, and this solution is drawn through the cake until all mercuric sulphide is dissolved. Usually 1 ton of solution is used per ton of residue. The resultant filtrate is agitated with aluminium, allowed to settle, and the clear solution decanted. The precipitate is dried, and the fluid mercury separated from the powdered portion, the latter being retorted.

The strength of solution is 4 per cent sodium sulphide and 1 per cent sodium hydroxide. The precipitant is a waste product from aluminium casting foundries, and about ¼ lb. is used per pound of mercury precipitated. Caustic soda is regenerated in the reaction, so that the consumption is but 1/10 lb. per pound of mercury recovered. Sodium sulphide also is regenerated, but there is a mechanical loss of about 20 per cent. The cost of recovering mercury by this process has been about 13 cents per pound.

Effect of Carbon or Graphite on Auriferous Cyanide Solutions.—In the June issue of this journal we presented an abstract of a paper by W. R. Feldtmann on the precipitating action of carbon in contact with auriferous cyanide solutions, originally presented before the Institution of Mining and Metallurgy. In *Bulletin* No. 130 of the same organization we note the following discussion of the subject by PAUL T. BRÜHL, who gives his experience with graphitic ore at the Prestea Block A mine, Gold Coast, Africa. The graphite had the following composition:

Carbon (with S and As)	11.00%
Silicious residue	75.00%
Fe_2O_3	6.56%
Al_2O_3	1.20%
CaO	4.50%
MgO	1.74%

The cyanide solution tested was the same in all cases, and assayed:

Potassium cyanide	0.20 %
Protective alkalinity	0.026%
Gold	61s. 4d.

Experiment 1—Two hundred and fifty grams of the mine graphite, which assayed 51s. 4d., and contained a little iron pyrites and mispickel, were agitated for four hours with 500 c.c. of the cyanide solution. The solution after filtering gave the following analysis:

KCN	0.07 %
P.A.	0.004%
Gold	0s. 4d.

Experiment 2—Two hundred and fifty grams of mine graphite, 50 grm. low grade concentrates, assaying 47s. 6d. per ton, and 600 c.c. of the solution were agitated together for four hours. The solution after filtering gave the following analysis:

KCN	0.07 %
P.A.	0.005%
Gold	1s. 6d.

Experiment 3—Two hundred and fifty grams of mine graphite, 50 grm. rich concentrates, assaying 50s. per ton, were agitated together for four hours. The solution after filtering gave the following analysis:

KCN	0.03 %
P.A.	0.003%
Gold	11s. 6d.

"These experiments indicate the powerful precipitating effect of the mine graphite. The solutions were progressively richer in gold because the sulphides were progressively richer, and the KCN had dissolved to some

extent the gold contents of the sulphides. Solution and precipitation of the gold take place simultaneously, the latter action being the more pronounced of the two in the early stages of the agitation.

"The fact, noticed by Mr. Feldtmann, that there is a load point at from eighteen to twenty-four hours beyond which precipitation is resumed, is one which I also noted when experimenting with slimes. In these experiments the most economic extraction was obtained from each particular charge by agitation for a certain definite number of hours, usually about eighteen; the time necessary varied and depended on the charge. Further agitation caused higher residue values."

In *Bulletin* No. 129, I. M. M., F. Wartenweiler confirms Mr. Feldtmann's conclusions that the precipitated gold is not soluble in any of the strong oxidizing agents, such as chlorine or bromine, and that these do not inhibit precipitation by graphite. Search for other solvents showed that neither sodium hyposulphite nor sodium thiocyanate were effective in redissolving precipitated gold or in preventing precipitation. Mr. Wartenweiler found, however, as did Mr. Feldtmann, that sodium sulphide (0.30 per cent Na_2S) did dissolve precipitated gold in post treatment of residues from cyanidation, and that copper in the form of shavings gave promise of affording a suitable solution precipitant. He found further that an extra treatment could be avoided by adding the alkaline sulphide directly to the cyanide solution for original treatment, and get the same results as by cyanidation plus subsequent treatment with alkaline sulphide. Zinc forms a good precipitant for the solution provided no free Na_2S is left in solution. A peculiar feature of the use of the sodic-sulpho-cyanide solution is that redissolved gold remains in solution for many hours while in contact with the schist, although sulphide may no longer be indicated by qualitative tests.

Comparing the relative gold solvent power of Na_2S solution and the sodic-sulpho-cyanide solution the following empirical statements may be offered:

(*a*) With a clean carbonaceous schist carrying considerable precipitated gold the simple Na_2S solution is the best solvent.

(*b*) With a works concentrator tailing carrying the fairly constant quantity of gold precipitated by the contained schist, the two solutions dissolve equally well the precipitated gold which varies from 2s. to 4s. per ton.

Lead and Zinc

Selective Flotation of Sulphide Minerals.—An Australian invention, recorded in the *Australian Statesman and Mining Standard* for July 22, 1915, provides for the separation of zinc sulphide from the sulphides of lead and iron in the flotation process, by adding to the pulp certain mineral salts which can be decomposed by the acid used in the process, liberating a reducing gas. Thus the inventor, Leslie Bradford of Broken Hill, Australia, uses thiosulphates, sulphites and bisulphites, which, in reaction with sulphuric acid, liberate sulphur dioxide. Or, the gas may be introduced into the pulp in any other manner with equally good results. The net effect is to produce a wetting of the zinc sulphide, causing it to remain in the pulp and be discharged with the gangue, while the lead and iron sulphides float. The separation of the blende from the gangue is then accomplished in a separate operation.

Crushing and Grinding

Scoop Discharges for Tube-Mills.—Though the idea of scoop discharges for tube-mills has received a great deal of attention recently, it is not wholly new. In a paper on the subject by Walter R. Dowling, published in the March, 1915, *Journal* of the Chem., Met. & Min. Soc. of S. Africa, the author illustrates "a scoop discharge with radial arms and perforated plate of 2-ft. diameter," originally installed at the Knights Deep. The drawing bears the date of April 20, 1907. This device was used on account of trouble experienced with backflow of pulp at the feed end of the tube, and was designed to lower the internal level of the pulp. Scoop discharges of improved design have been used at this plant ever since their first introduction.

Some time later Dr. W. A. Caldecott made experiments with an apparatus in which the scoop arms were long enough to cover an effective diameter of 50 in. The scoop consisted of four arms attached to a plate, which, when bolted to the discharge end of a tube, provided four chambers that brought up their quota of pulp as the mill revolved and delivered it to the outlet. A perforated plate was bolted in front of the scoop to prevent the discharge of pebbles. For purposes of experiment in determining the most effective depth of pulp in the mill, without varying the diameter of scoop arms, different effective diameters of perforated plate were used by covering annular areas of the outer portion of the plate. Tests were made at different times at different mills, in order to arrive at average conditions from which conclusions could be drawn.

Assuming that the present average duty, under ordinary conditions, of a standard 5½-ft. by 22-ft. tube-mill is 120 tons of minus 90-mesh product per twenty-four hours, the performances recorded in the tests with scoop discharge showed considerable improvement, the comparative duty being 143 tons. Increase of pebble load to a height materially above the axis of the mill is of little assistance, since the power consumption and pebble wear increase out of all proportion to the increase in quantity of minus 90-mesh product. Thus, in one case, a pebble load of 16.08 tons took 20.04 hp. more to produce only 3.22 tons more than a pebble load of 12.84 tons. The most effective diameter of scoop was found to be 24 in., considering the results obtained and the wear of liner and pebbles. With larger diameter scoop the wear is excessive. There does not appear to be any saving in power in the use of scoop discharge; but the real advantage lies in increased capacity, which is such that five tubes with scoop discharge will do the work of six trunnion discharge mills. Small sand feed decreases the tons of minus 90-mesh product; and as increased sand feeds up to 500 tons do not increase the power consumption of the mill, there is no reason why big feeds should not be given. The most suitable feed of sand per twenty-four hours as a pulp containing 40 per cent moisture, for a 5½-ft. by 22-ft. tube-mill appears to be about 400 tons. The reason for the increased capacity afforded by the scoop discharge is that the level of pulp is lowered and pebbles strike against each other, crushing the adhering grains of sand, rather than falling into a mud bath as under ordinary conditions.

Gas Producers

Wood-Gas Generators.—In the reconstruction of the surface plant at the Sons of Gwalia mine, Australia, wood-gas generators were substituted for charcoal-gas producers and have proved satisfactory and economical. The producers are of the Commonwealth modified downdraft type. Operating data are given by Mr. A. Wauchope in the July *Journal* of the Chamber of Mines of Western Australia.

Firewood in 5-ft. lengths is fed in at the top and the charcoal produced forms a glowing porous mass through which are drawn the products of distillation (i. e., hydrocarbons, steam, etc.) together with the necessary air, thus forming a gas consisting of carbon dioxide, carbon

monoxide, hydrogen, methane and nitrogen. A small amount of oxygen is usually also present in the gas. The following is an analysis of the composition of the gas under normal conditions:

Carbon dioxide (CO_2)	9.7 per cent
Carbon monoxide (CO)	19.5 per cent
Hydrogen (H)	14.1 per cent
Methane (CH_4)	2.1 per cent
Oxygen (O)	0.1 per cent
Nitrogen (N), by difference	54.5 per cent

Calorific value, estimated on composition, 125 B.t.u. per cubic foot.

The charcoal rests on an ordinary fire-bar grate through which the ashes and gas pass into a water-sealed hopper bottom. On a level with the grate there are several doors in the sides of the producer through which the grate is raked free of clinker and ashes. The opening of these doors does not appreciably affect the value of the gas within reasonable limits of time. The volume of gas produced is regulated by the suction of the engine which exerts a pull below the fire grate of the producer ranging from 2 in. to 5 in. of water.

Power costs on those sections of the cyanide mill driven by gas on a horsepower basis are 66 per cent of the power costs of those sections driven by steam. Mulga firewood, having a calorific value of about 7000 B.t.u., is consumed at the rate of from 2 to 2.2 lb. per brake-horsepower-hour.

Fused Silica Ware Made in United States

Things are moving in the chemical industries of the United States. The latest example of the establishment of a new American industry is the announcement that the firm of Lenz & Naumann, Inc., of New York City, has acquired all the American and Canadian patents and manufacturing rights for the system of Dr. Voelker and is equipping now a plant for manufacturing "quartz glass."

Dr. A. Voelker of Cologne, Germany, has been working on the problems of making fused silica ware for many years, as in 1899 he perfected his process and since then, in years of untiring efforts, he slowly developed his large-scale manufacturing methods which to-day make it possible to produce not only ordinary laboratory ware, but articles in such large sizes and such shapes as were considered impossible in former years. The Voelker process permits of the manufacture from ordinary quartz sand not only of opaque but also of transparent (semi-translucent) and translucent quartz. Waterclear quartz glass is made from rock crystal.

This fused silica ware is being introduced by Messrs. Lenz & Naumann under the name of Silicium Dioxyde.

Chain Screen Doors for Oven and Furnace Openings

Everyone who has had to work around ovens and furnaces knows what discomfort has to be endured by the attendants from the heat and gases coming out through the uncovered opening, when the doors are thrown open, and, further, what a chilling effect the inrushing cold air has upon the interior of the furnace and its contents. Doors, however, must be opened; be it to renew the charge, manipulate the contents, or study the interior conditions.

The Wiegand chain screen doors, in the form used mostly around glass, metal and chemical furnaces, consist of a multitude of freely hanging individual strands of steel chain suspended close together from a steel bar in a manner to form a continuous sheet or curtain of chain, not unlike the familiar Japanese screen.

This curtain of chain, hung before the uncovered opening to a furnace and looking like a coat of mail,

FIG. 1—WORKMEN PROTECTED BY CHAIN SCREEN IN GLASS WORKS

effectively hinders the heat, glare and gases from leaving the furnace and the cold air from entering. The loosely hanging strands of light chain are parted with ease and pressed aside by the tools or other objects projected into the furnace, only to fall together again when entrance has been effected.

The holes in the links of chain permit an unhampered view of the interior—in fact, a better survey than under ordinary conditions may be obtained, as the glare is toned down and the effect is similar to looking into the furnace through a piece of wire gauze.

In some plants, when it is necessary to work in front of the uncovered oven or furnace, the workmen are obliged to stand back a great distance from their work and to protect their bodies from the heat and glare with large sheet iron shields which are supported by one hand, while the other manipulates the tools. This seriously handicaps the workman and cuts his efficiency in half. In those plants where the new chain screens have been employed the workman has both hands available for his work and may, with comfort, freely manipulate his tools while standing within a few inches of his work.

FIG. 2—REMOVING HOT POT FROM GLASS FURNACE THROUGH CHAIN SCREEN

When it is necessary to remove a damaged pot in a glass works the chain screen shield is lowered in front of the wall enclosing the pot that is to be removed. The wall is then torn down, and the hot blocks composing the same are dragged through the chain shield and set aside. Now the broken pot is clearly seen in the furnace behind the screen, which closes the opening to the furnace, and the workmen may operate without discomfort close to the pot itself. The absence of heat and glare, coupled with the ability to see clearly what they are doing, enables the workmen to quickly pry up the pot, shove the nose of the pot truck under the pot and drag it through the perfectly flexible and penetrable shield out of the furnace. The strands of chain offer no obstruction to the passage of the truck and pot, immediately falling together again when the pot has passed, closing the opening; thus keeping the heat within and the cold drafts out of the oven or furnace.

When the truck carrying the new pot glowing with heat arrives before the screen shield, protecting the furnace, it is pushed boldly through the same. When once the truck and its pot have passed through the chains the latter close together, protecting the workmen from the radiant heat and the new pot and the whole furnace from drafts of cold air.

The doors are supplied in "automatic" and "non-automatic" forms. The automatic is employed mostly on boiler furnaces, where the opening of the ordinary fire door causes the screen to unroll from a cylinder hung above the furnace opening. The non-automatic, which is much used on ovens and other furnaces, is much simpler in construction. The chains forming the screen are suspended from a bar and may be raised out of the way by a hand chain running through a pulley overhead. When needed the screen is lowered into supporting brackets fixed at the sides of the opening.

In the glass factory, where a very large screen is needed and not more than one opening is made in the furnace at one time, a single screen is made to do duty for a whole furnace. Wherever the wall is to be torn down for the removal of a pot the screen is hung up by its pulley.

These chain screen doors are the result of several years of experimentation, having been first adapted for use on boiler furnaces, where they have been in practical operation for three years. They are made by the E. J. Codd Company, 700 South Caroline Street, Baltimore, Md.

Bihn-Jones Automatic Air Device for Raising or Handling Large Quantities of Liquids

In chemical and industrial plants there are many processes in use requiring the raising or handling of large quantities of liquids, and the use of compressed air has long been considered in this connection as a useful and necessary means of power transmission.

In making use of this compressed-air power for handling liquids, it is necessary to have a blow-case or air-tight chamber into which the liquid is admitted (usually by gravity), and from which it is forced to its destination by the compressed air, the latter being also admitted to the blow-case at necessary intervals. The process consists, therefore, in admitting liquid until the blow-case is filled, then turning off the liquid and turning on an air valve which admits the air. This operation is repeated continuously as long as liquid is to be lifted.

It has long been the effort of inventors to obtain an automatic device which will turn on and off the valves necessary for this operation, and a number of apparatus have from time to time appeared which have been claimed to accomplish this purpose. The chief objection, however, to these apparatus has always been their complicated construction, allowing too great an opportunity for trouble in the mechanical operation.

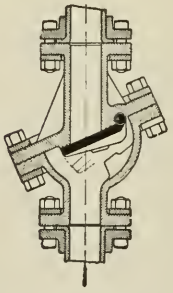


FIG. 1—ANY-POSITION CHECK VALVE

The latest of these devices, known as the Bihn-Jones automatic air device, seems to have overcome all these objections and is very simple in construction and operation. As it attracted considerable and well deserved attention at the recent National Exposition of Chemical Industries in New York City, a somewhat more detailed description should be of interest.

The apparatus consists of two parts. The first is an any-position check valve (Fig. 1), which is composed of two essential parts, namely, a body which contains the valve seat and a flapper which swings on trunnions, thus constituting a valve which will operate in any position. The second piece of apparatus is the automatic air device proper. It is composed, first, of a body in

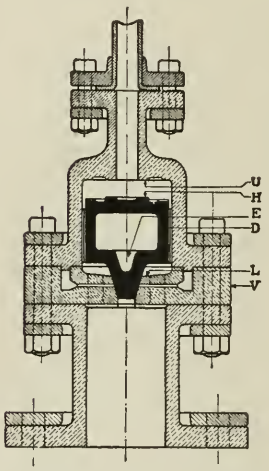

FIG. 2—POSITION OF AIR DEVICE WHEN TANK IS FILLING

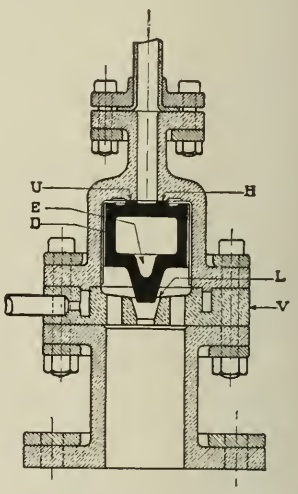

FIG. 3—POSITION OF AIR DEVICE WHEN TANK IS EMPTYING

which is formed the seat of the valve, through which the ports for the admission of compressed air open, the upper portion of the body also containing the exhaust port. Secondly, a disk of a cone and piston type is provided which has two seats, at the bottom a cone

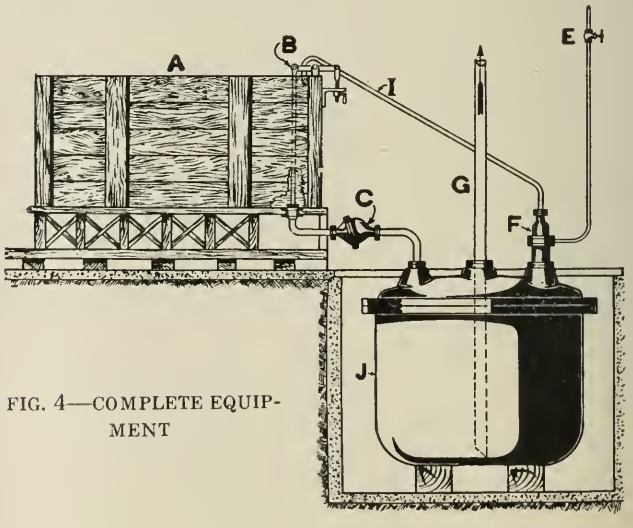

FIG. 4—COMPLETE EQUIPMENT

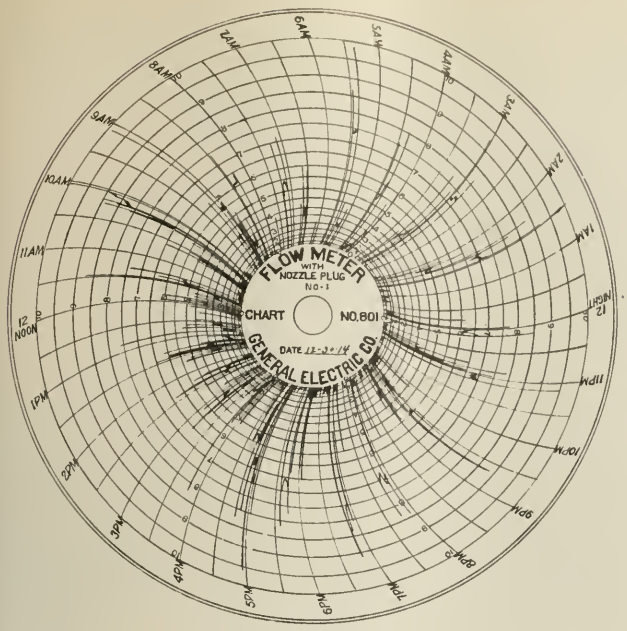

FIG. 5—RECORD CHART

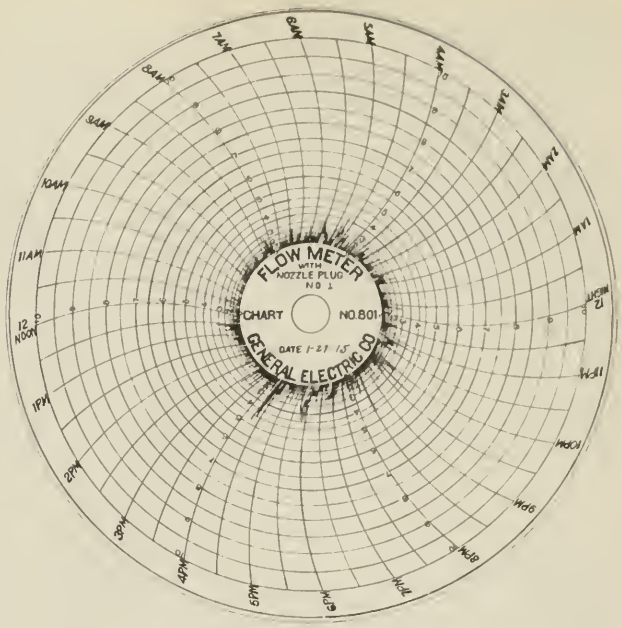

FIG. 6—RECORD CHART

which closes the compressed-air ports and at the top a flat seat which closes the exhaust port. These devices are illustrated in Figs. 2 and 3 respectively.

DETAILED ACTION OF DEVICE

Parts of Air Device.—The air device consists of the following parts:

1. Valve body *V*, which contains a seat *L* controlling the ports for the admission of compressed air, and a seat *U* for controlling the exhaust ports.

2. Disk *D*, of the cone and piston type, the cone *E* being at the base and completes the compressed-air valve. At the top of the disk *D* is a seat *H*, which completes the exhaust-air valve.

The device is actuated by the liquid from storage tank *A*, which flows through the check valve *C* into the blow-case *J*. This liquid rises until it reaches the cone of the disk *D* of the automatic-air device *F*, which it raises, thus permitting compressed air to enter.

The sudden release of the compressed air forces the disk *D* upward against its upper seat *U*, thus closing the exhaust port to vent pipe *I*.

The air pressure is thus prevented from escaping and the pressure exerted on top of the liquid closes the check valve *C* and forces the liquid through discharge pipe *G* to its destination.

When the level of the liquid reaches the opening of the discharge pipe at bottom of blow-case, the compressed air rushes out with the liquid, thus clearing the discharge pipe. The result of the air rushing out the discharge pipe causes a considerable drop of pressure within the blow-case, thus allowing the disk *D* of the air device to drop to its lower seat *L* due to its own weight, simultaneously cutting off the supply of compressed air and opening the exhaust port.

The check valve *C* in the supply line has remained closed during the emptying of the blow-case, but immediately upon the reduction of pressure within the blow-case the check valve opens (due to the head of the liquid in the supply line) and allows the blow-case to refill.

The free air or gas from liquid displaced from blow-case due to refilling is discharged to atmosphere through vent *I*.

The flow of liquid from tank to blow-case may be regulated by a plunger and thumb screw arrangement, as shown at *B* in Fig. 4, or by means of a stop valve. Accordingly, by regulating the supply, the contents of blow-case may be automatically discharged in any specified time.

It will be noticed from the above illustration that the apparatus is entirely outside of the blow-case, no part of it extending within the same, but resting upon a flange collar above the case. It can therefore be readily removed for examination, and its ease of operation may be readily understood.

Aside from being entirely automatic in operation and simple in construction, this device is claimed to reduce considerably the consumption of compressed air which is known to be quite expensive. The charts, Fig. 5 and Fig. 6, were made in a plant where forty blow-cases are in use, seven of which were equipped with the Bihn-Jones automatic air device at the time the test was made. The heavy irregular lines indicate the exact travel of the needle, which indicate the comparative consumption of compressed air. Fig. 5 was produced when the blow-cases were operated by hand, that is, compressed air turned on and off each time the blow-case was discharged, while Fig. 6 illustrates the consumption of air by the seven blow-cases which were equipped with the Bihn-Jones device.

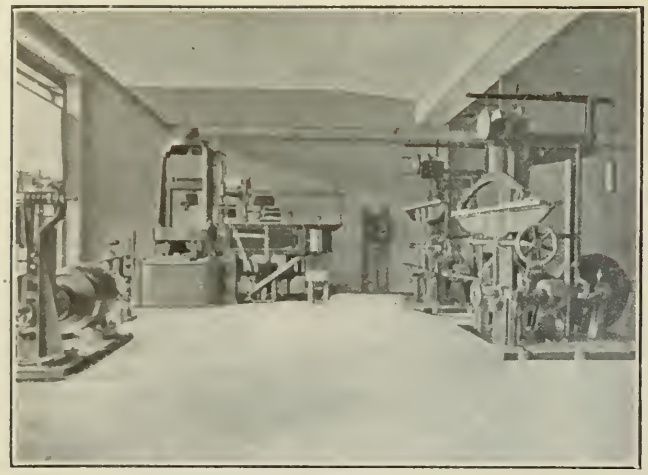
The saving in compressed air is further illustrated by the fact that in the above-mentioned case, in which the forty blow-cases, of 3 to 5½ tons capacity, are being filled and discharged continuously day and night, after the installation of the seven Bihn-Jones automatic air devices one of the compressors was shut down and has since been kept as a reserve unit.

This device is claimed to be particularly adaptable to conditions wherein large bulks of liquids are to be handled, and by properly selecting the material from which it is made it will handle with equal efficiency corrosive material, oily liquids, and, in fact, any material which may be readily caused to flow by compressed air. Its most extensive application is found in handling of sulphuric acid in fertilizer and acid manufacturing plants.

The device is being manufactured by The Schutte & Koerting Company of Philadelphia, Pa.

The Scientific Study of Steel

With a view to taking up the study of the numerous problems in iron and steel on a broader ad more complete scale the Western Spring & Axle Company, whose



TESTING MACHINES IN PHYSICAL LABORATORY

main offices are at Cincinnati, Ohio, have constructed new chemical, physical and microscopical laboratories at Detroit, Mich. This central group of laboratories is larger and more completely equipped than any single member company would be justified in maintaining.

The *chemical laboratory* is completely equipped for the analysis of each shipment of steel as it comes from the mill.

The *physical laboratory* for heat treatment and physical testing contains electric furnaces and a number of testing machines, as shown in the illustration. The machine on the extreme left is a special Upton-Lewis fatigue testing machine. This machine will take any size test bar up to 2 in. wide and ⅜ in. thick and subject the metal to any desired fiber stress and vibrate it at a maximum rate of 1000 r.p.m. It also automatically describes a curve showing the relation between fiber stress and the number of vibrations and the behavior of the steel during the test.

The *microscopical laboratory* is completely equipped for the photographing and examination of metal test specimens, including a recently perfected "inverted" microscope with camera attached having a magnifying range of 20 to 1000 diameters.

The laboratories were instituted not only for member companies, but in their careful planning and complete equipment there has been the thought of a larger usefulness, through co-operative effort with engineers in solving the many problems that arise in this field. The laboratories are in charge of Mr. Erwin C. Arndts, and the company extends a cordial invitation to all who are interested to visit the new laboratories at Detroit.

Personal

Mr. **Charles W. Baker** will take charge of the recently opened New York office of the American Zinc, Lead & Smelting Co. in the Equitable Building. Mr. Baker was recently elected a director of the company.

Mr. **George B. Clark** has sold his Pueblo, Col., assay office and has taken a position as assayer and chemist for the River Smelting and Refining Company, Florence, Col.

Mr. **John Gross**, mining and metallurgical engineer, has recently opened on office at 523 McPhee Building, Denver, Col.

Mr. **E. M. Hamilton**, Mr. **F. A. Beauchamp** and Mr. **S. E. Woodworth** have gone into business together as metallurgists. Their offices will be at 419 Embarcadero, San Francisco.

Mr. **F. E. Marcy** has given up the management of the Salt Lake City office of the Mine & Smelter Supply Company, and will devote his time to the promotion of the Marcy mill, which is made by that company.

Mr. **F. E. Parks** will become manager of the Minnequa works of the Colorado Fuel & Iron Company, succeeding J. B. McKennan, who becomes general manager of the company.

Mr. **James Coles Roberts** of the U. S. Bureau of Mines, Denver, Col., has been selected for the Joseph Austin Holmes Professorship of Safety and Efficiency Engineering at the Colorado School of Mines.

Mr. **L. Selmi**, chemist and metallurgist of the Otis Steel Co., Cleveland, Ohio, has resigned to take charge of the chemical and physical laboratories of Corrigan, McKinney & Co. of Cleveland, a new steel plant.

Mr. **R. G. Williams**, safety engineer of the Norton Company, Worcester, Mass., has succeeded Mr. F. C. Schwedtman as chairman of the committee on accident prevention of the National Association of Manufacturers.

Mr. **F. O. Williamson**, representative of the Hardinge Conical Mill Co., T. L. Smith Co., and Smith Engineering Works in Chicago, is taking a trip through the Western mining districts.

Book Reviews

Molecular Association. By **W. E. S. Turner.** Octavo, 170 pages, 6 illus. Price, $1.40. New York: Longmans, Green & Co.

This is one of the monographs on inorganic and physical chemistry, edited by Dr. Alexander Findley. The topics principally dealt with are molecular association in gases (a comparatively simple field), of dissolved substances (an uncertain subject), the molecular complexity of the liquid state (an almost unknown territory), and of the solid state (a collection of speculations). While the monograph may be styled "satisfactory" because it presents nearly all that can now be said on the subject, yet it is necessary to say that the subject itself (aside from the topic of gases) is in a highly unsatisfactory condition, and there is not much gratification in store for the reader who peruses the book with the thought of learning something definite about the molecular state of solutions, liquids and solids. The author himself appreciates this situation, saying at one place: "There is great need of some guiding and reconciling principle like Avogadro's hypothesis." The reader will agree with him.

Methods in Metallurgical Analysis. By **Charles H. White.** 356 pages, 106 illus. Price, $2.50. New York: D. Van Nostrand Company.

Professor White writes from the standpoint of his experience in the Harvard School of Mining and Metallurgy. This is a text-book of quantitative analysis for metallurgical students. It is plainly written, in simple, direct style, giving the information needed in the fewest possible words.

It is an admirable repository of methods, so abridged as to read almost like recipes. In fact, this is the chief lack of the book, the frequent absence of reasons for the steps described. Assuming that the book is to be used under the careful supervision of a capable instructor, who will explain the *why* and *wherefore* (and thus, in reality, instruct and educate the student), it is an admirable laboratory manual; but for a man working without such assistance it would be an unsatisfactory guide.

It deserves a place in the commercial laboratory analyzing ores, metals or alloys, but the information is rather elementary for this purpose and must be used discriminatingly.

Flow-Sheets of Organization

In his opening address as Honorary President of the recent International Engineering Congress, General Goethals enlarged on the subject of organization as a factor in carrying engineering projects to a successful issue. The ability to create and maintain a loyal and efficient organization of the human element in any project is one of the first essentials to success. With it there is harmony and economy; without it, confusion and waste.

Borrowing an analogy from a well-established metallurgical custom, a flow-sheet of organization will be found quite as useful in visualizing the proper relations between the different departments of a company, as a flow-sheet of ore-treatment is in illustrating the different steps in a process. The very act of reducing the details of an organization to diagrammatic form will clarify the scheme in the mind of the chief, crystallize a more efficient method of transacting business through subordinate channels, and establish responsibility throughout the entire force.

It is a well-recognized and fundamental principle of organization that definite authority must be delegated if responsibility is to be demanded, just as in military affairs rank is established to insure command. Once established, the integrity of the organization must be maintained, and loyalty becomes the important consideration. The individual must recognize that the organization represents a purpose or object greater than any one factor in it, which can be attained only by harmonious and co-operative effort.

The more diverse the activities of an organization the greater the need for a well-established flow-sheet of authority and responsibility. For instance, some mining and metallurgical concerns carry on the three operations of mining, concentrating and smelting. It is self-evident that each of these operations is but a single factor in the accomplishment of a certain purpose, and ultimate success requires the proper correlation of work in the several departments. Loyalty demands that, so far as possible, the mine shall meet the requirements of the mill, and the mill of the smelter. Any attempt on the part of one to make a record at the expense of the other defeats the ultimate object.

Within a department the status of the individual must be recognized by his subordinates and superiors, orders being transmitted down the line of authority, and grievances, complaints and suggestions upward through the line of responsibility; provided, that in the latter case a channel be open to the head of the organization if the established flow-sheet is rendered

ineffective for a subordinate through unfairness on the part of an immediate or intermediate superior.

All these and many other features of organization and management will become apparent, and their importance more fully realized, if delineated in the form of a flow-sheet. Every factor in the organization will understand his position and appreciate his importance, with the result that an *esprit de corps* will be created that will overcome many obstacles tending to wreck an otherwise well-conceived and meritorious project.

Productive Capacities in the Iron and Steel Industry

The present general advance in iron and steel-market prices began at the end of last December, for on the first day of this year the regularly quoted market on bars, plates and shapes advanced from 1.05 cent to 1.10 cent. Throughout the first half of the year these commodities, and practically all other finished steel products, advanced in a moderate way. The average advance was about $2 per ton. The demand was steadily increasing, though it was not until July or August that it was sufficient to engage the full capacity of the steel industry. During the first half of the year, however, there was no general advance in pig iron.

By the first of September steel, merely as steel, had become scarce, while pig iron was still plentiful. The condition was precisely the one observers had not expected. Since 1912, when pig iron and steel prices were fairly well aligned with each other, there had been much more new construction of steel-making capacity than of blast furnaces, and from this showing pig iron should have grown scarce first. Like many other things, a condition could be explained when realized, although it could not be predicted. The blast furnaces individually were making better records than ever before, and the country's capacity, based on the performance of individual furnaces in the past few months, appears to be nearer 40,000,000 tons a year than the 35,000,000 tons estimated not so long ago. Furthermore, the demands of the foundry trade were light and more merchant furnaces served the steel instead of the foundry trade.

A new turn seems to have been given the kaleidoscope, and while steel prices have not ceased advancing by any means the pig iron market is now advancing very sharply. It is estimated that the average advance in pig iron during November has been not less than $1.50 a ton, whereas during all the movement that preceded there was an advance of only about $2.50. Nevertheless the foundry trade is still not busy and there is reason to believe that should the buying of foundry pig iron become as heavy as has been the buying of steel the demands upon the merchant furnaces could not be met. Blast furnace capacity might then be found to be deficient with respect to steel-making capacity, which would fit expectations entertained until recently.

There is so much news in the iron and steel trade, even in dull times, and events move so rapidly, that it is seldom long range comparisons are made. Comparison of pig iron and steel prices suggests a very interesting one. Pig iron has now advanced about $4 a ton, while finished steel prices have advanced more than $10 a ton. It is not more than ten years ago that in most quarters the impression prevailed that the strength of a large steel-producing interest lay chiefly in its control of raw materials, and iron ore in particular. Should materials become scarce those that lay closest to being in the raw stage should advance the most. Such was the case in the market movement of 1905-6-7, when Bessemer pig iron advanced to $23.25 and basic to $23 at Valley furnaces, while the large mills did not quote above 1.70 cent for plates and shapes and 1.60 cent for bars. On Nov. 18 last the Carnegie Steel Company advanced its price on bars, plates and shapes to 1.70 cent, but on that day Bessemer pig iron was $16.75, Valley, and basic iron $16. The spread between pig iron and finished steel was $7 wider than was the spread when the 1907 market was at its top. Ore is less important and steel making and finishing capacity more important.

Flotation and Cyanidation

The success of flotation as a concentration process is bringing in its wake a number of interesting problems in metallurgy, not the least of which relates to the cyanidation of flotation products—concentrates and tailings. In fact the future development of flotation may have an economic bearing on the continued use of the cyanide process in some places.

It has long been customary in many cyanide mills to combine table concentration with cyanidation for a variety of purposes: the removal of a refractory portion of the ore as a concentrate for smelting, followed by cyanidation of the tailing; the production of a barren tailing which is discarded, while the concentrate is cyanided; or, the separation of a concentrate for regrinding, after which it is again combined with the tailing for cyanidation. These processes have become standard and their details are well understood.

With the introduction of oil flotation a question naturally arose as to the possibility of cyaniding its products just as table products had been treated. At present it does not seem at all certain that the idea is easy of general accomplishment. In some cases it has been possible to substitute oil flotation for gravity concentration and cyanide the concentrates without difficulty. On the other hand, however, one metallurgist experienced in cyanidation has said that thus far he has been unable to cyanide raw flotation concentrates. And in another case where table tailing is being successfully treated by cyanidation, it has been impossible, at least in preliminary tests, to cyanide the tailing from the same ore when concentrated by flotation.

The difficulty is not regarded as insurmountable, and in all probability the problem will be solved in the extended research that is now under way. A rare opportunity is offered to study the physical and chemical effect of a small quantity of oil to see how far it may inhibit the chemical and electrochemical phenomena involved in cyanidation. It is not in concentrates alone that oil may cause trouble, for in the use of the more water-miscible oils, such as turpentine, appreciable quantities may exist in the tailings. Again, it is possible, through selective action, that in the treatment of

some ores flotation may fail to remove as a concentrate the refractory portion which gravity concentration handles successfully, thereby leaving in the tailing a valuable constituent not amenable to cyanidation.

With regard to flotation as a menace to the continued success of cyanidation in some districts, it has been suggested that the latter process may find it difficult to maintain permanently its present supremacy. The economic balance may swing in favor of a combination of flotation and smelting, as against cyanidation. Capital and operating cost would seem to favor flotation, and with a normal recovery and favorable smelting rates it is quite possible that flotation could appear as an active competitor to cyanidation. The cost of flotation oils is increasing, due to the unusual demand for tar products and the limited production of wood oils. But the oil cost is not the major item in the total cost and an increase in price will not be prohibitive.

Imports and Exports of Steel

Few industries have experienced such changes in the character of their foreign trade as has the iron and steel industry, and quite naturally, since substantially all the countries apart from the United States that produce iron and steel are at war with each other. While iron and steel is one of the most nearly self-contained of all industries it is not wholly so, and thus the country that exports some descriptions of material usually imports others. The United States, for instance, has had its imports of iron ore cut down. The latest import and export statistics available are those for the month of September and the nine months of the calendar year ending September, hence a comparison, to illustrate war conditions, is naturally made between the first nine months of the years 1913 and 1915 respectively. There was no very great difference in the industrial activity in the two periods, the production of pig iron in the United States being 15 per cent less in the later than in the earlier pig iron. Imports of iron ore, however, decreased from 1,916,733 tons to 971,098 tons, or practically 50 per cent, there being decreases in imports alike from Sweden, Spain, Canada and Cuba. There were also great decreases in imports of pig iron and ferromanganese. Imports of unfinished steel, chiefly high-grade alloy steel, decreased from 18,000 tons to 9300 tons. Imports of machinery, cutlery and the like suffered large decreases.

Our exports of iron and steel and manufactures thereof are always vastly greater than our imports of corresponding material, the calendar year 1913 showing imports (not including iron ore) of $33,601,985 against exports of $293,934,160, nearly nine times as great. Naturally one expects to find great changes in the iron and steel export trade, and a glance at the statistics does not disappoint him. By setting in antithesis some of the items one may see quite clearly a few of the changes that war has wrought. Comparing, as before, figures for the first nine months of 1913 and 1915 respectively, exports of agricultural implements, hitherto taken largely by Europe, have decreased from $27,622,594 to $10,371,379, while exports of breadstuffs have increased from $166,848,067 to $423,360,972. Europe must have the food ready to eat. The wheelbarrow yields to the motorcycle, the wagon to the motor truck and the carriage to the passenger automobile. Exports of wheelbarrows, push carts, etc., decreased from $598,648 to $232,391, while the number of motorcycles exported increased from 3459 to 11,859; wagons exported decreased from 16,980 to 5949, while motor trucks increased from 778 to 17,269; carriages decreased from 13,458 to 1139, while passenger automobiles increased from 20,175 to 31,036. This is a modern war and there is nothing slow about it. Exports of railway cars to North and South America and Japan decreased from $12,883,673 to $1,234,168, or 88 per cent, while exports to "other countries" undoubtedly Europe almost exclusively, increased from $618,773 to $1,721,620, or 180 per cent.

Exports of cash registers decreased from 33,064 to 11,920, but horseshoe exports increased from 950 tons to 14,000 tons. Printing press exports decreased from $2,031,774 to $1,065,529, but exports of metal working machinery increased from $11,980,778 to $30,844,199. From the ordinary steel mill products antitheses can readily be picked out. Steel bars, used chiefly for the manufacture of shells, increased from 164,000 tons to 300,000 tons, while structural iron and steel, not particularly useful for war purposes, decreased from 309,000 tons to 169,000 tons.

The government export statistics customarily give the principal countries of destination in the case of important exports, but as the classification was established before the present conditions arose it is not well fitted for the presentation of illuminating statistics. In the case of plain and Barb wire, for instance, the adopted classification is: Canada, Mexico, Cuba, Argentina, Brazil, other South America, British Oceania, British Africa and "other countries." The exports to the countries named increased from 124,000 tons to 145,000 tons, their total imports being undoubtedly decreased, but a much larger proportion being drawn from the United States, while the "other countries" increased their imports from 18,000 tons to 196,000 tons. There is reason to infer that plain and barb wire has been taken for war purposes at the rate of 225,000 or 250,000 tons a year.

Exports of such iron and steel commodities as are returned by weight, including scrap, pig iron, unfinished steel, rolled iron and steel, cast and wrought pipe, nails, wire, etc., but no machinery, have been as follows in gross tons:

1912	2,948,466
1913	2,730,681
1914	2,085,511
First quarter, 1915	458,470
Second quarter	842,291
Third quarter	1,166,667

Thus these exports have reached a rate of 4,650,000 gross tons a year. Iron and steel used in the manufacture of shells, machinery, automobiles, railway rolling stock, etc., undoubtedly amounts to more than the equivalent of 2,400,000 tons a year, so that iron and steel to the extent of more than 7,000,000 tons a year is involved in the direct and indirect exports.

Readers' Views and Comments

Wet Ores in Charcoal Blast Furnaces

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I read with a great deal of interest Mr. Johnson's working out mathematically the effect of wet ores in charcoal practice. The actual fact that filling wet ores was injurious to the efficiency of charcoal furnaces both in output and fuel consumption has been a well-known fact ever since iron was made with charcoal in blast furnaces, and the main reason, viz., that the stack heat was lessened, was also perfectly well understood.

In my own experience, when quite a young man, I often had occasion to notice the tremendous difference in furnace working between wet and dry ores.

One of the furnaces under my charge was a small cold-blast charcoal furnace using soft fossil ores from the company's mines. An attempt was always made to have a sufficient supply of ore on hand for six months' use at least. This ore was unloaded from the mine cars on piles, not over 6 ft. or 8 ft. high, and under a shed with open sides. The ore merely being protected by a roof.

The ore in the course of time became air-dried, and the moisture would not average over from 4 to 6 per cent. The dried ore itself averaged about 45 per cent in iron with 15 to 18 silica and 4 to 6 alumina.

The burden was 600 lb. ore, 30 to 40 lb. limestone on a charcoal unit of 18 bu., or 360 lb. well-mixed coal.

Sometimes, however, the ore stocks would run out and we would be compelled to use ore direct from the mines, often running as high as 15 and even 20 per cent of water. In such cases the burden would have to be cut to 525 and even as low as 500 lb. with a corresponding reduction in iron, and the iron generally a grade or two lower than made with the full burden of dry ore. I have often seen the temperature of the escaping gases drop to 120 deg. Fahr., so cool, in fact, that the hand could be held in the gases issuing from the open top. For they were so wet that they would not ignite until they went into the boiler combustion chamber, where a couple of logs of wood had generally to be kept burning to light the wet gases.

This was the common practice and experience all over central Pennsylvania where fossil ores were used, and I remember seeing at Mount Alto several large ore roasters which the superintendent, Col. John Weistling, had built to dehydrate the ordinary brown hematite (limonite) ores used at this plant. These ores were the average brown hematite found throughout Pennsylvania and Virginia running after washing about 40 to 45 per cent in iron, and containing 10 to 13 per cent combined water, very little if any sulphur, and no carbonic acid. He roasted these ores simply to drive off the moisture, as they were amply porous for easy reduction, and he told me he had found by experience that the use of roasted ore made a reduction of from 10 to 12 per cent in his fuel. It was also a common practice throughout central Pennsylvania at the old charcoal furnaces to pile the brown hematite ores in piles sometimes several hundred feet long, 8 to 10 ft. high and 20 ft. wide. These piles were formed by a layer of cordwood and kindling on the ground, then about a foot of ore, 2 to 3 in. of charcoal breeze, 1 ft. of ore and so on to the top. The pile was lit at one end and used while piling was going on at the other. Whenever roasted ore ran out and raw was used it was necessary to cut the burden.

Pennsylvania Steel Company,
Lebanon, Pa. R. H. Lee.

The Electric Furnace in the Foundry

To the Editor of Metallurgical & Chemical Engineering:

Sir:—For some time past, the various technical journals have contained articles on "the electric furnace in the foundry." Each author of these articles has given his opinions and experiences, with the uncorroborated experiences of others.

But with all this, and in summing up the substance of the literature the vital question stands out, "Why is electric-process steel superior to steel made by other processes?"

To answer this question we can find a considerable amount of literature. Good authorities say that the conditions of melting and refining in the electric furnace, out of contact with the flame and gases, and in a neutral or reducing atmosphere, contribute to the superiority of the product. Others state that the high temperature and the reducing conditions make a superior product. Numerous convincing reasons are given by the manufacturers of electric-steel furnaces. Among them we can cite the following from their advertisements in the technical journals: "Crucible steel quality, with maximum of uniformity," "will produce high-grade tool steel from pig and ore," "excellent castings," "low cost of upkeep in producing every grade of iron and steel," and many more that have the same tone. On the other side the operators have arranged themselves, with an equally imposing lineup of statements. As their argument for superiority of electric-process steel they give: "Homogeneity," "absence of segregation," "elimination of oxides," "complete control of elements," "great tenacity to finished product," "high elastic limit," "high ratio of elastic limit to ultimate strength," "ready response to heat treatment," "ability to obtain very hot metal," and many more that I have not compiled.

In the capitulation of all this literature, it appears that the manufacturers of the electric furnaces, and the operators of the electric process have come to the same general conclusion, namely, that "the electric process for steel outclasses anything yet produced for an as-near-to-perfect product."

My remarks might have the tone of an antagonist to the electric-steel process. But quite to the contrary. What I am endeavoring to bring out is the point, why the electric-steel process *necessarily* should outclass anything ever produced in an as-near-to-perfect product.

Primarily, the melting chamber is enclosed from outside atmospheric effects. The melting down is carried on in a slightly oxidizing condition. The refining is decidedly reducing and neutral. No oxidizing gases have contact with the bath, as in the processes using a gas flame for melting. The protection of the metal from contaminations taken up from the gases, as in gas-fired furnaces. The electrodes give no contaminating elements to the metal. The temperature can be controlled by regulating the amperage going to the furnace. These facts from a physical standpoint of advantages of the apparatus have a great effect on the chemical properties of the product.

Some operators and owners of the electric furnace for steel have made statements that "they did not have the anticipated results from the furnace they put in their plant." Others said "they had trouble in understanding the electrical machinery connected with it." And still another stated "he was always afraid some-

thing was going wrong with the juice." One owner told me it was difficult to sell their castings, when another process at less cost was in the field, making cheaper castings. As a general thing, users of steel castings and steel are not looking for something cheaper, but something better, to fill their requirements.

The first essential in any furnace is the proper design of the apparatus, to carry out economically and satisfactorily the duty imposed upon it. Most foundrymen are men of limited technical training, and do not readily take up a complicated contrivance, especially an electrical one on a furnace. This feature is a very commendable one to the manufacturers of electric furnaces in America. Simplicity of the American-made furnace is characteristic. With such an apparatus the foundryman can manipulate the furnace without days or weeks of instructions.

A furnace might be supplied to a customer to handle a certain maximum size scrap. A large supply, or a large field to draw from, might exist at the time the furnace was installed. Eventually this supply of scrap is consumed, and a less desirable material must be utilized for the furnace. Possibly furnace alterations become necessary, causing an extra expenditure to the owner. The operator may not be able to operate his furnace as he did when he had the desirable and satisfactory scrap available. His costs increase, other irregularities present themselves such as, time to charge up, melting down, refining. Indirectly he finds that his production has decreased slightly.

An instance of this took place at a plant at which I was. The furnace was originally built to handle scrap of a certain maximum size. This pertains to the size of the charging-door openings. Small shovel scrap and such scrap as could be charged easily, had been available for some time. Eventually this desirable scrap became depleted. The management purchased an 80-ton lot of scrap split-steel gears, weighing approximately 120 lb. each, and 20 in. in diameter. Each gear was bolted with two 1½-in. steel bolts. The gears as they were were too large for our furnace. Consequently each gear had to be cut apart by taking off the two nuts. This necessitated extra expense in handling the scrap; the large chunks took a longer time to charge; the time of melting down was increased, and the output of the furnace for a given time was decreased. The cost per ton increased. Here the proper scrap was the vital point in the economy of the operations.

Right here I wish to state that, in my opinion, the "sesame" to making high-grade superior steel by the electric process, both economically and satisfactorily, is dependent on the scrap and the purity and condition of the materials charged into the furnace.

In using the all-scrap process, which I consider the simplest of processes for electric-steel castings, the scrap must be given careful attention. In packing crucibles for the crucible process, only the cleanest and most desirable selected material was used. Punchings of medium open-hearth steel were riddled to take out all dirt and loose rust. Manufacturers of crucible steel made a special iron for their crucible plants, to get the best materials for the process. Careful supervision during melting and careful selection of the materials charged produced a high-grade superior-quality steel. Up to the advent of the electric-furnace process, crucible steel was considered without a competitor. But without the careful selection of the melting scrap, crucible steel would not have been what crucible steel is known to be.

Electric steel now has the same chance that crucible steel had. The materials must have the necessary attention to guarantee a product from them. Unless the cleanest and best selected scrap is utilized for the electric furnace, electric-process steel will not fulfill the claims made for it.

When a manufacturer of castings by the electric-furnace process made the remark that he had not found the electric furnace what had been claimed for it, I questioned him on several points. Among them I asked to see his scrap. He showed me his stocks. The purchased scrap was out in the weather, coated with rust and dirt. Layers of rust peeled from the material. His scrap castings were sandy and dirty. The fillets of the castings contained considerable sand, as well as sand sticking all over them. The sprue was likewise sandy and unclean. Core sand was still in the cored holes of the castings. And this scrap went to the furnace just as I saw it. The punchings, of which there was a large stock, were shoveled from the floor, and, sand and dirt and rust mixed with them, taken to the furnace.

With such materials charged no process will turn out a high-grade superior product, especially what is desired for a steel casting. Every bit of dirt put into the furnace must rise through the molten bath and be taken off by the slag. Unnecessary dirt charged takes unnecessary time to finish the heat. Time in the electric process means power consumption, and power consumption means dollars and cents. Eventually a heat is poured exhibiting dirt holes and entrained slag in the castings, and the furnace and the process is condemned. The presence of iron oxide, as rust on the scrap charged, increases the labor of "killing" or deoxidizing the metal. Ferrous oxide is very soluble in a melted steel bath. During the melting down of a cold charge of scrap, oxidation of the metalloids and metal takes place. These metallic oxides must be reduced, the solid product brought to the surface and the gaseous products allowed to escape. By adding an unnecessary amount of oxides from the scrap an unnecessary amount has to be reduced in cleaning the metal. This increases the time of making a heat, because unnecessary labor and time has to be expended to get the metal ready to pour. As the atmosphere of the melting chamber during melting down of the charge is oxidizing, sufficient oxidation goes on to oxidize phosphorous, etc., without adding any outside oxidizer.

By proper protection against the weather, sand blasting of the extremely dirty and heavy pieces, and rattling of the lighter shovel scrap, a clean and acceptable charge can be provided for the furnace. This might militate against costs. But with a superior product a better price can be obtained for it.

Absence of segregation, elimination of oxides can be controlled to a considerable extent by careful observance of the scrap charged. The presence of manganese sulphide has considerable to do with the defects of segregation. Much of the so-called "blowholes" are due to the presence of manganese sulphide. The oxidation effect and the presence of oxides might exist after the metal has been tested and found to be deoxidized. The extremely high temperature of the electric furnace causes the metal to become considerably superheated. At the time of pouring from the furnace into the ladles a state of oxidization could exist, in which the metal becomes oxidized and gets "wild." Then the purging of the molds shows a gas evolution in the metal.

In conclusion, I consider the use of clean scrap to be the most essential and primary factor toward turning out a superior and high-grade product from the electric steel furnace. With the small capacity per heat, and the necessity of selecting clean and desirable scrap for each heat, the electric-furnace process for steel making can be made to give a product superior to anything on the market, and at a price that can compete with other processes.

R. C. GOSROW.

Heroult, California.

Award of Nobel Prize in Chemistry to Theodore W. Richards

The award of the Nobel prize for 1915 to Prof. Theodore W. Richards of Harvard University has been announced. The work of Professor Richards on the atomic weights is well known and is generally recognized as the best work which has been done on this subject. With the help of assistants he has so far revised the atomic weights of about twenty elements. The results were published in various papers, published in the *Journal* of the American Chemical Society and elsewhere, and in a book "Experimentelle Untersuchungen über Atomgewichte" 1909. He has made many other contributions to physical chemistry, thermochemistry and electrochemistry. Professor Richards has been connected with Harvard for a long time, having taught there since 1889. In 1901 he was offered a chair in chemistry at the University of Göttingen, Germany, but declined, deciding to stay at Harvard. In 1907 he was visiting professor at the University of Berlin and in 1914 was president of the American Chemical Society.

The Failure of the Hull of the Sea Call

In view of the publicity which has been given the failure of the hull of the splendid schooner Sea Call, belonging to Alexander Cochran of Yonkers, N. Y., it is timely to have a statement from the Supplee-Biddle Hardware Company, Philadelphia, Pa., dealers in Monel metal, as the hull of the Sea Call was composed of Monel metal below the water line. This statement of the causes of the failure, given in the November number of the Supplee-Biddle *Bulletin*, points out that the failure was due to electrolytic action between steel as negative pole and Monel metal as positive pole.

Steel plates were used above the water line, and by mistake a few steel rivets were used in some of the Monel metal plates below the water line. It was the eating away of these rivets which first showed the corrosion that was taking place. The Monel metal was not affected. The most rigid examination was made of this hull, in view of the importance of the question, and it was concluded that had the hull been made only of Monel metal corrosion would not have taken place.

The hull was hauled out of water on Aug. 24 in the presence of a number of engineers representing prominent builders and owners.

The most exhaustive examination was made by these gentlemen to satisfy themselves and the companies they represent of the facts. It was therefore gratifying to every one interested in the production and use of Monel metal to know of the perfect condition of Monel metal in resisting the galvanic action that had destroyed steel and rendered an investment said to be half of a million dollars practically worthless.

SECTION SHOWING STEEL PITTED AND MONEL SHEET UNINJURED

The examination showed that the steel section under the water had seriously corroded. One of the most noticeable instances was that of the fine steel rib of the rudder frame. The interior framing of the vessel was of steel and this was, of course, connected with the Monel metal plates which made it possible that under the action of the bilge water corrosion would extend to all this steel work until the inner frame of the yacht was in a dangerous condition.

If the fault lay with Monel metal and there was danger of corrosion and rusting away it can readily be seen that its future as a roofing and as a general utility metal would be killed. It was on this account that the exhaustive study of the case was made to determine exactly where the responsibility lay. It is therefore gratifying to its makers and to the judgment of the various engineers concerned, that the cause of the trouble and resulting loss was found entirely outside of this valuable natural alloy and due alone to the combination of steel with the action of salt water.

Coming Society Meetings

A joint meeting of the New York Sections of the American Chemical Society, American Electrochemical Society and Society of Chemical Industry will be held in Rumford Hall, Chemists Club, on Friday evening, Dec. 10. The subject will be a continuation of that taken up at the last meeting of the American Chemical Society and also of the Society of Chemical Industry, viz.: Research and Chemical Industry. This will be Boston "Tech" night, the first A. C. S. meeting having been given over to Columbia University.

The winter meeting of the American Institute of Chemical Engineers will be held in Baltimore, Md., Jan. 12-15. A number of excursions to some of Baltimore's important industries will be arranged and the experimental laboratories of Johns Hopkins University and the U. S. Naval Academy at Annapolis will be visited.

The second Pan-American Scientific Congress will be held in Washington, D. C., Dec. 27 to Jan. 8. One of the nine sections will be devoted to mining and metallurgy, economic geology and applied chemistry.

The spring meeting of the American Electrochemical Society will be held in Washington, D. C., from April 27 to 29, 1916.

Electrochemistry and Lighting

Joint Meeting of New York Section of American Electrochemical Society and Illuminating Engineering Society

A very interesting joint meeting of the New York Section of the American Electrochemical Society and of the Illuminating Engineering Society was held on Thursday, Nov. 11, 1915, at the United Engineering Societies Building in New York. The program of the evening was electric conduction through gases in its relation to light production. Dr. **Colin G. Fink**, of the Edison Lamp Works, Harrison, N. J., chairman of the New York Section of the American Electrochemical Society, presided.

UNSTABLE STATES OF THE ARC

The first paper was presented by Professor **W. G. Cady**, of Wesleyan University, on "Unstable States in Arc and Glow." This paper, which we published in full in our issue of Nov. 15 (page 866), was illustrated by lantern slides and at its conclusion Professor Cady

made some very interesting experimental demonstrations of the singing arc, showing the possibilities of exact tuning. The paper was discussed by Dr. Moore, Mr. Mott and Dr. McKay.

A TRUE DAYLIGHT ARC LAMP

Mr. D. McFarlan Moore of the Edison Lamp Works, Harrison, N. J., followed with an elaborate and long paper on the latest developments of Moore tube lamps. One of his most interesting exhibits was a *neon tube* lamp, but the main part of the paper dealt with his *carbon dioxide tube lamp for color matching.* He employs in it a new principle for automatically replenishing the supply of gas within the tube as the gas is used up during the operation of the lamp.

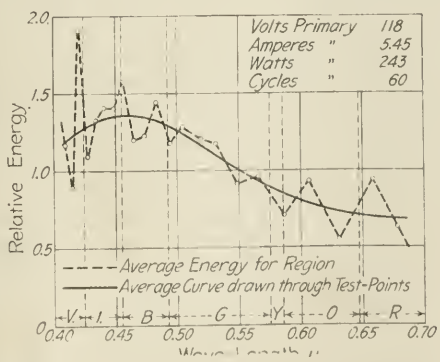
The application of this lamp was also illustrated by showing the difference in the color value of objects such as dress goods, silks, meat and flowers when illuminated first solely by the light of the standard tungsten lamp and then solely by the light of the Moore daylight tube lamp. In the course of his paper Mr. Moore called attention to the possibilities of the development of gaseous conductor lighting and the limitations of solid conductor lighting.

Elaborate spectrophotometric investigations have been made to show that articles of various colors, when viewed solely by the light of the new tube lamp, have exactly the same shades of color which they display when viewed by the light from a clear sky. Dyers and other color experts thoroughly agree that the standard light which they wish for color judging is that which enters a window from a clear north sky at an angle of about 45 deg., and preferably about mid-afternoon with a clear sun shining in the south.

There is reproduced in Fig. 1 the spectrophotometric curve of the CO_2 spectrum, which consists of a broken line with many jagged peaks, but an average of these peaks results in a smooth curve which gives a correct idea of the effective color characteristics so that it should be used for comparison with other line and continuous spectra. The effect of the banded character of the CO_2 spectrum, the tabulation of which consists of a broken line, was thoroughly investigated to determine its relation to the color-matching properties of the lamp.

The following samples of colored silk taken from the National Color Card of America were selected to represent the various parts of the spectrum and were spectrophotometrically tested to determine what the actual color composition was: violet, national blue, Yale blue, emerald, lemon, orange and scarlet.

The result of each of these tests was carefully plotted in the form of a curve, and a review of the data obtained in connection with these reflection curves showed that the irregularities in the CO_2 spectrum were absolutely without visible effect, and that they deviated only very slightly from north-sky values, to which they were compared. But it may be pointed out that if these north-sky values had all been taken at an angle of about 45 deg. there would have been no detectable variation, and that therefore the color-matching values of the CO_2 spectrum were all that could be desired.



CURVE SHOWING DISTRIBUTION OF ENERGY IN SPECTRUM OF CARBON-DIOXIDE TUBE LAMP

The straight-tube lamp is contained in an elongated sheet-metal case, which, however, is provided with a screw base similar to that used on the larger sizes of incandescent lamps. Instead of the lamp being fed CO_2 gas by means of an auto-magnetic feed valve, the gas is generated automatically within the tube itself. Near each electrode is placed a small bulb about an inch long, containing calcium carbonate, from which emanates the carbon-dioxide CO_2 when the resistance wires embedded in it become heated to the proper degree by reason of their being connected in shunt to the gas column. The gas column measures $\frac{7}{8}$ in. in diameter and 1 ft. in length, and appears as a solid bar of light of intense whiteness.

The foot-candles available near the tube total more than 200, making this apparatus suitable for the very closest color discriminations. The degree of vacuum is automatically held within 0.001 mm. of mercury column, and the apparatus will stand wide line-voltage fluctuations without becoming disarranged in any way.

This new lamp is suitable for making absolutely correct color determinations, and while it is applicable to a very wide field, it is particularly useful in enabling the dye shops of the great textile industry to run night shifts.

Since light is the source of all color, it has been proposed that this new lamp receive official recognition as a color unit from the International Conference on Electrical Units and Standards.

A NEW ARC LAMP WITH UNCONSUMED ELECTRODES

The last paper of the session was presented by Mr. **W. A. Darrah,** of the Westinghouse Company, on "The Electric Arc in Vapors and Gases at Reduced Pressures." The idea of the lamp seems fundamentally new as it is a flame arc lamp between tungsten electrodes which are not consumed. The light-giving qualities are obtained from special vapors introduced into the lamp. The paper was illustrated by lantern slides and experimental demonstrations, and was discussed by Dr. Moore and Mr. Mott. Mr. Darrah's paper is printed almost in full elsewhere in this issue.

Co-operation Between University and Industry

Meeting of New York Section of American Chemical Society

The first of a series of meetings to be held by the New York Section of the American Chemical Society for the discussion of the problem of co-operation between university and industry was held in Rumford Hall, Chemists' Club, Friday evening, Nov. 12. The attendance was very good and the hall was well filled.

After a short business meeting Dr. **T. B. Wagner,** chairman of the New York Section, said in his introductory remarks that research has not been developed in this country to the same extent as teaching. Even though many of our large establishments maintain finely equipped research laboratories we must look to the university for the training of the young man in research. Further activity in this work on the part of the universities is much needed. The far-reaching potential influence of university on chemical industry was forcibly brought to his attention when some years ago he visited his old teacher Emil Fischer and upon being shown into his study, he found the professor discussing an important industrial problem with the director of one of Germany's largest chemical concerns.

The speakers of the evening, President Butler and Professors Whitaker, Gies and Lucke, all of Columbia University, told of the work done there to aid the industries and of the further work which could be done. Their remarks were not intended, however, to apply only to Columbia but to every university.

President **Nicolas Murray Butler** of Columbia University, recalled with pleasure the chemical lectures of Professor Chandler he attended thirty-five years ago. He hesitated, however, to dwell upon the chemistry he learned in those early days fearing that the audience might regard it as archeology rather than chemistry. Chemistry has undergone many great changes in the last thirty-five years and the present European war has brought to the attention of the world the various stages of development in the different countries. In recent years we have heard much of the development and conservation of our natural resources, but not until this country felt the shock of the European war did it begin to realize the importance of organizing its forces, scientific and natural, for the strength of the nation.

Dr. Butler said great harm had been done in this country through the misuse of the word university. Any three men could get together in most States, except New York and Pennsylvania, he said, and form a university, so that the name has not had the proper significance to the general public and its aims and functions were little understood, consequently co-operation between the university and industry was not to be expected. But we are now beginning to see that a university is not only a place where persons are taught, but it is a public service institution. In the secondary schools and colleges knowledge is imparted to the young men, but in the university school emphasis is laid upon the extension and application of knowledge and upon the service of the public. A real university must be inspired and directed by the spirit of investigation and research.

Dr. Butler emphasized the performing of practical research. "Why do things for exercise in a university when there are so many practical questions waiting to be taken up." In this connection Dr. Butler told a story of a farmer digging a hole in front of his house and filling it up again for exercise while hiring a man to dig a trench for him. The university wants to keep down to a minimum the contrast between the academic and the practical. The university needs contact with and the co-operation of organized bodies of practical men, and these men should familiarize themselves with the university laboratories.

In America there is already more co-operation between the university and the industry than in England. At the School of Architecture at Columbia there is a visitors' committee of nine. Three of the large architectural societies of this country have each appointed three members to serve on this committee. It is the duty of this committee to make periodical visits to the university, to investigate the methods of teaching and to offer such improvements as they consider advisable. A similar committee would be of great service to the School of Chemistry and thereby further the co-operation of the school with the factory. The universities are ready and willing to welcome committees of this kind.

Prof. **M. C. Whitaker** took for his subject the work of Columbia in helping the chemical industries. Chemistry is very closely related to industrial development and the function of training men is one of the most important. The training which a man receives in order to eventually become a works manager, or to hold other responsible managerial positions may be divided into two parts, the portion done by the school and the portion done by the industry. The school gives the fundamentals and furnishes the student with a working basis. The industry is then responsible for allowing the man to gain the essential experience.

Professor Whitaker said the school is not able to make the rigid examination and inspection of its raw material as a manufacturer does in producing a manufactured product. The people of the industry should bear in mind that the university has no control over the "raw material" or student quality and should overlook a pardonable pride of the university whenever from rather crude material it turns out a "work of art." For this reason the yield cannot be 100 per cent from the combined training of school and industry. The industries often fail to appreciate this and expect too much. On the other hand they often fail to give the man the necessary opportunities to develop.

Industrial research has often been badly handicapped on account of unsympathetic surroundings of many of the factory laboratories. The young chemist is continually reminded of the importance of "production" and "profit" so that sooner or later he leaves his research and joins the factory force and his only chemical activity consists in the analysis of the shipments of coal.

The most important function of the educational institution is the opportunity for research. While it is true that some of our large companies have finely equipped and excellently conducted research laboratories, free from the hampering influence of the commercial production department, yet these involve a great expense and are not available to the average company. The university is the best place for research for most concerns. Professor Whitaker gave a brief outline of the course of chemical engineering at Columbia. All university research is industrial research. As regards pure research, the chief charm of it lies in its vagueness. The European war has forced us to realize that it is high time "to cash in" our scientific knowledge and make it immediately available.

Prof. **W. J. Gies,** in speaking for the department of biological chemistry said he represented the side on which both the industry and the university might help the investigator. He reviewed the work of Pasteur on the tartrates, fermentation and the French silk industry, and showed how Pasteur's researches had been of great practical application and had been suggested and helped along by his contact with the industries. He said the biological department of Columbia had been hampered in helping the industries because it had to uphold the honesty of its work. He said it was the exception rather than the rule to be asked to do honest work for some industrials. The biological department has been approached with all sorts of crooked food and medicine schemes but has had to refuse all except where a direct public benefit was to be gained. Professor Gies emphasized that it was "up to the industry. Gentlemen of the industry, it is your move."

Prof. **Charles E. Lucke,** in speaking for the mechanical engineering department said that mechanical engineering must necessarily follow chemistry and furnish the means for transferring its principles into practice. Taking the chemical industry as a whole, the equipment is largely made up of standard machinery for the different operations, such as filter presses, centrifuges, crushers, etc. The improvements arising from research in the chemical industry are not, however, all chemical. The indirect aids may sometimes be forgotten. So many contributions of the universities are indirect that they are unfamiliar to the industries and hence do not receive the proper application. New apparatus and equipment is the most important indirect contribution. The next important is fault discovery. This is a duty which

can be performed by the university investigation.

In taking up new ideas it is all important to have an experimental construction to obtain accurate data. Here is where a great barrier has arisen. Many splendid ideas have never had the necessary experimental trials for accurately deciding upon their value, and on the other hand many poor ideas have been tried and when they failed the commercial men have become discouraged and looked with disfavor upon new ideas and tests. After an experimental trial has been brought to a successful termination the final stage is the design of the apparatus. Here the university laboratory can play no part. Any correct analysis of the relations between university and industry will show that the industry is receiving both direct and indirect contributions limited only by financial support.

The chairman, Dr. Wagner, announced that the discussion would be postponed to a later meeting inasmuch as several meetings are to take up the same subject.

American Institute of Mining Engineers

New York Section

The New York Section of the American Institute of Mining Engineers, of which Mr. David H. Browne is the chairman, is arranging an interesting program for this season. The meetings will be informal dinner-meetings, affording a means of friendly intercourse, and the general tendency was well indicated by the first meeting held on Oct. 28, devoted to a discussion of the New York Subways, when the presentation of this subject by the engineers of the Subway Commission was appreciated by a large audience. The endeavor is to handle matters of general and timely interest rather than technical subjects which interest only a few. Among the subjects which will be taken up in later meetings are "The Engineer in Modern Warfare" and "The Problems of the Naval Advisory Board."

Coal and Iron in Nova Scotia and Newfoundland

Meeting of the Mining and Metallurgical Society

On Thursday, Nov. 18, a meeting of the Mining and Metallurgical Society was held at the Machinery Club, New York City. After an informal dinner, the address of the evening was made by Major C. L. CANTLEY of New Glasgow, Nova Scotia, assistant to Mr. Thomas Cantley, the president and general manager of the Nova Scotia Steel & Coal Company, concerning the coal mines of Nova Scotia and the ore mines of Newfoundland.

Major Cantley has had an acquaintance with these properties from boyhood up, not only from an office point of view, but has spent several years at and in the mines themselves, participating in the very extensive and thorough geological studies which resulted in proving definitely the extent of the ore mines, whose outcrops occur on the land, but the vast proportion of which extends out under the ocean.

Major Cantley first described, briefly, the coal mines of the Pictou region, which are not particularly large and do not differ in important parts from other coal mines, and then passed to a description of the vast coal beds at the northeast end of Cape Breton Island. These outcrop on the land, but dip at a low and uniform angle out under the ocean, the farthest commercial outcrop being only about a mile and a half back from the shore. The Dominion Coal Company and the Nova Scotia Steel & Coal Company now control practically all the important part of this field. They have each patented submarine areas many square miles in extent out under the ocean off Sydney Harbor. The commercial development of these mines is much older than is generally realized in the United States, there having been coal mines of commercial importance in the district for over a century. By far the greater proportion of the coal mined in this field is used for bunker and commercial purposes, but the slack which results, is washed to reduce its ash and sulphur and then coked. When properly handled, the coal from some of the seams makes a good metallurgical coke.

The outcrops of the ore body are quite close to the shore of Bell Isle, a small island in Conception Bay on the extreme southeast corner of Newfoundland. The ore beds of commercial size are three in number and exceedingly uniform; even more uniform than those of the Birmingham district, as well as much richer, the ore running regularly from 50 per cent to 53 per cent in iron. These ore beds are separated and overlaid by strata of sandstone and shale, the sandstone forming the roof and greatly facilitating mining, since absolutely no timber is required. The ore beds dip out to sea at a very uniform rate of about 10 deg. and the mines are now being worked a mile and a half or two miles out under the sea.

Very careful geological examinations indicate that the quantity of ore commercially available is not less than half a billion tons and may be as high as three billion tons, constituting one of the largest of the world's ore reserves. This ore is transported to Sydney and used in the blast furnaces, of which there are nine of moderate size and good modern construction on Sydney Harbor, owned by the two companies above mentioned. The output of these furnaces is converted to steel in basic open-hearth furnaces at the two plants.

The Dominion company finishes its steel at the Sydney plant, but the Nova Scotia Steel & Coal Company ships ingots from its plant to New Glasgow where the parent works are. These include blooming mill, finishing mills and very extensive hydraulic forging plant, where forgings of very large size are produced, as well as railroad axles and the like. There are also shops for converting steel into track material, concrete bars and the like.

Just recently, a magnificent car plant has been completed and is now turning out a large number of steel and steel-and-wood cars for foreign governments.

Colonel Cantley's talk was informal and was supplemented by the replies to a great number of questions which were asked by the members.

After this technical discussion was concluded, Colonel Cantley acceded to the request of the members to tell them something of his experience in the trenches, he having been in Flanders until the late summer, when he was detailed home to assist in the manufacture of war munitions. His talk on this subject was of the keenest interest to all and a hearty vote of thanks was extended to the speaker for the pleasure and entertainment he had afforded the meeting.

The Western Metallurgical Field

Canadian Bounty on Zinc

Announcement was recently made in press dispatches emanating from Ottawa that the Canadian Government had offered a limited bounty on zinc produced in the Dominion from Canadian ores. The object of the bounty is to encourage the immediate refining of zinc within the country, and to protect producers from possible decline in the price of zinc between the end of the European war and July 31, 1917. The total amount of bounty to be paid is not to exceed $400,000, and individual payments will be made on a sliding scale not exceeding 2 cents per pound of zinc containing not more than 2 per cent impurities, when the standard

London price for zinc falls below £33 per ton. The bounty is not payable on zinc produced before the expiration of the war or after July 31, 1915, or on zinc that is sold to the Government at a price of 8 cents or more per pound.

Zinc in British Columbia

The value of the zinc deposits of British Columbia and the metallurgical problem presented in their profitable treatment have been fully recognized for many years, at least since 1906, when Messrs. Ingalls, Argall and Gardé made an elaborate report on their investigations for the Canadian Government. Zinc in British Columbia occurs associated with lead, and has been an impediment to the reduction of the ores. Concentration has accounted for a considerable production, however, which has been shipped to the United States for smelting. Electric smelting has been tried, a plant having been erected at Frank, Alberta, in 1904, and at Nelson, B. C., in 1908. Further experiments were made at McGill University in 1910 and again at Nelson in 1913, but none was commercially successful, mainly due to difficulties in condensation of the zinc vapor.

At the present time the problem is being attacked along different lines, looking toward a hydrometallurgical treatment of the ores and electrolytic reduction of zinc. Different processes are being tested, but in general they involve the roasting of the zinc-lead-silver ores, extraction of the zinc by leaching, electrolysis of the lixivium and smelting of the lead-silver residue. At Trail, B. C., the Consolidated Mining & Smelting Co. is using sulphuric acid as the solvent and electrolyzing zinc sulphate solution. The Weedon Mining Co. is using the Watts process in a new plant at Welland, Ont., and the Standard Silver Lead Mining Co. has adopted the French process at its works at Silverton, B. C.

The French Process for Electrolytic Zinc

The process of A. Gordon French was recently described in the *Bulletin* of the Canadian Mining Institute, in an excerpt from an article contributed by a metallurgical engineer to the Nelson *Daily News*. "The method consists in the use of a solution of bisulphate of soda, which is a cheap waste product, and a small quantity of manganese—an ingredient which occurs with most zinc ores. Bisulphate of soda dissolves the zinc from the roasted ore almost instantaneously. Along with the manganese in solution it completely prevents the anodes from being affected and after years of constant use they are as good to-day as at the beginning. This solution also has very little resistance to the passage of the electric current in the electrolytic vats and the consumption of current is thus lowered. It has also the peculiarity of throwing out of solution practically all the impurities which usually contaminate the zinc. Early in 1912 the Consolidated Mining & Smelting Company of Canada acquired the sole rights for the use of this process in Canada. It was only toward the end of last year that they had partially erected a plant of somewhat large dimensions, and after they had produced a few tons of zinc the contract between French's company and the Consolidated was canceled.

"A demonstrating plant was then erected at Silverton, Slocan Lake, by the Standard Silver-Lead Mining Co., on a large enough scale to thoroughly prove that the process would work equally well on a very large scale. It comprised two completely equipped dissolving vats, each capable of dealing wth 2500 lb. of liquor at a time and about 1000 lb. of ore. The zinc-depleted liquor containing bisulphate of soda from the electrolytic vat is pumped into the upper of these two vats. There is then added 700 to 1000 lb. of roasted ore from which the zinc has been partially extracted in a previous operation. In about an hour solution of the zinc is finished and when the liquor has settled for a short time it is allowed to run down into the second dissolver, placed at a lower level. The sludge remaining in the bottom of the dissolver is then pumped through a filter press to remove the water and the residue contains all the silver and lead. As the sulphur to the extent of more than 20 per cent has been driven off in the roasting operation and zinc to the amount of about 40 per cent has been extracted, the residue of the ore, of which a large quantity was treated, only weighed about 45 per cent of the original ore used. As it contained all the silver and lead originally in the roasted ore, the percentage of these metals was more than doubled. For instance, the ore treated had 31 per cent zinc, 3.5 per cent lead, and 32 oz. silver per ton. The zinc depleted residue contained 76 oz. silver per ton, and 8.7 per cent lead, and 92 per cent of the zinc had been taken out, i. e., 2.7 per cent of the zinc counted on the original ore used was left in the residue. This residue is now ready for smelting or other treatment for the recovery of its lead and silver in the usual way.

"To the liquor which has been run down into the second dissolver, a quantity of roasted ore is again add to neutralize the bisulphate of soda. As soon as this has taken place the liquid settles very rapidly to a clear solution, which is pumped through a clarifying filter press, and is then ready to have its zinc deposited in the electrolytic vats. At the Standard Co.'s plant only one electrolytic vat was used, as the dynamo power at disposal there was limited. Nine anodes were used and eight cathodes of the largest size each with an area of 8 sq. ft. What can be done with one vat can be done with any number on a large scale, a reduplication of vats of the same sizes being all that is necessary. The plant was well designed and erected and the results of running a large quantity of ore gave a remarkable good current consumption. Although 4000 kw.-hr. were allowed in costing for the deposition of 1 ton of zinc, only 3000 kw. were actually required, the lowest reading over a period of 48 hr. having been 2680 kw.-hr. On another occasion a 70-hr. run gave 2860 kw.-hr. As the zinc is deposited from solution in the electrolytic vat, the bisulphate of soda with which it was combined is regenerated and is used again in the next dissolving. The working costs vary with the ore, but they are now well defined and it is possible to give with some accuracy an idea of the profit which the district will derive from the working of this process near Nelson.

"The plant is expensive, but very much less than that required for a zinc smeltery of similar capacity. To deal with all the ores in this district some millions of dollars would be required for the plant alone. Ores of almost any grade above 10 per cent zinc can be treated equally well, but naturally the cost of treatment for an ore with a larger zinc content is less. As an example, an ore containing 24 per cent zinc, 24 per cent lead and 20 oz. silver per ton may be taken. Almost any of the mines can supply this or a better grade by picking or slight concentration without much loss of value. Taking zinc at 5 cents a pound, the lowest price at which it is possible for an ordinary zinc smeltery to work, and allowing freight on metallic zinc as far as Europe or China; lead at £20 per ton (London), and silver at 50 cents per ounce, and deducting ample costs for treatment, depreciation, management and royalty, the miner would receive for his ore about $18.50 net per ton. It is only necessary to deduct cost of mining, picking the ore and freight to determine the net amount per ton the miner would receive for his ore, i. e., in the

neighborhood of $15 per ton. For a supply of 500 tons of ore per day the net benefit to the miners would amount to upward of $2,500,000 per annum."

New Chloridizing Mill for Tintic District, Utah

By early spring next year it is expected that a new mill will be operating in the Tintic district, Utah, using the process of chloridizing, roasting and leaching that has been described on several occasions in this journal. The new mill is being built by a company representing a consolidation of interests formerly operating separately at Park City and Silver City, Utah. The Mines Operating Co. was treating ore from the Ontario mine at Park City, using the Holt-Dern roaster, while the Knight-Christensen Metallurgical Co. built a mill at Silver City and used a Christensen roaster. The Mines Operating Co. found it inadvisable to continue operations under the conditions existing at Park City, and the Knight-Christensen company lost its Silver City mill by fire. As a result of a combination of circumstances, a consolidation of interests has been effected, and the Tintic Milling Co. has been organized to construct a new mill on the site of the old Knight smelter at Silver City. The officers of the new concern are: Jesse Knight, president; W. Lester Magnum, secretary; George H. Dern, vice-president and general manager; Theo. P. Holt, superintendent. The new mill will contain three Holt-Dern and one Christensen roasters, and as the two will be operated under identical conditions, an excellent opportunity will be afforded to compare their relative merits. The Tintic district affords an unlimited quantity of ore suitable to the process, and the new venture is expected to prove a boon to the district and yield a satisfactory profit to its promoters.

The Iron and Steel Market

The runaway in steel prices has proceeded farther and has perhaps reached the stage at which buying for ordinary purchases ceases, for the time being at least. Buyers, as a rule, are covered for many months ahead and chiefly, of course, at prices much below the advanced level now ruling. New wants arise, but there will naturally be hesitation about filling them. Thus the Pennsylvania Railroad has decided not to buy the 11,000 freight cars against which it recently issued inquiries, announcing that bids made are too high and deliveries proposed too slow. In the case of ship material buyers might not hesitate to pay prices asked, or even higher prices, but there is not much ship material coming up now, the yards being already well filled with business.

A decided increase is noted in inquiry for structural material, suggesting that much more building is planned for next year than has occurred in the past two years, but it remains to be seen whether a large volume of business can be put through at present prices.

Specifications on steel contracts continue to come in at a great rate and the mills are falling still farther behind in deliveries. Some of these current contracts for bars, plates and shapes are at 1.15 cent and 1.20 cent and specifications now filed against them will not be filled in many instances in less than from two to four months, so that a very wide range exists in invoice prices, since the current quotation on bars, plates and shapes for shipment at mill convenience is 1.70 cent, and small lots of bars and plates are bringing as high as 2.00 cent.

From some quarters come urgent requests to the mills for quicker deliveries, but there is no doubt that many buyers are comfortably fixed as to deliveries, if, indeed, they are not receiving material faster than they need it. Naturally buyers take all the material their low-priced contracts permit, even if this causes the accumulation of considerable stocks. A condition that always obtains after a material rise in steel prices is that of some buyers, who were fortunate in placing large contracts at low prices, accumulating stocks of material or piling up specifications at the mills, and the existence of such a condition makes it difficult to judge the future, for one does not know whether buyers would be as enthusiastic about securing deliveries if they saw the market become stationary or start declining. Their physical needs might be the same, but their interpretation of them would be different.

In most finished lines the mills have business on books insuring operation at full capacity to about the middle of next year, and the chief exceptions to this condition are lines that do not customarily book business so far ahead. As a rule, new contracts could be taken only for third quarter of next year, and the mills do not wish to look so far ahead.

The production of steel is not increasing further, as the limit of capacity had already been reached. It seems safe to estimate that ingots are being produced at the rate of more than 40,000,000 tons a year.

Pig Iron

Prices have been advancing sharply in the past fortnight in nearly all markets. The advance is due much less to heavy market demand than it is to the productive ranks being well obligated to buyers already. Until but a few weeks ago advances in pig iron were either forestalled, or were greatly restricted in amount by the blowing in of idle furnaces. With considerable suddenness the limit is being reached, there being few idle merchant furnaces remaining, and some of those cannot blow in because they are not provided with ore, and nothing can be done with them until ore comes down the lakes next season. There has been, on the whole, a slight improvement in pig iron demand from foundries, but the foundries are still far from taking the tonnages they require in normally prosperous times. The steel works are not heavy buyers, but such purchases as are made count strongly in the market for the reason that the steel works that normally buy iron had already bought for forward delivery and present purchases are of additional lots. The furnaces claim to be well sold up, and effect price advances without any difficulty, but experience shows that in conditions like those of the present furnaces may have the appearance of being more sold up than is the case. If an accident occurs in the market it always turns out that there was more unsold iron than was estimated. As the market is trending now there will be sharper advances in the next two months than have occurred lately, even though during November the average price of all important descriptions of pig iron has advanced fully $1.50. The more important advances in the past fortnight are 50 cents in Bessemer and basic $1 in found iron at valley furnaces, $1 in the Buffalo market and 50 cents at Philadelphia and Cleveland. We quote: No. 2 foundry iron, delivered Philadelphia, $17.75 to $18.25; f.o.b. furnace, Buffalo, $17.50 to $18; delivered Cleveland, $17.30; f.o.b. furnace, Chicago, $17.50 to $18; f.o.b. Birmingham, $13.50 to $14; at valley furnaces, 95 cents higher delivered Pittsburgh; Bessemer, $17.50 to $18.00; basic, $16.50 to $17; No. 2 foundry and malleable, $17; gray forge, $16.50.

Statistics returned from upper lake docks indicate that the movement of iron ore out of the Lake Superior region this season, including all-rail traffic, will total about 47,000,0000 tons, or within 3,000,000 tons of the record, made in 1913. Ore prices for next season are expected to be announced shortly, at an advance of 75 cents to $1 a ton over the schedule for the season just

closing, a schedule identical with that of 1912 and 1914, prices in these three years having been the lowest since 1904.

Steel

Transactions in billets and sheet bars have been limited almost entirely to sales to regular consumers, who depend upon some particular source of supply, and odd lots disposed of by brokers. There is no regular market for Bessemer steel, while there is practically no market at all for open-hearth. Prices nominally representing the market so far as there can be said to be one, are approximately as follows: Bessemer billets, $28; sheet bars, $28 to $28.50; open-hearth billets, $29 to $30; sheet bars, $29.50 to $30, f.o.b. maker's mill, Pittsburgh or Youngstown. Forging billets are $48 to $50 and wire rods about $35.

Finished Steel

Prices have been advancing sharply almost all along the line. Nov. 18 the Carnegie Steel Company advanced bars, plates and shapes $2 a ton, to 1.70 cent, this price instantly becoming the minimum of the market. Premiums are the rule in bars and plates for early deliveries. Prices quoted are f.o.b. Pittsburgh unless otherwise noted, and are for ordinary deliveries:

Rails, standard sections, 1.25 cent for Bessemer, 1.34 cent for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.70 cent.

Shapes, 1.70 cent.

Steel bars and bands, 1.70 cent, base; steel hoops, 1.75 cent, base.

Iron bars, 1.759 cent to 1.809 cent, Philadelphia; 1.60 cent, Chicago; 1.60 cent, Pittsburgh.

Plain wire, 1.75 cent; wire nails, $1.90 per keg, base; painted barb wire, 2.05 cent; galvanized barb wire, 2.75 cent.

Sheets, blue annealed, 2.00 cent to 2.10 cent; black, 2.40 cent to 2.50 cent; galvanized, 4.50 cent to 5.25 cent; painted corrugated, 2.20 cent to 2.30 cent; galvanized corrugated, 4.55 cent to 5.30 cent.

Tin plate, $3.60 for 100-pound cokes.

Steel pipe, ¾ to 3-in., black, 78 per cent off list; galvanized, 63½ per cent off list.

Boiler tubes (less than carloads) 3½ to 4½ in., 69 per cent off list.

Structural rivets, 2.40 cent; boiler rivets, 2.50 cent.

Non-Ferrous Metal Market

The situation in this market for the two weeks ending Nov. 23 has been one of advancing tendency in all directions. These advances for the most part have been legitimate, and due to increased demand. There is great difficulty in obtaining spot deliveries and futures are well sold up.

Copper.—On Nov. 8 electrolytic was quoted at 18@18¼ cents. This price remained fairly steady for a week despite the closing of the Nichols Refinery at Laurel Hill, L. I., by strike on Nov. 10, which removed more than a million pounds from the daily production. On Nov. 12 the price had risen to 18½ cents for electrolytic, and by the 17th the price was 19 cents. Consumers may have been frightened into buying by the advancing market. By Nov. 20 the price had reached 19½ cents, and on the 22nd the much talked of 20-cent copper was realized. Exports up to Nov. 23 were 16,570 tons (compiled by N. Y. Metal Exchange). The strike at Laurel Hill was settled Nov. 16.

Tin.—The condition in the tin market has been one of extreme irregularity. The limited supply available and the uncertain reports have upset the market. Demand has not been normal, otherwise an acute situation might have developed. On Nov. 10 the spot market was 37 cents, when the report of the closing of the Suez Canal drove the price up until 44½ cents had been reached on Nov. 15. The market then reacted when it was found that this report was not true, and on the 22nd the market was weak and dull, with spot at 39 cents. Total arrivals up to Nov. 23, 1100 tons.

Lead.—The lead market was strong, with two advances recorded by the Trust between Nov. 8 and 23. On Nov. 10 the price was advanced 0.15 to 5.15 and on Nov. 15 it was advanced 0.10 to 5.25. This price has held steady. The market is pretty well in the hands of the Trust, and there was little inquiry in the outside market. There has been an absence of speculation.

Spelter.—The demand for this metal has been extremely good, and an advance of substantially 3 cents was recorded. On Nov. 8 spot was quoted at 15.20 New York. During the next two weeks heavy buying and a flood of inquiry sent prices soaring, and on Nov. 22 prime virgin spelter was quoted at 18.75@19.25 on the N. Y. Metal Exchange.

Other Metals.—Aluminium has held firm at approximately 56@59. On Nov. 18 sales of 200 tons were reported at close to 58, which staggered the market momentarily, but the price has, however, held firm. Antimony has advanced about 3 cents per pound on heavy demand, and on Nov. 22 was quoted at 38@39. Silver rose from 50⅛ on Nov. 8 to 52⅛ on Nov. 22. Platinum, on account of the French embargo, is now quoted $68 for soft. Quicksilver rose $5, to $105 per flask.

The Roessler & Hasslacher Chemical Co., New York, was awarded a gold medal at the Panama-Pacific Exposition for its exhibit of cyanides.

Iron in Utah—Articles of incorporation have been filed by the Utah Iron & Steel Co., capitalized at $300,000. This is the first step in developing the iron fields of Utah, the company having a new plant in operation at Midvale which may be enlarged. The headquarters will be at Salt Lake City.

Antimony mining in Japan has had a great impetus as a result of the war. Prior to 1914 the mining of this metal in Japan was neglected on account of the cheapness of imported Chinese sulphide of antimony, but at the present time the production is about 50 tons a month. Consumption in Japan is roughly about 450 tons a month.

Mineral Resources of Quebec—According to a recent consular report, by far the greater part of the Province of Quebec is as yet unprospected. The mineral products produced are aluminium, asbestos, antimony, arsenic, chromite, copper, feldspar, gold, graphite, iron, lead, zinc, magnesite, mica, molybdenum, phosphate and ocher. An important amendment to the mining laws of this province was passed in 1914. Lands containing combustible natural gas, mineral oil, or naphtha may now be staked, either ordinary or for a long term, upon conditions which are favorable for exploration.

The famous "silver sidewalk," considered to be the largest slab of native silver in the world, has been removed from the La Rose property at Cobalt, Canada, and placed in the museum in Toronto. The preservation of this remarkable specimen of silver ore was undertaken by the provincial government, and the greatest care was exercised in its removal. It is reported that drill holes surrounding the mass were filled with unslaked lime, after which water was added and the holes plugged. The pressure exerted by the slaking of the lime dislodged the slab with the least possibility of fracture.

Alumina in Steel

BY GEORGE F. COMSTOCK

One reason for the value of the microscope in the examination of steel is its ability to give evidence as to the cleanness of the metal, or as to the number and character of the non-metallic inclusions embedded in it. By preparing a surface with a sufficiently perfect polish, not only the number of inclusions per given area can be ascertained, but their shape, color and arrangement through the metal can also be plainly seen if lenses of good quality and fairly high magnifying power are used. After examination of many samples of steel with especial regard to the non-metallic inclusions, experience is acquired by which these inclusions may be classified into several different types based on their appearance in a well-polished unetched steel surface.

The sulphides are the most common inclusions in steel, and their appearance is well known to all metallographers. Inclusions of this type used to be known as "manganese sulphide," but investigations made in recent years have shown that iron sulphide also enters into their composition to a considerable and variable extent. Next to the sulphides, the most common inclusions are the silicates, or true slag inclusions. These are always darker than the sulphides and usually of more irregular form. To some writers, all inclusions except sulphides are "slag," and others do not even make this exception, calling everything "slag" in a polished section that is not metal. From evidence obtained recently in these laboratories, however, it has seemed justifiable to differentiate between slag or silicate inclusions and those consisting wholly or chiefly of titanium nitride, or of alumina, respectively. The titanium nitride inclusions were described in the METALLURGICAL AND CHEMICAL ENGINEERING for September, 1914, Vol. XII, page 577, and are easily distinguished from all other inclusions in steel by their pink color. In this report is presented the evidence on which the identification of alumina in steel has been made.

A few years ago an ingot of good steel was treated, in the mold, with a large excess of aluminium, and the bars forged from this ingot were very seamy. Photomicrograph Fig. 1 shows the appearance of the inclusions in this steel, which must evidently be alumina, since nothing but this was added to the molten metal.

These inclusions are in the form of small rounded spots, arranged close together in an elongated streak. They are of a very dark bluish-gray color, when examined with the white light of an electric arc, appearing black unless highly magnified, and it is practically impossible to polish them without forming little pits around each inclusion. If the polishing is done very carefully these pits may be kept very small; but with certain methods of polishing the pits are made so large that the original inclusions cannot be seen at all. Titanium nitride inclusions will form pits in the same way if poorly polished. If the specimen is not rotated constantly during the final polishing, the pits take the form of short scratches, and each inclusion will have a little tail, like a comet.

It will be noticed in photomicrograph* Fig. 1 that although this shows a longitudinal view of a bar, the individual inclusions have not been elongated by the forging at all, but merely the group as a whole has been drawn out into a streak. Compare this with Fig. 2, which shows some silicates in the web of a rail, and a great difference will be apparent, for the silicates have been elongated even by the crosswise pressure of the rolls forming the web, while the drawing effect of the forging did not elongate the alumina particles even in the same direction that the bar was drawn out.

The difference between inclusions of alumina and ordinary slag or silicates in steel may then be summarized as follows:

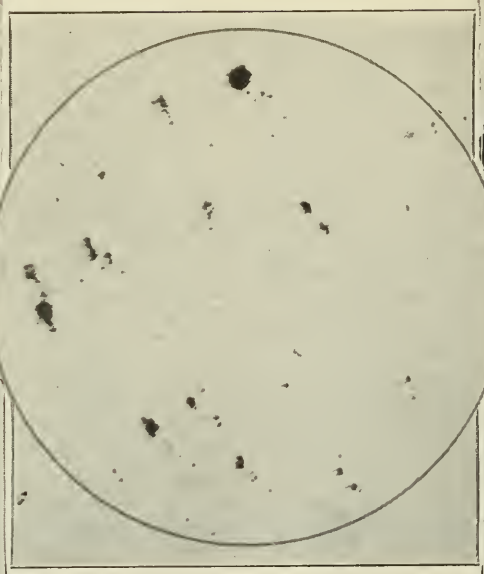
*All photomicrographs show unetched sections.

NO. 1—INCLUSIONS OF ALUMINA IN SECTION PARALLEL TO DIRECTION OF FORGING OF STEEL TREATED WITH A LARGE EXCESS OF ALUMINIUM. THE FEW GRAY SPOTS ARE SULPHIDES. MAGNIFIED 200 DIAMETERS AND UNETCHED.

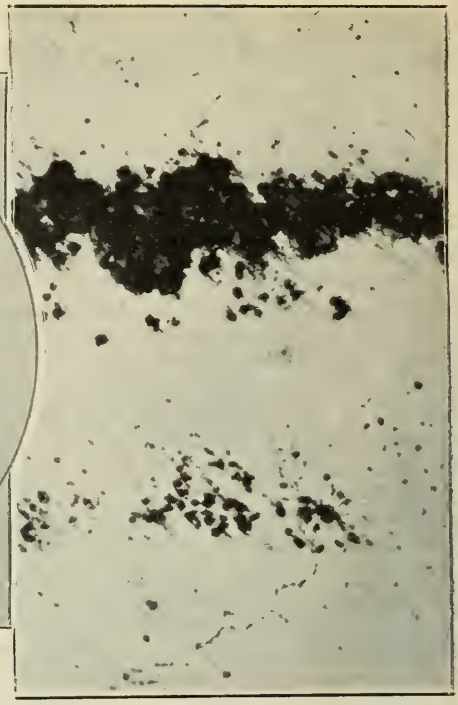
NO. 2—SILICATE OR SLAG INCLUSIONS (WITH A FEW GRAY SULPHIDES) IN THE CROSS SECTION OF THE WEB OF A RAIL. MAGNIFIED 200 DIAMETERS AND UNETCHED.

NO. 3—ALUMINA INCLUSIONS IN A SOFT STEEL INGOT IN WHICH MORE ALUMINA WAS FOUND BY CHEMICAL ANALYSIS THAN ALL OTHER OXIDES. MAGNIFIED 200 DIAMETERS AND UNETCHED.

NO. 4—SILICATE OR SLAG INCLUSIONS IN THE CROSS SECTION OF THE HEAD OF A RAIL. MAGNIFIED 200 DIAMETERS AND UNETCHED.



NO. 5—SECTION OF BROKEN SPLICE-BAR IN WHICH 0.019 PER CENT OF ALUMINA WAS FOUND BY CHEMICAL ANALYSIS. 200 DIAMETERS.



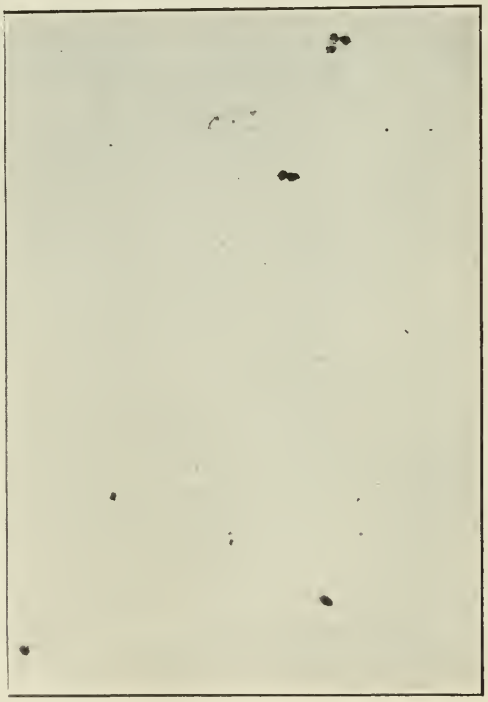
NO. 6—ALLOY, MADE IN SMALL ELECTRIC FURNACE, OF ALUMINO-THERMIC FERRO-TITANIUM WITH SWEDISH IRON. 400 DIAMETERS.

(1) Silicate inclusions will generally take a fairly smooth polish in a section prepared for microscopic examination, while alumina is very hard to polish without pitting.

(2) Silicate inclusions are always elongated in the direction of rolling or forging, while alumina particles are not (the *groups* of particles are, of course, elongated, but not the particles themselves).

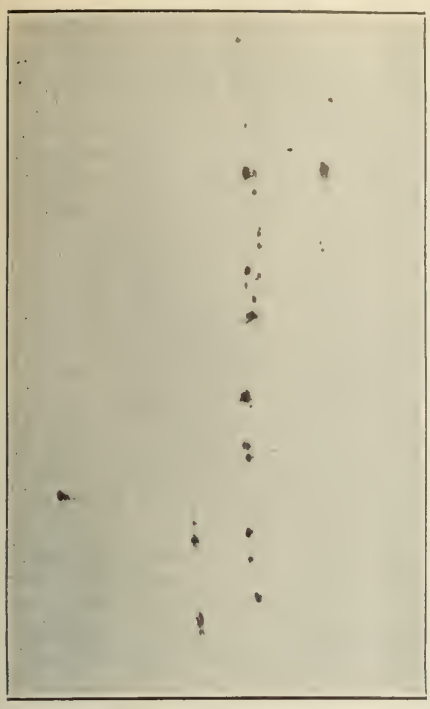
(3) Silicate inclusions are often found of quite large size (as well as very small), while particles of alumina are always small, and do not seem to coalesce into larger bodies even when closely grouped together.

NO. 7—GROUP OF SEGREGATED INCLUSIONS IN CROSS SECTION OF THE WEB OF A RAIL, IN WHICH 0.003 PER CENT OF ALUMINA WAS FOUND BY CHEMICAL ANALYSIS. MAGNIFIED 200 DIAMETERS.

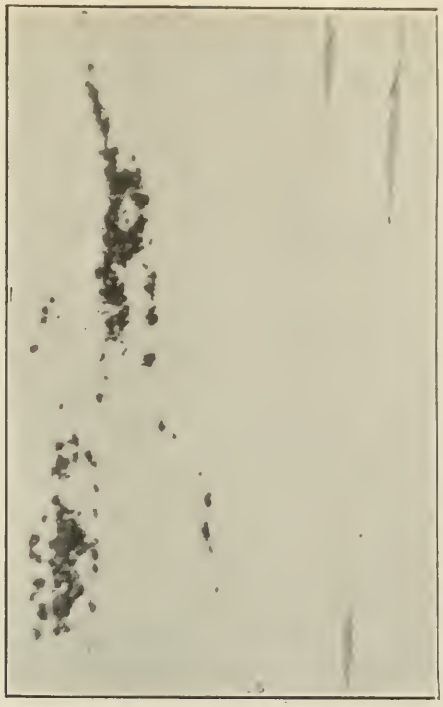


NO. 8—AVERAGE VIEW OF THE CROSS SECTION OF THE HEAD OF A RAIL IN WHICH 0.010 PER CENT OF ALUMINA WAS FOUND BY CHEMICAL ANALYSIS. MAGNIFIED 200 DIAMETERS.

NO. 9—STREAK OF ALUMINA INCLUSIONS BADLY POLISHED, SHOWING PITS AND SCRATCHES. MAGNIFIED 200 DIAMETERS AND UNETCHED, SHOWING "COMET TAILS" DUE TO POLISHING.



NO. 10—SAME STREAK SHOWN IN NO. 9 AFTER GRINDING AND MORE CAREFUL POLISHING. MAGNIFIED 200 DIAMETERS AND UNETCHED. THE ALUMINA INCLUSIONS SHOW NO "COMET TAILS" AS PITTING HAS BEEN AVOIDED.



NO. 11—LONGITUDINAL SECTION OF A STREAK THAT CAUSED THE TOP OF THE HEAD OF A RAIL TO SHELL OFF, SHOWING ALUMINA INCLUSIONS AT THE LEFT AND SULPHIDES AT THE RIGHT. MAGNIFIED 200 DIAMETERS AND UNETCHED.

NO. 12—TYPICAL LARGE SILICATE OR SLAG STREAK IN THE CROSS SECTION OF THE WEB OF A RAIL, SHOWING ALSO TWO PARTICLES OF ALUMINA AND SOME FINE GRAY SULPHIDES. MAGNIFIED 200 DIAMETERS AND UNETCHED.

These characteristics of the alumina inclusions agree with what is known of the properties of alumina. Its great hardness and brittleness would account for the pitting effect; its infusibility would account for the small size of the particles and the tendency not to coalesce; and both of these properties together would account for the particles not being elongated by forging or rolling of the steel in which they are embedded.

NO. 13—ALUMINA INCLUSIONS IN CLEAN RAIL STEEL TREATED WITH AN EXCESS OF ALUMINIUM. MAGNIFIED 200 DIAMETERS.

NO. 14—SLAG INCLUSIONS IN SIMILAR STEEL TREATED WITH OXIDE OF TITANIUM BEFORE CASTING. MAGNIFIED 200 DIAMETERS.

NO. 15—STEEL TREATED WITH OXIDE OF CHROMIUM, SHOWING END OF A BROAD STREAK, WITH TYPICAL SMALL PARTICLES EMBEDDED IN THE METAL. 200 DIAMETERS.

Inclusions having all the characteristics of those seen in steel known to contain alumina have been found in many samples of steel examined in the course of our work here, but it could not be stated positively that any of these were alumina until a method was found for determining this substance quantitatively by chemical analysis. Eventually such a method was found, not only in our laboratory, but also independently by Mr. F. O. Kichline, chemist at the Saucon plant, Bethlehem Steel Co. (published in the September, 1915, issue of the *Journal* of Industrial and Engineering Chemistry) and the results from it have been very interesting.

All samples in which more than the merest trace of alumina was found by analysis were seen to contain the typical inclusions as described above, and those in which alumina was not found by analysis did not contain these inclusions. Furthermore, those in which more alumina was found by analysis contained more of these inclusions than those in which only a very little was found.

NO. 16—STEEL TREATED WITH OXIDE OF NICKEL, SHOWING TYPICAL INCLUSIONS OF EITHER NICKEL OXIDE OR IRON OXIDE. MAGNIFIED 200 DIAMETERS.

These facts have been considered as a good confirmation of the theory that the typical small inclusions, as described above, found in so many commercial steels are chiefly, if not wholly, alumina. Of course, the purity of the alumina in these inclusions is not known, but even if it is fluxed with some impurity it would seem proper to call the inclusions "alumina" when it is known that their character is determined by the presence of this substance.

Photomicrograph Fig. 3 shows the inclusions in an ingot of soft steel in which chemical analysis showed the presence of a much larger amount of alumina than of all other insoluble oxides, thus proving the presence of a considerable quantity of free alumina.

Fig. 4 shows some ordinary slag inclusions in a cross-section of the head of a rail.

This photomicrograph and Figs. 2 and 12 are included to show the difference between silicates and alumina.

Fig. 5 shows a section of a splice-bar which broke in a railroad track and was found by analysis to contain 0.019 per cent of alumina.

Fig. 6 is an alloy made on a very small scale of Swedish iron and aluminothermic ferrotitanium, and shows alumina which was not present in the original iron.

Fig. 7 shows a spot where alumina particles are segregated in the web of a rail, in which 0.003 per cent was found, and Fig. 8 is an average view of the head of another rail containing 0.010 per cent of alumina. Fig. 8 shows the most common mode of occurrence of these particles, that is, scattered thinly through the metal. In Fig. 7 most of the specimen showed very few inclusions, but the small segregated streaks shown in the photomicrograph are more dangerous to the life of the rail than the larger total amount of alumina in Fig. 8, where it is arranged differently.

Figs. 9 and 10 are photomicrographs of the same streak, differently polished; the former shows the comet-tails mentioned above, while in the latter the pitting has been more successfully avoided.

Fig. 11 is a view of some streaks that caused the top of the head of a rail to shell off from the rest of the section. The form of the alumina is well contrasted with the sulphides and with the large slag inclusion in Fig. 12, which is a large but typical silicate streak in the web of another rail.

All these photomicrographs show open-hearth steel, except possibly Fig. 5, which may be Bessemer, and Fig. 6, which is an electric-furnace melt. All show unetched surfaces, and all except Fig. 6 were taken with a magnification of 200 diameters. Fig. 6 was magnified twice as much as the others.

As a final check on the accuracy of the assumption that all inclusions in steel, having exactly the same characteristics as those shown in photomicrograph Fig. 1, are alumina, several experimental melts were made of rail steel with the addition of various oxides. The steel used was seen by previous microscopic examination to be practically free from non-metallic inclusions except sulphides, and ten-pound ingots were cast from it each treated with one of the following oxides: alumina, titanium oxide, chromium oxide, and nickel oxide. The tops of these ingots were forged from the original 2-in. square section to 1-in. square, and longitudinal sections were cut and carefully polished for microscopic examination.

The treatment with alumina was not successful, as this treated bar appeared just as clean as the original steel, so this melt was made over again with the use of metallic aluminium. Characteristic inclusions of alumina were then found in the forged bar, as shown in photomicrograph Fig. 13.

Fig. 14 shows part of a small streak found near the top of the bar made with titanium oxide. The rest of this bar was clean, and the inclusions shown would ordinarily be classed as silicates or slag. They show a peculiar duplex composition and would not be mistaken for alumina.

The steel treated with chromium oxide had small smooth purplish spots scattered all through it, but they were especially segregated in some streaks at the top of the ingot. Some of these inclusions were angular and some rounded, and like alumina they were not elongated by the forging. Where they were not too thickly segregated, however, they took a good smooth polish easily like the silicates, and from this fact and their purplish color they may be easily distinguished from alumina.

The photomicrograph Fig. 15 shows the end of one of the segregated streaks, where small particles of this oxide seem to be breaking away and entering into the steel, and the difference between these and alumina is readily apparent. The steel around these inclusions was very readily stained or tarnished during the polishing, and this effect, though noticed also with the nickel oxide and sometimes with titanium nitride, has not

been seen by the writer around the streaks of alumina.

The last photomicrograph, Fig. 16, shows some of the steel treated with nickel oxide, but these inclusions look exactly like iron oxide, and it may be that the nickel oxide was reduced by the metallic iron present, forming metallic nickel and iron oxide. At any rate these inclusions are entirely different in appearance from alumina. They look very much like sulphides, but are a little darker, and stand out more in relief from the surrounding metal.

The evidence available is thus seen to point uniformly to the conclusion that it is proper to identify as alumina all inclusions, seen in polished steel surfaces, that have exactly the characteristics of the alumina inclusions shown in photomicrographs Figs. 1 and 13. At present no other substance is known to the writer which has the same appearance in a polished steel surface as alumina. Ordinary slag inclusions, as well as the oxides of titanium, chromium and nickel, have been shown to be very different. Of course, there is a possibility that some substance may be found at some future time that has identically the same appearance, but the writer sees no reason to expect such an event, and believes that the work described above renders the identification of alumina in steel with the microscope a matter of as much certainty as the similar identification of sulphides or silicates, which has long been considered reliable.

Titanium Alloy Manufacturing Co.,
Niagara Falls, N. Y.

Solution Stratification as an Aid in the Purification of Electrolytes*

BY FRANCIS R. PYNE

In the electrolytic refining of copper there are two attendant evils of special prominence. One is the tendency of the electrolyte to stratify or form layers of various compositions, and the other is the accumulation of impurities in the electrolyte.

The stratification is caused by the formation of a heavy solution at the surface of the anode owing to the solution of copper, and by the formation of a lighter solution at the cathode owing to the plating out of copper. Unless the degree of stratification is greatly impeded, the result will be a very unsatisfactory cathode deposit, which will be at best heavy and lumpy at the bottom, while mealy and of poor quality at the top. The greater part of the current will pass through the strata of highest concentration, causing frequent short circuits and uneven dissolving action at the anode, with all the attendant deposition troubles.

As a preventive, the electrolyte is circulated throughout the tanks at a rate which varies with local conditions at each plant. Too rapid a circulation is liable to carry slime, if present, to the cathode, fouling it and causing metal losses in silver and gold. Too slow a circulation does not sufficiently suppress the stratification. Where the current density is high the circulation must be more rapid than would be the case with a lower density.

To show the degree to which stratification will take place, the figures in Table I are taken from a paper by Mr. W. T. Burns on "The Great Falls Electrolytic Plant" (Trans. A. I. Mining Eng., August, 1913). This illustration is selected on account of the high current density in use at Great Falls, 36 amp. per square foot (400 per sq. m.), which is conducive to very marked stratification. Samples of the electrolyte were taken between the center pair of electrodes at the following levels below the solution line: Zone 1, 6 in. (15 cm.); Zone 2, 17 in. (43 cm.); Zone 3, 28 in. (70 cm.); Zone 4, 39 in. (100 cm.).

The figures represent the average of 104 samples taken during seven consecutive days, and the results are reported in grams per liter.

TABLE I

	Zone	Sp. Gr.	Acid	Copper
Circulation at the rate of 6 gal. (23 liters) per minute	1	1 213	174	38 4
	2	1 216	172	39 2
	3	1 216	171	40 2
	4	1 228	153	49 9

The above figures clearly show the increase in stratification with decrease in circulation.

Regarding the accumulation of impurities in the electrolyte, these impurities are present in the anode, whence they pass into solution through the action of the current, or they may come from some outside source, for example, an addition agent. If allowed to accumulate in the electrolyte without restraint they may foul the cathode by being deposited thereon either electrically or mechanically. They may also increase the resistance of the electrolyte causing thereby a loss of power, or they may increase the specific gravity so that the settling of the slime is hindered, with a possible loss of slime in the cathode. In order to prevent these undesirable effects, the impurities in the electrolyte are not permitted to go above certain limits, and this is accomplished by withdrawing a certain amount of electrolyte from time to time for the removal therefrom of the undesirable constituents, and this removal must be done in such a manner that the valuable ingredients, such as copper and acid, shall not be wasted.

The customary method in use at the present time is to withdraw daily from the electrolyte a certain portion which is either worked for bluestone ($CuSO_4.5H_2O$), or else passed through tanks containing insoluble anodes. It is with the latter method that this paper deals. The treatment with insoluble anodes removes a large part of the copper from the electrolyte, but requires a large power expenditure, the output per kilowatt-hour being one to two pounds (0.45 to 0.90 kg.) as against an output of eight pounds (3.63 kg.) in the regular refining tanks. Moreover the quality of the deposited copper is greatly inferior to the regular cathodes.

The solution from this first set of insoluble anode tanks is then passed through a second set, usually at a slower rate of circulation, and this second set of tanks removes the balance of the copper and practically all of the arsenic and antimony. The solution is then treated in any suitable manner for the elimination of such other impurities as may be desired.

From the above it is evident that could a solution be secured from the regular tanks sufficiently low in copper to avoid treatment in the first set of insoluble anode tanks, there would result a considerable saving in power, assuming that it contained practically an undiminished amount of impurities.

*A paper read at the San Francisco meeting of the American Electrochemical Society, Sept. 17, 1915.

Knowing the tendency of the electrolyte to stratify, an endeavor was made to utilize this principle as a means to this end. Accordingly a tank was constructed in which the circulation was so arranged that stratification would readily occur. The electrolyte entered the tank just above the slime and was drawn off through two outlets, one at the solution line, the other just above the slime line and opposite the inlet. (U. S. Patent No. 1,148,798, see Met. & Chem. Nov. 1, '15, Pg. 816.)

The accompanying figure shows a sectional elevation

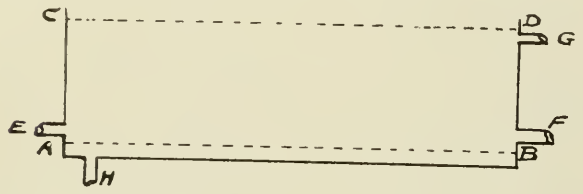

FIG. 1—SHOWING DIAGRAMMATICALLY THE TANK OPENINGS

of the tank as applied to copper refining. *AB* is the slime line, *H* the outlet for removal of slime from the tank, *CD* is the solution line. The electrodes have been omitted for the sake of clearness. The electrolyte enters the tank at *E* and is withdrawn through the upper and lower outlets, *G* and *F* respectively.

If the tank is filled with electrolyte and the upper outlet closed, any solution entering the tank through the inlet *E* will pass directly to the outlet *F* without disturbing the solution in the tank, providing the amount entering and leaving the tank is the same. If, however, the upper outlet *G* is open as well as the outlet *F*, a part of the incoming solution will flow through *F* while the remainder will rise in the tank to take the place of that withdrawn through the outlet *G*.

Now if the electrodes are in place and the normal current is passing and all circulation is stopped, the heavy solution formed at the anode by the copper passing into solution will stream downwards to the bottom of the tank, while the lighter solution at the cathode, due to the removal of the copper from solution, will rise. This is very clearly shown by the test made by Mr. Burns, in which the circulation was stopped for a period of 7 hr. Therefore, there will eventually be a stratum of heavy copper solution around the lower part of the cathode, while the solution in the upper part of the tank will be very low in copper and consequently lighter. The deposit on the lower part of the cathode will be rough and heavy while that on the upper part of the cathode will be loose and mealy.

As stated before, this is a very unsatisfactory condition of affairs, and it is therefore necessary to have such a circulation that the cathode will receive a satisfactory deposit throughout. This is accomplished by so regulating the flow from the upper and lower outlets that the heavy solution at the bottom of the tank will rise to such a height that there is a sufficient amount of copper at all points of the cathode. When proper regulation has been made, the regular tank room solution enters the tank through the inlet *E*, a solution high in copper is withdrawn from the tank through the outlet *F*, while the solution from *G* is low in copper and the cathode is in all respects similar to those drawn from the regular refining tanks.

The low grade solution withdrawn from the outlet *G* has been found in practice to be lower in copper than is usually obtained from the outlet of the first set of insoluble anode tanks mentioned above, and it is delivered directly to the second set of insoluble anode tanks for the removal of the last traces of copper.

The tanks have shown no increase in voltage over that of the regular refining tanks and there is no increase in the labor or material required in their operation. The solution withdrawn from the upper outlet can be varied through quite a range of copper content, and as it is a simple matter to equip a tank for this operation, a large or small number can be kept ready to respond to variations in the amount of solution to be withdrawn from the main circulation. They can be cut in or out at any time and in any part of the circuit, without reference to the age of the copper in the remaining tanks, which must be considered when using insoluble anode tanks unless the latter form a separate section apart from the regular refining tanks. A comparison of the two methods may be seen from the following:

Former Method.—Tank house electrolyte first passed through tanks containing insoluble anodes, to remove a portion of the copper, requiring high power consumption and giving a product of inferior quality, thence to a second set of insoluble anode tanks to remove the remainder of the copper and some of the impurities, after which the solution is treated in any desired manner.

Present Method.—Tank house electrolyte drawn directly from the special stratification tanks, requiring no increase in power and avoiding the production of inferior grades of product; thence to the final insoluble anode tanks, as above.

The net saving is therefore the operation of one set of insoluble anode tanks.

Chrome, N. J.

Determination of Mercury in Amalgamation Tailings

At the Buffalo mill, Cobalt, Ontario, Canada, high-grade silver ore is amalgamated in a tube-mill containing a large quantity of mercury and strong cyanide solution. The tailings contain mercury, both metallic and sulphide, which is recovered by dissolution in alkaline sulphide and precipitation with aluminum. The laboratory method of determining mercury in the products of the process is described by E. B. Thornhill in his paper presented to the A. I. M. E. To determine the total mercury (both metallic and sulphide) 0.5 g. of the material is well mixed with cast-iron filings, free from grease, and placed in a hard-glass tube, sealed at one end, with a contraction at about 2 in. from the sealed end. The mercury is distilled off, by heating the bulb containing the charge, and condensed in the tube just beyond the contraction. After the distillation is complete the contracted portion of the tube is heated, the bulb portion pulled off and the end of the tube sealed. The tube containing the condensed mercury is allowed to cool, filled one-half full of 0.1 per cent KCN solution, and 10 to 15 100-mg. gold beads added. Each bead will amalgamate with about 1 mg. of mercury. The tube is shaken until all the mercury is amalgamated; the beads are transferred to a small porcelain cup, washed with water, dried with alcohol and weighed. After retorting off the mercury they are again weighed. From ten to twelve determinations can be made in 1 hr. by this method and it is accurate enough for control of operations.

When it is necessary to know the proportionate amounts of mercury as metallic and sulphide two 2-g. samples are weighed out. One sample is digested with concentrated nitric acid and the other with a 10 per cent solution of sodium sulphide. The mercury in the residue from each is then determined by the method just given.

Flotation at the Consolidated Arizona Smelting Co., Humboldt, Arizona

(Editorial Correspondence)

The introduction of flotation, together with other changes in the milling scheme, at the copper concentrator of the Consolidated Arizona Smelting Co., increased the recovery of copper by more than 20 per cent over the best saving previously made with jigs, tables and vanners. The margin is quite sufficient to represent a difference between profit and loss, particularly when it is accompanied by a simplification of the process and reduction in cost for power and labor.

Milling ore from the company's Blue Bell and DeSoto mines is a silicious sulphide containing pyrite and chalcopyrite in a gangue of quartz and schist. The average composition of the ore and mill products is shown in Table I. In addition to mine ore, a variable quantity of mill tailing from former operations is also reground and concentrated. This material contains about 2 per cent copper.

TABLE I—AVERAGE COMPOSITION, ORE AND MILL PRODUCTS

(Gold and silver in oz. per ton. Other constituents in per cent)

Mill Tailing / Flotation Tailing	0.01	0.4	0.3	...	3.0	..	..	..	...

During the month of September, 1915, the total quantity of ore milled was 7173 tons. The average grade of mine ore was 2.7 per cent copper, and of all material, including old tailing, 2.65 per cent. The percentage recovery of valuable metals was 90.9 per cent copper, 68 per cent gold and 72 per cent silver. The gross amount of copper in concentrates was 345,000 lb., of which 240,000 lb., or nearly 70 per cent, was recovered by flotation. The usual recovery by flotation will average about 75 per cent of the total. The ratio of concentration in the entire mill was about 4, and in flotation between 7 and 8.

Effect of Changes in Milling Practice

A diagram of the present flow-sheet is given in Fig. 1. The ore is crushed dry in Blake crusher and rolls, screened in trommels and handled by belt conveyors and elevators in the usual manner. Water is first added at the boot of the main elevator indicated at the right of the diagram. Hardinge mills are used for final grinding, and Wilfley tables and an 11-cell Minerals Separation flotation machine recover the valuable metals.

The changes that have been made during the past year and a half, under the direction of G. M. Colvocoresses, general manager, and J. N. D. Gray, mill superintendent, have been directed toward simplifying and increasing the efficiency of the process, eliminating useless machines and reducing the cost of operation.

By taking out the jigs several beneficial results were obtained. The cost for power and labor was reduced and the general grade of concentrate increased. Also more favorable conditions for flotation were created, because the jigs used a large amount of water which made it difficult to maintain that uniformity in the flow of mill pulp which is essential to good work in flotation. The abandonment of vanners was a natural consequence of the adoption of flotation.

In its present simplified form the milling scheme differs radically from that used in an earlier day. Harz jigs, tables and vanners were formerly used, but the recovery of copper under that system did not exceed 70 per cent, in spite of the complicated treatment to which the ore was subjected. The pyrite, breaking coarser than the chalcopyrite, was easily concentrated, but the softer and more friable copper mineral entailed a heavy loss.

Similar ore conditions prevail to-day; but now the flotation process is effective at the very point in the treatment where tables and vanners proved inefficient. Wilfley tables are now used only for rough concentration, and flotation is relied upon for the major part of copper recovery. Reference to Table I will show that the proportionate iron and copper contents of table and flotation concentrates are reversed. Pyrite concentrates easily on the tables, but floats less readily than chalcopyrite. The flotation product, on the other hand, not only contains twice the percentage of copper found in the table concentrate, but also represents 75 per cent of the total recovery. Furthermore, about 60 per cent of the flotation product is finer than 200-mesh, showing the need of an efficient method of fine concentration if a heavy loss is to be avoided.

Data on Regrinding

Detailed figures on the performance of Hardinge mills are given in Tables II and III. These mills are lined with pebbles set in cement, but a Komata manganese-steel liner is to be given a trial soon. An objection to the present liner is the adverse effect on flotation results, caused by the cement which enters the pulp when a newly lined mill is put in operation. This objection will be overcome by the metal lining.

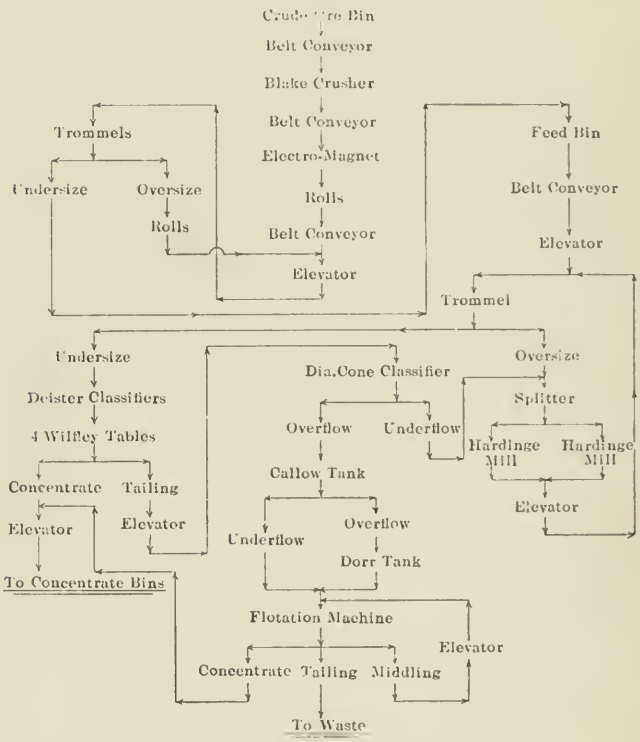

FIG. 1—CONCENTRATOR FLOW SHEET

Selected pieces of copper-bearing rock have been used, instead of pebbles, as the grinding medium. The consumption is indicated in the tables under the headings "Feed to Mill Rock Tons," and "Per Ton Crude Ore." When the Komata lining is installed it is planned to conduct experiments with different grinders—selected ore, chrome-steel balls and "manganoid" balls.

Flotation of Table Tailing

The Consolidated Arizona Smelting Co. was one of the first in this country to adopt the Minerals Separa-

Tons crude ore milled, 7173. Pounds oil used, 6580. Pounds oil per ton crude ore, 0.917. Cost oil per pound, 2.8 cents

tion process of flotation, producing a mineral-bearing froth by violent agitation. No acid is used and the work is done at mill temperature. The flotation feed is table tailing thickened to the desired consistency by means of cones and Dorr thickener. The diaphragm cone cuts out some coarse ore for regrinding. The Callow tank removes sand from the feed to the Dorr thickener so that the latter machine will not become overloaded. The thickened pulps from both the Callow tank and Dorr thickener are combined for flotation treatment.

Oil is added continuously to the inflowing pulp and the mixture then passes successively through the 11 cells of the machine. There is no retreatment or cleaning of concentrate, the froths from all cells being combined. The overflow of the last spitzkasten is regarded as a middling and is returned to the machine. The underflow from the last spitzkasten is final tailing.

All of the essential data on flotation at this mill are embodied in Tables IV and V, which require little explanation. Referring to the weekly gradings and analyses of feed and tailing, "per cent solids" indicates the customary screen analysis; "assay value," the actual percentage of copper in each grade, and "per cent copper," the proportionate percentage of total copper represented by each grade. Examination of these figures for "feed" will show that the actual copper content increases with the fineness of the grade; and since the major portion of the pulp is ground to minus 200-mesh, the greatest proportionate percentage of total copper is carried in the finest material. In Table V attention should be directed to the percentage recovery for January, which is much lower than for other months on account of the treatment at that time of a large quantity of oxidized ore. The treatment of this material resulted from an accident to the hoist at the Blue Bell mine, which prevented the usual production of ore for several weeks, and necessitated filling the mill bins very largely with oxidized material from surface dumps. In June a somewhat similar condition arose for a short period, and some oxidized material again found its way to the flotation department.

Ever since flotation has been in use here, it has been necessary

to pay the closest attention to the chemical condition of the ore. A splendid recovery is made on clean, bright, fresh sulphides, but when the minerals become tarnished or suffer surface oxidation to a slight extent, or if the gangue becomes oxidized and forms decomposition products such as oxide of iron and carbonate of magnesia, the flotation froth is almost immediately "killed" and a serious drop in percentage recovery is noted. Extreme care is used, therefore, to send to the mill only clean sulphide ore. Oxidized material from the upper levels of the mine is smelted directly or, if it is high in silica, it is used for converter flux and fettling.

The reduced recovery of January and June due to the involuntary treatment of oxidized material, is clearly shown in the flotation record, Table V, and in total mill recovery, Table VI.

TABLE VI.

Total Mill Recovery.

1915	Per cent Copper.
January	74.6
February	91.6
March	90.2
April	92.7
May	92.7
June	86.2
July	92.2
August	92.0
September	90.9

In Table V will be seen the variety of oils and mixtures tested with a view to getting the best metallurgical results with the cheapest materials. In July and subsequent months, "No. 200 oil" (refined wood creosote) has replaced cresol, turpentine and tar oil, with a consequent increase in stove oil, a cheaper oil. The mixture is now two parts stove oil and one part No. 200 oil.

Cost of Flotation

The total cost of concentration, including coarse crushing and flotation royalty, is slightly over $1 per ton. In September it was $1.03. The cost of the flotation process, exclusive of royalty, has been $0.27 per ton over a period of six months. The oil cost has been gradually reduced to 2.8 cents per pound,[1] and the consumption averages a little less than one pound per ton of crude ore. The power consumed by the flotation machine for a period of 24 hours is 32.7 kw.

The record recovery in January made at this plant are but part of a comprehensive plan laid out by the management for placing the company's entire property—mines, concentrator and smelter—on an economic and profitable basis. The foregoing data on the mill speak for themselves and indicate the vast

[1]Pounds per gallon: Stove oil, 7.12; wood creosote, 8.25; fuel oil, 7.48.

improvement that has already been made. With the anticipated development of the mines and increased mill capacity it is expected that the tonnage treated will be increased from 225 to 400 tons per day and that the cost for milling will be reduced from about $1 to under $0.90 per ton. In a later issue we shall publish some notes on the smelting practice at Humboldt.

To Mr. Colvocoresses and members of his staff we are indebted for many courtesies extended and for permission to publish valuable and timely data on the flotation of copper ores.

The Treatment of Sewage by Aeration in the Presence of Activated Sludge*

BY EDWARD BARTOW

Director of the Illinois State Water Survey

Sewage treatment by aeration in the presence of sludge is the latest development in sewage disposal. Air has always played an important rôle in sewage disposal. The earliest application of air was the exposure of sewage on the ground or in shallow pools. The disposal of sewage by irrigation is, therefore, an aeration process. No more sewage can be added to land than can be thoroughly oxidized. The disposal of sewage by dilution in streams also depends on the amount of air present. The amount of sewage which can be purified by a stream is limited by the amount of dissolved oxygen present. The efficiency of the stream depends upon the amount of water or the amount of oxygen in solution or the possibility of reaeration.

Intermittent sand filtration, where sewage is added intermittently to sand beds, is an aeration process, for between the periods of flooding with sewage, air is allowed to enter the pores of the sand. The action of contact beds is of a similar nature. Coarser material is used and between the periods of flooding, air enters the interstices and is the purifying agent. Sprinkling filters, the most practical process up to the time of the suggestion of activated sludge, depend upon aeration accomplished by spreading the sewage in a finely divided state into the air.

Preliminary to these aeration processes preparatory treatment is necessary. Preparatory treatment consists in using screens, grit chambers, settling tanks, digestion tanks or chemical precipitation. The preparatory treatment varies according to conditions. For example, three cities visited in Europe use different degrees of preparatory treatment prior to disposal by dilution. Munich uses no screening whatever, the water in the Iser being of sufficient quantity and sufficiently aerated to dispose of the sewage. Hamburg can dispose of its sewage in the lower Elbe using only coarse screening, but Dresden on the upper Elbe must pass its sewage through fine screens before emptying it into the river.

Grit chambers and settling tanks remove suspended matter. The amount of purification is comparable with the amount of purification by screening.

Digestion tanks accomplish the partial destruction of the suspended solids and soluble organic matter by anaerobic bacteria.

The addition of chemicals assists sedimentation and retards digestion, giving an increased amount of sludge, but a much improved effluent. Neither the screening nor the sedimentation nor the digestion nor the chemical precipitation produce complete purification. Aeration processes must complete the purification.

The latest process, the aeration of sewage in the presence of sludge, has had a gradual development. Numerous experiments of blowing air into sewage have been made both in America and in Europe. Until recently none of the experiments were at all promising and the conclusion was that such means of purification was not practical. In this country, the first promising method was that used by Black and Phelps[1] in New York. They blew air through the sewage as it passed over a series of inclined wooden gratings. This sewage was in contact with the air for varying periods up to twenty-four hours. The results were promising enough to cause Black and Phelps to recommend the construction of a larger plant for Greater New York. That plant has not been constructed and the experimental tank has been adapted to experiments with activated sludge.

The next experiments are those reported by Clark and Gage and Adams[2] at the Massachusetts State Board of Health Experiment Station in Lawrence. Air blown through sewage reduced the organic constituents. The seeding of the sewage with green growths accelerated the action. Their best results were obtained when the tank contained slabs of slate covered with a brown growth of sewage matters. This treatment produced an effluent which could be filtered at several times the normal rate. It, however, simply prepared the sewage for addition to sand beds, and was not considered a final process.

Gilbert J. Fowler of the University of Manchester was in this country in November, 1912, in connection with the disposal of the sewage of Greater New York, and visited the Massachusetts Experiment Station. Fowler and Mumford carried on experiments with a specific bacillus, which they named M-7, which was collected from the waste water from a colliery. This bacillus with aeration has the power of separating iron as ferric hydroxide from iron-bearing sewages, carrying down with it the suspended matter and furnishing a non-putrescible effluent. Fowler suggested to Ardern and Lockett, who were in charge of the Manchester Sewage Disposal Works, that they try experiments in aerating sewage on lines somewhat similar to what he saw in Massachusetts. As a result the *activated sludge process* is being developed.

DESCRIPTION OF ACTIVATED SLUDGE PROCESS

The first description of it was given by Ardern and Lockett[3] on April 3, 1914, at a meeting of the Manchester Section of the Society of Chemical Industry. In their first experiments Ardern and Lockett used 5-pint bottles and drew the air through the sewage by means of an ordinary filter pump. Air was drawn through the sewage until it was completely nitrified, requiring about five weeks. The supernatant liquid was drawn off and additional sewage added. This method of treatment was repeated a number of times with the retention each time of the deposited solids. As the amount of deposited matter increased the time required for each succeeding oxidation gradually diminished. Finally a well-oxidized effluent, equal to that from efficient bacterial filters, was obtained in from six to nine hours.

In their second series of experiments, reported to the Manchester Section of the Society of Chemical Industry[4] on Nov. 6, 1914, they used barrels of 50 gal. capacity and added the air through porous tile. They had tried treatment with a continuous flow of sewage without conclusive results. In later experiments they used tanks of 20,000 gal. capacity. Their results were very satis-

*A paper read at the San Francisco meeting of the American Institute of Chemical Engineers, in the Palo Alto session, on Aug. 27, 1915.

factory and led to additional work in England, especially at Salford, where Duckworth[5] and Melling[6] adapted scrubbing filters to the use of the activated sludge process with great success.

In August, 1914, I had the privilege of meeting Professor Fowler and of seeing the work which had been done under his direction. On returning to this country, consulting with Fowler, experiments[7] were begun with F. W. Mohlman at the University of Illinois on Nov. 2, 1914, using 3-gal. bottles. On Jan. 4, 1915, a tank 9 in. square and 4½ ft. deep was put in operation. In the bottom of this tank was placed a porous plate made of material as "Filtros,"[8] furnished by the General Filtration Company, Rochester, N. Y.

The results of our first experiments were similar to those of Ardern and Lockett. Sewage placed in the bottles or in the little tank was submitted to a current of air for a sufficient period to oxidize it completely. The oxidation is best measured by the content of ammonia, nitrate and nitrite nitrogen. Oxidation has been carried to completion five different times with practically the same results. The time required for oxidation differed, but the courses of the reaction were similar.

As an example, in one of these experiments at the beginning 35 parts per million of ammonia nitrogen were present. (See Fig. 1.) The ammonia nitrogen remained practically constant for about four days, and then quite rapidly decreased, so that at the end of about seven days it was gone. There were no nitrates nor nitrites present in the raw sewage. The nitrites increased as the ammonia decreased. Then for a few

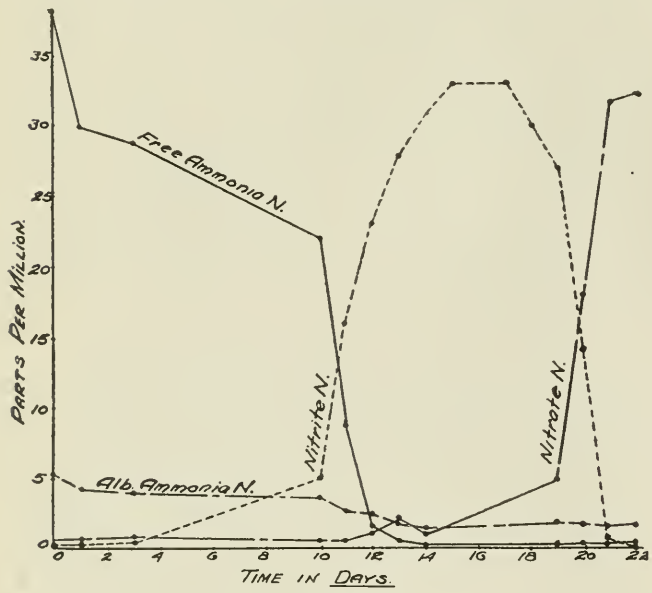

FIG. 1—NITRIFICATION OF SEWAGE—NO ACTIVATED SLUDGE PRESENT

days the nitrites remained constant and then decreased, the nitrates which were zero at the start increasing as the nitrites decreased. At the end of fifteen days nitrification was complete, the nitrite nitrogen had practically disappeared and the nitrate nitrogen had increased to about 25 parts per million. When the oxidation was complete the supernatant liquid was replaced by fresh sewage, the sludge being left. This process was repeated. With each change less time was required for oxidation, as, for example, fifteen days for the first, four days for the second, and two days for the third, and so on, until with the thirty-first treatment oxidation was complete in five hours.

With accumulation of sludge as the process is repeated the reaction follows a different course; for example (see Fig. 2), using a sewage with 27 parts per million of ammonia nitrogen, the ammonia decreases and is practically eliminated in five hours. The nitrite nitrogen never increases to any extent; the nitrate nitrogen begins to increase almost at the start, increasing as the ammonia nitrogen decreases, and reaches its maximum when the ammonia nitrogen has disappeared. It is not necessary to obtain complete nitrification to obtain a clear or stable effluent. More information must be obtained before the amount of nitrification required can be known.

The process is undoubtedly bacteriological. The sludge is very rich in bacteria, but the number in the

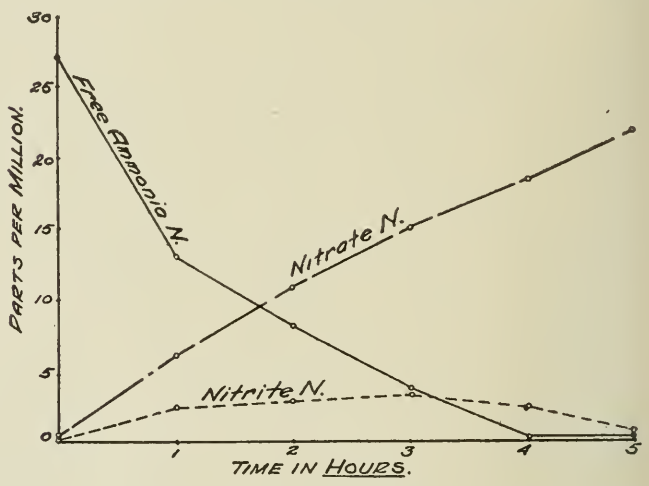

FIG. 2—NITRIFICATION OF SEWAGE—ACTIVATED SLUDGE PRESENT: 1 SLUDGE, 5 SEWAGE

effluent is comparatively small. Mr. Robbins Russell investigated the bacteriological properties of the sludge. Several species of bacteria were isolated from the sludge, including two kinds of nitrifiers and about fifteen other varieties. Experimenting with sterilized sewage it was found that the nitrifiers alone would not purify the sewage. Mixtures of the nitrifiers with the other bacteria would completely purify the sterilized sewage.

In an article which was presented before the American Chemical Society[9] mention was made of some worms which developed in the process, and which were identified by Professor Frank Smith of the Zoological Department of the University of Illinois as Aeolosoma Hemprichi. It seemed possible that these worms might play an important rôle in the purification process. Having isolated about 200 of these worms as completely as possible from the bacteria and sewage, Mr. Russell added them to sterilized ammonia broth and aerated it, obtaining practically no nitrification. The worms are, therefore, not essential and the bacteria which were isolated from the sludge did nitrify sterilized sewage.

PROPERTIES OF SLUDGE

The fresh sludge is odorless. It will putrefy if left with a large amount of water. After filter pressing it is stable. The dried sludge has an odor similar to that of fertilizers. The sludge is rich in nitrogen, 4.0 to 6.4 per cent. Its value as a fertilizer has been shown by pot cultures, made by W. D. Hatfield under the general direction of Prof. C. G. Hopkins and with the

FIG. 3—POT CULTURES, WHEAT TWENTY-THREE DAYS AFTER PLANTING

Each pot contains pure white sand to which the same amount of plant foods except nitrogen have been added. No. 3 contains 20 g. dried activated sludge. No. 1 contains the same amount extracted with ligroin. No. 2 contains an equivalent of nitrogen from dried blood, and No. 1 contains no nitrogen.

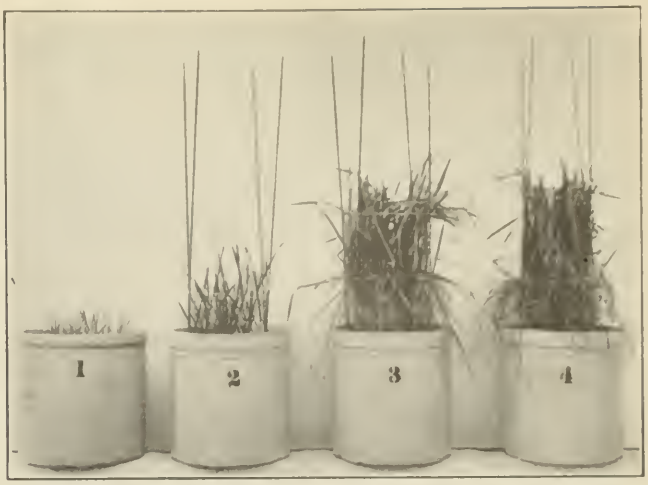

FIG. 4—POT CULTURES, WHEAT SIXTY-THREE DAYS AFTER PLANTING

Each pot contains pure white sand to which the same amount of plant foods except nitrogen have been added. No. 3 contains 20 g. dried activated sludge. No. 4 contains the same amount extracted with ligroin. No. 2 contains an equivalent of nitrogen from dried blood, and No. 1 contains no nitrogen.

assistance of Mr. J. C. Anderson of the University of Illinois. The pot cultures are made according to a standard method. Each pot contains 19,820 grams of pure white sea sand, 60 grams of dolomite, 6 grams of bone meal, and 3 grams of potassium sulphate; that is, each pot contained an equivalent of 5 tons per acre of dolomite, ½ ton of bone meal, and 500 lb. of potassium sulphate. There is in the pots all of the constituents of a plant food except nitrogen.

Pot 1 contained no nitrogen. Pot 2 contained dried blood equivalent to 120 lb. of nitrogen per acre. Pots 3 and 4 contained the equivalent of 120 lb. nitrogen, or 1 ton of sludge per acre. Thirty wheat seeds were planted in each pot. In four days the plants were up in each pot, and in ten days were 5 in. high. At the end of eighteen days each pot was thinned to fifteen of the best plants. A noticeable difference was observed after twenty-three days. (See Fig. 3.) The pots fertilized with the sludge grew very much more rapidly than any of the others. The difference at the end of nine weeks (see Fig. 4) was very marked. The differences seemed too great to be true, so another series was planted. Similar results were obtained. (See Fig. 5).

Judgment of the results of such an experiment depend on the crop. In pot No. 1 the number of heads was fourteen and the number of seeds eighty-five, corresponding to 6.2 bu. per acre. In No. 2, fertilized with dried blood, the number of heads was fifteen, seeds 189, corresponding to 13.6 bu. per acre. Dried blood is not a satisfactory fertilizer with some soils, which may account for poor results. In pots 3 and 4, fertilized with sludge, the number of heads was twenty-two and twenty-three, the number of seeds 491 and 518, corresponding to 35.9 and 37.7 bu. per acre. A very fair yield of wheat. The check experiment gave approximately the same results. The number of bushels per acre being 35.1 and 36.0.

The value of the sludge was tested with radishes and lettuce in the open field. Three plots, each 2 ft. by 3 ft., were laid out. One plot was fertilized with extracted sludge, a second with sludge and a third was not fertilized. Radishes and lettuce were planted in each. Thirty-eight days after planting the six best plants were taken from each plot. (See Fig. 6.) The difference in size was very marked. The fertilized lettuce weighed 40 per cent more than the unfertilized, and fertilized radishes weighed 150 per cent more than the unfertilized.

Both the pot cultures and the gardening experiments

FIG. 5—POT CULTURES, WHEAT SERIES 2, THIRTY-FIVE DAYS AFTER PLANTING

Each pot contains pure white sand to which the same amount of plant foods except nitrogen have been added. No. 3 contains 20 g. dried activated sludge. No. 5 contains 20 g. of dried activated sludge from which other soluble matter has been removed. No. 7 contains the nitrogen equivalent from sodium nitrate. No. 9 contains the nitrogen equivalent from ammonium sulphates. No. 11 contains the nitrogen equivalent from gluten meal. No. 13 contains the nitrogen equivalent from dried blood.

FIG. 6—GARDENING EXPERIMENTS, THIRTY-EIGHT DAYS AFTER PLANTING

Radishes. From left to right six radishes fertilized with extracted sludge, six radishes fertilized with sludge, six radishes unfertilized. Lettuce. Six heads fertilized with extracted sludge, six heads fertilized with sludge, six heads unfertilized. The fertilized lettuce weighed 40 per cent more than the unfertilized and fertilized radishes 150 per cent more than unfertilized.

show that the nitrogen in activated sludge is in a very available form, and that the sludge is valuable as a fertilizer.

APPLICATIONS OF THIS PROCESS IN AMERICA

The process is attracting a great deal of attention in America, and a very good statement[10] concerning the work being done is given in *Engineering News*, July 15. Mr. M. N. Baker has given an editorial review of the subject.

The most extensive work is being done at Milwaukee. An article by Mr. T. Chalkley Hatton[11] gives a more complete account of the Milwaukee experiments. Two tanks of 1 x 5 x 10 ft. deep and one tank 10½ x 32 x 10 ft. deep have been operated on the fill-and-draw plan, and one tank, 10½ x 32 x 10 ft. deep, is operated on the continuous plan. The Milwaukee Sewerage Commission has awarded contracts for the construction of a plant to treat 2,000,000 gal. of sewage per day by continuous flow.

At Baltimore they have been working on a small scale, but have adapted two of the new Imhoff tanks for use by this process, and it is expected that in a short time they will be using activated sludge on a large scale.

At Washington, the Hygienic Laboratory of the Public Health Service is experimenting on a small scale and is co-operating with the department at Baltimore in their experiments.

At Cleveland experiments are being carried on in the sewage experiment station. They have adapted tanks 5 x 10 and 5 ft. deep, which they used in their sewage experiments to the process, and while it has barely begun they are getting promising results. Experiments are to be carried out on a larger scale.

At Regina, Saskatchewan, experiments on a considerable scale have been carried out and their results are reported by R. O. Wynne-Roberts.[12]

At Houston, Tex., they are planning to use the process in a plant to ultimately treat the sewage from 160,000 people. They do not expect to obtain complete nitrification, as they do not believe that a completely purified effluent is necessary.

In Chicago the Sanitary District of Chicago is using tanks about 2 ft. in diameter and 8 or 10 ft. high with quite satisfactory results, using the waste from the stockyards, one of the most difficult wastes that we have to treat.

At the University of Illinois, Urbana, we are operating four tanks on the fill-and-draw plan. Each tank has an area of 10 sq. ft. and a depth of 8 ft. About 400 gal. can be added to each tank at each filling. The bottoms are one-ninth, one-third, and all (in two tanks) covered with filtros plates to try to determine the best arrangement for the diffusion of air. Of the three schemes tried one-third of the bottom with the rest slanting toward the plates seems better than the other schemes.

A study of methods of developing sludge shows that sludge can be developed from raw sewage by changing the sewage every six hours. A full description of the plant and the experiments will be given in a later article.

From 1 to 2 cu. ft. of air per gallon of sewage is needed, and the cost of the air, with electric current at 2 cents per kilowatt-hour, we estimate will be from $5 to $8 per million gallons. At Milwaukee, where they are using a little more air, they estimate the cost of the air with electric current, at 1 cent per kilowatt-hour, to be $1 per hour of aeration. If they aerate for four hours that would be $4 per million gallons for the cost of the air.

[10] *Eng. News*, 74, 164-71.
[11] *Eng. News*, 74, 134-7.
[12] *Canadian Engineer*, 29, 112-3.

This method of sewage purification is giving such satisfactory results in the purification of sewage on a small scale under summer conditions, that it will be tried on a large scale and under winter conditions, so that we ought to know by spring whether it is a success.

State Water Survey, University of Illinois,
Urbana, Ill.

Columbia Section, American Institute of Mining Engineers

The fifth annual meeting of the Columbia Section, A. I. M. E., will be held in Wallace, Idaho, Nov. 19-20, 1915. Arrangements have been made for trips to the Tamarack, Interstate, Success and other mines and to the concentrating mills of the Cœur d'Alene district. The sessions of the first day will be devoted to the reading and discussion of the following papers: "Progress in Ore-Dressing," by D. W. Buckby; "Mine Accounting," by J. E. Chapman; "Zinc Smelting and Smelter Rates," by W. E. Henry. The business session and banquet will be held on the second day. A special invitation is extended to members of the Montana Section to attend this meeting.

Equipment of Arizona Smelters

In one of the papers presented at the recent sessions of the International Engineering Congress, in San Francisco, Dr. James Douglas gave the following condensed data on the equipment of smelting plants in the State of Arizona. A notable feature is the increasing number of reverberatory furnaces and the absence of blast furnaces in the newer plants.

Copper Queen Cons. Mining Co. at Douglas, Arizona.
10 blast furnaces, 18 ft. and 20 ft. by 42 ft.
3 reverberatories, 91½ ft. by 19 ft.
7 12-ft. converters.
16 roasters.

Calumet & Arizona Mining Co. at Douglas, Arizona.
2 40-ft. blast furnaces.
4 reverberatories, 19 ft. by 100 ft.
6 stands 12-ft. upright converters of the Great Falls type.
12 roasters.

United Verde Copper Co. at Jerome, Arizona.
4 blast furnaces, 27½ ft. by 4 ft.
4 reverberatories, 100 ft. by 19 ft.
6 roasters.
5 12-ft. upright converters of Great Falls type.

Arizona Copper Co. at Clifton, Arizona.
No blast furnaces.
4 reverberatories, 19 ft. by 100 ft.
6 roasters.
6 stands 12-ft. upright converters of Great Falls type.

The American Smelting & Refining Co. at Hayden, Arizona.
No blast furnaces.
2 reverberatories, 19 ft. by 112 ft.
8 roasters.
3 converters.

Detroit Copper Mining Co. of Arizona, Morenci, Arizona.
1 large blast furnace.
4 small converters.

Old Dominion Copper Mining and Smelting Co., Globe, Arizona.
The Old Dominion Company has not yet added a reverberatory to its cupola plant, as the volume of concentrates from the small concentrator has been insufficient to economically feed one. Its plant consists of
6 cupola furnaces, of which more than 4 are seldom used.
2 12-ft. converters of Great Falls type.
one only of which is retained in blast, and it has, without relining, turning out 43,000,000 lb. of copper.

Shannon Copper Co. at Clifton, Arizona.
3 blast furnaces.
2 stands of converters.

International Smelting & Refining Co., Globe, Arizona.
(to treat the Inspiration and Miami Concentrates)
No blast furnaces.
3 reverberatories.
6 roaster furnaces.
6 converters.

Consolidated Arizona Smelting Co., Humboldt, Arizona.
(Humboldt Smelter)
2 reverberatories, 19 ft. by 60 ft. and 19 ft. by 100 ft.
1 Wedge roaster.
2 converters.

Pulverizer Mill—The Fuller-Lehigh pulverizer mill is completely described in an excellent catalog recently issued by the makers, the Lehigh Car, Wheel & Axle Works, Catasaqua, Pa. Besides this description lists are given showing parts of the various sizes and types of mills and illustrations showing installations of Fuller mills in electrically driven and line-shaft driven plants.

Thermal Principles of the Blast Furnace—II

BY J. E. JOHNSON, JR.

In the first article on the thermal principles of the blast furnace I have explained that the heat balance of the blast furnace must be considered not as one, but as two; that there are, in fact, two sets of thermal requirements, one for the preparation of the ore for its descent into the hearth, the other for the production of thoroughly reduced and melted pig iron from the ore so prepared. The present article will show how these amounts may be calculated in detail and will analyze the effect of solution on fuel consumption.

The disposition made of the two kinds of heat had seemed until recently impossible to determine, partly on account of lack of data of actual furnace operations, particularly of accurate average analyses of top gases, since a variation of a few per cent of CO_2 makes a vast difference in the heat developed. Very recently, however, two excellent sets of such data have been published, one by Mr. Walther Mathesius in his paper before the American Institute of Mining Engineers on "The Use of High Blast Heats in Mesabi Ore Practice," the other by Mr. Sidney Cornell in an article, entitled "The Heat Balance of the Blast Furnace," in METALLURGICAL AND CHEMICAL ENGINEERING for December, 1914.

In the latter the unit of weight used is the furnace charge which yielded in that case 15,260 lb. of iron, in the former the unit used is the ton of iron, but I have reduced them both to the pound basis to which the charted results of Reece's work (Table IV) are directly reducible by simply pointing off two places, it being on the basis of 100 lb. of iron.

In order to reach comparative results we must decide what heat to consider as consumed by the furnace and what as simply developed and then carried out of it. I have adopted the rule that the heat brought in plus that developed less that taken out as sensible heat should be charged to the furnace as consumed.

A curious oversight has crept into the work of both Messrs. Mathesius and Cornell which it has been necessary to correct. They have given the furnace credit for the heat of dissociation of the moisture in the blast, but they have ignored the much larger quantity of heat required for the dissociation of moisture of the charge in the upper portion of the furnace.

Mr. Mathesius takes cognizance of 69 lb. of moisture dissociated per ton of iron from the blast, but the analysis he gives of top gas shows that 240 lb. of water in all are dissociated, there being 27.3 lb. of hydrogen per ton of iron in the top gases. This arises, as pointed out by A. N. Diehl in his paper "Data Pertaining to Gas Cleaning," from the dissociation of the moisture in the ore in the upper part of the furnace. It seems at first sight surprising that this should take place, but it is not when we consider that CO burnt to CO_2 develops 7650 B.t.u. per pound of oxygen, while H_2O to $H_2 + O$ absorbs only 6530 B.t.u. per pound of oxygen.

The heat necessary for this latter reaction has been entirely overlooked by both these writers, with the result that in one set of data the "loss by radiation and unaccounted for" is much larger than it should be. On the other hand, the oxygen arising from this reaction is similarly ignored and the gas analysis given does not account for all the oxygen which must have been present in the top gases.

Calculations based on operating data give us the only means we have of investigating what occurs inside the furnace, and the method of making these is of much importance to show this and simultaneously to obtain the correct figures for the heat developed. We may, therefore, give the calculations based on the excellent data of Mr. Mathesius.

His "Calculations of Operating Results," which contain the data we need, are reproduced here.

CALCULATION OF OPERATING DATA

Analysis of Top Gases

		By Volume	By Weight
(1)	CO_2	14.9	22.3
	CO	23.5	22.4
	H_2	4.1	0.3
	CH_4	0.2	0.1
	N_2	57.3	54.9

On the basis of above data 1 ton of this gas contains:

(2) $$\frac{22.3 \times 3}{100 \times 11} = 0.0608 \text{ ton of carbon as } CO_2$$

and $$\frac{22.4 \times 3}{100 \times 7} = 0.0960 \text{ ton of carbon as CO}$$

This carbon originates from:

(*a*) The carbon charged, minus the amount of carbon transferred to the iron and the amount carried off with the flue dust.

(*b*) The CO_2 content of the raw materials.

These items are calculated below:

(*a*) The total amount of coke charged during the period under consideration was

(3) 13,006 tons,

which analyzed:

(4)	Fixed Carbon	Ash	S	P	Volatile Matter
	89.00	9.40	0.59	0.008	1.35 per cent

(5) The coke as weighed averaged 2.30 per cent moisture, making the weight of dry coke charged:

(6) 12,707 tons.

The amount of fixed carbon charged is thus:

(7) $$\frac{12{,}707 \times 89.00}{100} = 11{,}310 \text{ tons.}$$

From this total is to be deducted:

(*a*1) The carbon carried off with the iron, which is calculated as follows:

(8) The carbon content of the metal was 4.20 per cent and

(9) 17,146 tons of iron were produced, besides

(10) 173 tons of scrap (ladle skullings and pig-machine scrap); therefore

(11) 17,319 tons of iron (17,146 + 173) carried off

(12) $$\frac{4.20 \times 17{,}319}{100} = 727 \text{ tons of carbon.}$$

Besides the regular burden, the furnace remelted 276 tons of scrap iron, which contained:

(13) $$\frac{276 \times 4.20}{100} = 11 \text{ tons of carbon.}$$

Therefore the net amount of coke carbon carried off with the metallic product is:

(14) 727 — 11 = 716 tons.

(*a*2) During the month 628 tons of flue dust were taken out of the dust catcher of the furnace. Assuming that the gas carried over an additional 10 per cent of this beyond the dust catcher, the total amount of flue dust produced by the furnace was,

(15) 691 tons.

(16) Since the average carbon content of the flue dust was 8.25 per cent, the amount of carbon carried from the furnace with the dust amounted to

(17) $$\frac{8.25 \times 691}{100} = 57 \text{ tons.}$$

Consequently the net amount of carbon gasified in the furnace is:

(18) 11,310 — (716 + 57) = 10,537 tons.

(*b*) The only burden constituent containing CO_2

(19) in larger quantities was limestone, of which 6154 tons were charged. It averaged 43.1 per cent CO_2, making the amount of CO_2 charged with the lime-

(20) stone $\frac{43.1 \times 6154}{100} = 2652$ tons which is equivalent

(21) to $\frac{2652 \times 12}{44} = 723$ tons of carbon.

(22) The CO_2 content of the other burden constituents (ore, scale and cinder) averaged about 1 per cent, giving off an additional

(23) $\frac{31,372 \times 1}{100} = 314$ tons CO_2, which is equivalent to

(24) $\frac{314 \times 12}{44} = 86$ tons of carbon.

The total amount of carbon which escaped from the furnace during the month in the shape of CO_2 and CO is, therefore (see 18, 21 and 24),

(25) $10,537 + 723 + 86 = 11,346$ tons

Each ton of the top gases containing 0.568 ton (see 2) of carbon, the total weight of the dry top gases for the month is:

(26) $\frac{11,346}{0.1568} = 72,360$ tons.

The total weight of water, which was charged into the furnace with the ore, coke and limestone, and which subsequently had to be evaporated, leaving the furnace together with the top gases, was, according to the analysis of the burden constituents,

(27) 4665 tons

The nitrogen content of the dry top gases (see 1) originating exclusively from the blast, and the nitrogen content of the air being known, the weight of the dry air which entered into the furnace through the tuyeres can be calculated as follows:

(28) $\frac{72,360 \times 54.9}{77} = 51,592$ tons.

(29) The average moisture of the atmosphere was 5.49 grains per cubic foot at 70 deg. Fahr., making the weight of natural air blown into the tuyeres,

(30) $51,592 + 539 = 52,131$ tons.

The slag volume according to the daily burden

(31) calculations averaged 45.5 per cent, making the

(32) total amount of slag produced, 7811 tons.

The weight of materials passed through the furnace was as follows:

(33)

Material	Total Tons	Per Ton of Product Including Scrap Produced	
		Tons	Pounds
Burden	31,645	1.827	4,093
Limestone	6,154	0.355	795
Coke	13,006	0.751	1,682
Product (including scrap)	17,319		
Slag	7,811	0.451	1,010
Flue dust	691	0.040	89
Blast (excluding moisture)	51,592	2.979	6,673
Moisture in blast	539	0.031	69
Top gas (excluding moisture)	72,360	4.173	9,359
Moisture in gas	4,665	0.269	603

According to the average monthly analysis the product consisted of,

(34)

C.	Si.	Sul.	Phos.	Mn.	Fe.
4.20	1.35	0.032	0.071	0.74	93.61 per cent

The iron content originated from the following amounts of burden constituents:

(35)

Material	Group 1	Group 5	Pewabic Genoa	Pit Cinder	Steel Scale	Scrap	Coke	Total
Iron, per cent	52.00	49.00	35.00	50.00	66.00	75.00	0.80	
Stage of oxidation	Fe_2O_3	Fe_2O_3	Fe_3O_4	Fe_3O_4	Fe_3O_4	Fe	Fe	
Pounds per ton of product	2,819	755	219	58	207	36	1,682	
Pounds minus 1 per cent. loss	2,791	748	217	57	205	35	1,665	
Pounds iron per ton of product	1,451	366	76	29	136	26	13	2,097

Consequently the iron content of 1 ton of product originated from the following stages of oxidation:

(36)

Fe	Fe_3O_4	Fe_2O_3
39	165	1,893 Pounds

(37) In the same manner it results that 1 ton of product contained 0.74 per cent, or 16.6 lb., of manganese; 16.3 lb. of which have been reduced from MnO, while 0.3 lb. were contained in the scrap charged.

(38) The phosphorus of the product amounts to 1.6 lb. per ton and has been reduced practically all from P_2O_5.

(39) The 1.35 per cent of silicon is equivalent to 30.2 lb. per ton, of which 29.7 lb. were reduced from SiO_2, while 0.5 lb. were contained in the scrap charged.

HEAT BALANCE

(a) *Heat Generation*

The total weight of carbon contained as CO_2 in the top gases per ton of product is (see 2 and 33):

(40) $0.0608 \times 9359 = 569.0$ lb.

The weight of carbon per ton of product, equivalent to the amount of CO_2 originating from the limestone and burden and contained in the top gases is (see 21, 24 and 33):

(41) $\frac{809 \times 2240}{17,319} = 104.6$ lb.

Deducting item (41) from (40) gives the weight of coke carbon burned to CO_2 per ton of product:

(42) $569.0 - 104.6 = 464.4$ lb.

One pound of carbon through combustion to CO_2

(43) generates 14,543 B.t.u.; the above 464.4 lb. gener-

(44) ated, therefore, 6,754,000 B.t.u.

The amount of carbon per ton of product burned

(45) to CO is (see 2 and 33): $0.0960 \times 9359 = 898.5$ lb.

One pound of carbon through combustion to CO

(46) generating 4446 B.t.u., the above 898.5 lb. generated

(47) 3,995,000 B.t.u.

(48) The specific heat of the air blast being 0.248 and

(49) the average hot-blast temperature 1248 deg. Fahr., the heat brought into the furnace with the blast

(50) (see 33) per ton of product is: $1243 \times 0.248 \times 6.673 = 2,057,000$ B.t.u.

In the same manner the amount of heat brought into the furnace per ton of product with the moisture (specific heat, 0.49) content of the blast (see 33) is:

(51) $1243 \times 0.49 \times 69 = 42,000$ B.t.u.

(b) *Heat Consumption*

The following data were used in these calculations:

(52)

	B.t.u.
Heat required to reduce Fe_2O_3 to 1 lb. of Fe	3,240
Heat required to reduce Fe_3O_4 to 1 lb. of Fe	2,970
Heat required to reduce MnO to 1 lb. of Mn	2,970
Heat required to reduce SiO_2 to 1 lb. of Si	14,090
Heat required to reduce P_2O_5 to 1 lb. of P	10,620

The reduction of 1 ton of product therefore requires the following heat (see 34, 36, 37 and 38):

(53)

		B.t.u.
1893	lb. of Fe from Fe_2O_3	6,133,300
165	lb. of Fe from Fe_3O_4	490,000
16.3	lb. of Mn from MnO	48,400
1.	lb. of P from P_2O_5	17,000
29.1	lb. of Si from SiO_2	418,500
	Total	7,107,200

The weight of CO_2 produced by the calcination of carbonates per ton of product is, according to (20, 23 and 33):

(54) $\frac{(2652 + 314) \times 2240}{17,319} = 384$ lb.

practically all of which was contained in the burden in the form of $CaCO_3$. The heat necessary to de-

(55) compose $CaCO_3$ into CaO and CO_2 is 1830 B.t.u. per pound of CO_2. The driving off of above 384 lb. required.

(56) $1830 \times 384 = 702{,}000$ B.t.u.

The amount of heat carried from the furnace by the slag and iron was not determined. The figures used represent the average results of former tests under similar conditions. According to these the heat carried off by 1 lb. of iron amounted to

(57) 510 B.t.u. and per pound of slag to 900 B.t.u.

The heat carried off per ton of product with the iron amounts to

(58) $510 \times 2240 = 1{,}142{,}500$ B.t.u.

and with the slag

(59) $900 \times 1010 = 909{,}000$ B.t.u.

The dissociation of the moisture as carried into the furnace with the blast requires, per pound of

(60) water vapor, 5760 B.t.u.; per ton of product, the heat required for this reaction was (see 33):

(61) $69 \times 5760 = 397{,}000$ B.t.u.

The dry top gases carried off the following amount of heat per ton of product. (The average top temperature was 325 deg. Fahr., (see 1) for the gas analysis and (33) for the weight of gas.)

	Gas analysis	× Weight of gas	× Top temperature	× Spec. Heat	= B.t.u.
CO_2	0.223	9,359	325	0.2169	147,100
CO	0.224	9,359	325	0.2426	165,300
(62) H_2	0.003	9,359	325	3.4090	31,100
CH_4	0.001	9,359	325	0.5930	1,800
N_2	0.549	9,359	325	0.2438	407,100
Total					752,400

The moisture carried out by the top gases entered the furnace at a temperature of 70 deg. Fahr., i.e., with a heat content (see 33) per ton of product of

(63) $(70 - 32) \times 603 = 22{,}900$ B.t.u.

Since the moisture was heated in the furnace to 212 deg. Fahr., and evaporated, and the resulting steam superheated to 325 deg. Fahr., the heating of the water required

(64) $(212 - 32) \times 603 - 22{,}900 = 85{,}600$ B.t.u.

The evaporation required

(65) $964.8 \times 603 = 581{,}800$ B.t.u.

The superheating required

(66) $0.48 \times (325 - 212) \times 603 = 32{,}700$ B.t.u.

Therefore the total heat carried off with the top gases per ton of product amounts to

B.t.u.	
85,600	(see 64)
581,800	(see 65)
32,700	(see 66)
(67) 700,100	

[End of quotation from Mathesius.]

In the following calculation the letter M followed by a number indicates the item bearing that number in the quotation from Mathesius.

Let us start with the fundamental fact that carbon in the gaseous condition whether CO_2, CO or CH_4 has a volume of 29.85 cu. ft. per pound of carbon.

The total carbon gasified (M25) is 11,346 tons per month and the iron produced (M33) is 17,319 tons per month, or 0.655 lb. C per pound of iron. Therefore the carbon gas per pound of iron is $0.655 \times 29.85 = 19.57$ cu. ft. The carbon gas in percentage of total (M1) is CO_2, 14.9 per cent, CO 23.5 per cent or 38.4 per cent total. (We can disregard the CH_4 because no account is taken of the volatile matter of the coke, which undoubtedly contains some carbon). 19.57 being the volume of carbon in cubic feet and 38.4 in percentage, the total volume of gas is $\frac{19.57}{0.384}$ or 50.9 cu. ft. per pound of iron. The nitrogen is (M1) 57.3 per cent of this or 29.2 cu. ft. and as all this comes from the blast of which it constitutes 79.3 per cent, the blast blown must have been 36.8 cu. ft. per pound of iron. This weighs 0.0807 per cubic foot or 2.97 lb. of which 23 per cent by weight is oxygen or 0.683 lb. The oxygen from the charge may be obtained most easily from M53 and 54.

1893	lb.	Fe as Fe_2O_3 carries	$\frac{3}{7} \times 1893$	= 810	lb. O.
165	lb.	Fe as Fe_3O_4 carries	$\frac{64}{168} \times 165$	= 62 9	lb. O.
16.3	lb.	Mn as MnO carries	$\frac{16}{55} \times 16\ 3$	= 4 8	lb. O.
1 6	lb.	P as P_2O_5 carries	$\frac{80}{62} \times 1\ 6$	= 2 1	lb. O.
29 7	lb.	Si as SiO_2 carries	$\frac{32}{28} \times 29\ 7$	= 33 9	lb. O.
				913 7	

From (M54) we find 384 lb. of CO_2 carrying $32 \div 44 \times 384 = 279$ lb. per ton, a total from these sources of $913.7 + 279 = 1192.7$ lb. per ton or 0.5325 lb. per pound of iron. To this must be added the oxygen of the blast 0.683 lb.

The moisture in the blast is dissociated in the hearth and the oxygen is added to that from the other sources and Mr. Mathesius has added this, which is quite proper as far as it goes, but it takes no account of the oxygen which comes from the dissociation of the water in the *upper* portion of the furnace. The moisture in the blast is 69 lb. per ton of which one-ninth or 7.68 lb. per ton or 0.0034 lb. per pound of iron is hydrogen. The hydrogen in the top gas is, however, 4.1 per cent by volume, while the carbon gas is 38.4 per cent and 19.57 cu. ft. therefore the volume of hydrogen is $4.1 \div 38.4 \times 19.57 = 2.09$ cu. ft. or $2.09 \div 178.23 = 0.0117$ lb. or over *three times* as much as the moisture of the blast accounts for. This hydrogen can only come from one source, the dissociation of water. The volatile matter of the coke would not account for all of it if the latter were *all* hydrogen, and such analyses as we have show it to contain little or none of that gas. We must, therefore, take account of the heat absorbed by this reaction and of the oxygen as well as the hydrogen produced by it. This oxygen is obviously $0.0117 \times 8 = 0.0936$ lb. per pound of iron. We have then finally

Oxygen from oxides of charge	0.407
Oxygen from carbonates of charge	0.124
Oxygen from blast	0.683
Oxygen from dissociation of water of charge	0.0940
	1.3081

Oxygen required for oxydizing 0.655 C to CO is $0.655 \times 1\ 1/3 = 0.874$ lb. $1.308 - 0.874 = 0.434$ lb. O left to oxydize CO to CO_2 which suffices to convert 0.326 lb. of C from CO to CO_2. Of this C $12 \div 44 \times 384 \div 2240 = 0.047$ lb. came from the carbonates as CO_2 and therefore generates no heat. We have therefore $0.326 - 0.047 = 0.279$ lb. C burnt to CO_2 and $0.655 - 0.326 = 0.329$ C burnt to CO.

0.279 C to CO_2 at 14,750 B.t.u	= 4115
0.32 C to CO at 4375 B.t.u	= 1437
Brought in by blast and moisture (M) $\frac{2{,}099{,}000}{2240}$	= 937
	6489 B.t.u. per lb. of iron

The heat taken out may be considered in various ways: Cornell considers all the heat taken out whether sensible, latent or potential as having been developed in the furnace and then abstracted, while Mathesius considers the latent heat of evaporating the water of the charge as generated and taken out but not the heat of the unburned gases. On the basis previously adopted of considering only sensible heat as taken out I consider that

the latent heat of the water of the charge represents part of the heat consumed in the furnace which is what we are trying to determine. On the other hand the heat which the gas can develop by further combustion obviously plays no part in the operation and should not be considered. On this basis the rule is that sensible heat taken out should be credited to the furnace, but not latent heat, in order to determine its actual heat consumption.

For convenience the sensible heat of the water vapor is taken as starting a 0 deg. although, of course, it is not actually evaporated until many degrees above that point. The error so produced is immaterial especially as there are necessarily many other errors of greater extent due to uncertainties in our data.

The heat removed on this basis is then found as follows:

The specific heat of furnace gas is ordinarily 0.02 B.t.u. per cubic foot, but in this case, on account of the large percentage of CO_2, it is about 0.0205. The volume of the top gases is 50.9, the top temperature is 325 deg., and the heat removed per pound of iron by dry gas is $50.9 \times 325 \times 0.0205 = 340$ B.t.u., and the sensible heat of the water vapor is 0.269 lb. per pound of iron $\times$ 0.46 $\times$ 325 = 40 B.t.u. a total deduction of 380 B.t.u.

The net heat consumed, therefore, is 6489 — 380 = 6109, say, 6110 B.t.u. per pound.

To this we should add the heat brought in by the raw materials at, say, 60 deg. Their weight is about 3½ lb. per pound of iron, and their specific heat about 0.18, so the heat introduced in this way is about 35 B.t.u., which is not worth bothering with.

Before proceeding to the discussion of heat utilization we may compare the analysis derived from these figures with those given in the paper. The total carbon gas remains the same as does its percentage of the whole; we have therefore only to divide the total percentage of carbon gas 38.4 per cent in the ratio of 0.326 and 0.329, which gives 19.2 per cent CO_2 and 19.3 per cent CO, as against the initial figures given by Mathesius of 14.9 and 23.5. In the data given by Cornell there are included an estimate and an actual gas analysis, and the CO_2 in the estimate is 12.50 per cent and in the test 13.06 per cent, while my estimate made as above is 14.2 per cent.

We have therefore a considerable discrepancy which we can only account for in one of two ways:

A. The analyses are wrong as to the subdivision of the carbon gas, due to some error of not absorbing the CO_2 completely before proceding to determine the CO or the like.

B. The hydrogen does not arise from the dissociation of water, but is driven off as such from some portion of the charge, presumably the volatile matter of the coke, which, as before stated, is hardly possible.

Fortunately for the correctness of our estimate of heat development, this uncertainty makes very little difference, strange as this may seem, for if the hydrogen *does* come from the dissociation of water we obtain the corresponding oxygen which must oxidize the carbon to the extent shown with the corresponding development of heat, six-sevenths of which must be applied to the dissociation of the water. On the other hand, if the hydrogen does not come from this source, this heat of dissociation is not required and the oxygen resulting therefrom is not produced to cause the oxidation of the carbon to the corresponding extent.

We find then that the total heat consumption per pound of iron in the three cases is as follows:

Mathesius	Cornell	Reece
6110	6860	6440

Reece's furnace had a considerably smaller output than the others; in fact, not much over half, while the external dimensions of the shell in his case were not very much smaller than theirs, so that the radiation loss is probably considerably larger per pound of iron. On the other hand, no hydrogen is given in his gas analysis, and if this were correct (which the use of a large proportion of hard ore in his practice renders probable), we have a considerably larger consumption of heat per pound of iron than in Mathesius' case.

The total heat consumed in the Cornell example is greater than in Mathesius' by about 10 per cent, of which a part is to be accounted for by the evaporation of more water and the dissociation of more coke in the shaft, but proper allowance for these items still leaves a discrepancy of 7 or 8 per cent for which we are frankly unable to account except on the basis of errors in the gas analyses which underlie the whole structure and which are easily possible.

It should be noted that this variation of 8 per cent corresponds with one of nearly 40 per cent in fuel consumed in the two cases, and is in a broad way a confirmation of the fact that the heat consumption of furnaces working under very different conditions varies but little, as compared with variations in the fuel consumption.

It is a matter of interest also that the heat consumption in the cases of Reece and Cornell are almost identical if we omit from the latter the heat charged to it for the dissociation of water in the shaft, for which nothing has been charged in the case of Reece for the reasons given.

As to the radiation loss per square foot of furnace surface at different temperatures we know little or nothing; the difficulties in the way of investigation are great, and as we do not know how to improve our construction from the point of view of reducing radiation losses it has not seemed worth while to investigate them, and it has apparently never been done thoroughly.

It is well to point out that in those coke furnaces in which the deficiency of heat is in the hearth—that is, those which need more blast heat than they can obtain—the heat carried off from the hearth and bosh is the only portion whose loss affects the economy of the furnace, because it represents a loss of that portion which is already deficient, whereas any heat lost by radiation from the upper part of the stack represents only the loss of a surplus which would pass off as additional sensible heat in the gas if it were not lost by radiation. One proof of this is the fact that at a number of plants the stock going into the top of the furnace is thoroughly watered down to reduce the flue dust losses, and in some cases the top temperature is frankly controlled by the amount of water used. This water has all to be evaporated in the upper regions of the furnace, which requires a great quantity of heat; but no additional fuel is charged for the purpose, merely the sensible heat in the top gases is reduced.

This condition is so familiar to coke furnace operators that it is hard for them to realize that the opposite condition can ever prevail and that the economy of the charcoal furnace is at least sometimes limited by the heat developed in the shaft. But no one who considers the results of the calculations and experiment given above need ever feel any doubt of this.

Since this was written I have been told by one of the best furnacemen in the country that when the thin-lined furnace was used the cooling of the top was so considerable that the wetting of the ore to keep down flue dust had to be discontinued as it reduced the economy of the furnace. This would seem to be a direct confirmation of my results with charcoal.

We find here a smaller development of hearth heat per

pound of iron in the more economical furnace than in the less economical exactly as we found in a considerably greater degree in the charcoal furnace with wet and with dry ore, for while the dry ore figures were theoretical when made, their results were so remarkably confirmed by practice as to give them complete validity.

We have practically proven in the case of the charcoal furnace that the surplus hearth heat was utilized for relatively low-temperature operations; we shall presently see that the same is almost certainly true in the case of the coke furnace having the excess of hearth heat.

The development of hearth heat in the three cases is obtained from the actual carbon burnt in the hearth multiplied by the heat per pound of coke for the given conditions taken from chart I (page 720 of issue of Oct. 15) and divided by 0.85, the chart being for 0.85 carbon burnt.

The carbon burnt at the tuyeres is simply three-fourths the weight of the oxygen of the blast dry plus that of its contained moisture. We omit that reduced from the Si, Mn, and P, which enter the iron, although these are admittedly reduced only with incandescent carbon in the bosh because the reduction of these does not generate but absorbs heat.

The results are as follows:

Mathesius

$$\frac{0.512}{0.85} \times 1670 = 1005$$

Cornell

$$\frac{0.78}{0.85} \times 1360 = 1250$$

Reece

$$\frac{0.57}{0.85} \times 1740 = 1170$$

It will, I think, be conceded that these show a very fair agreement, especially as the slag volume in the data by Mathesius was exceedingly small.

Turning now to the method by which the hearth heat is developed we find that practically 50 per cent more carbon is burnt in the hearth in No. 2 (Cornell) than in No. 1 (Mathesius), but that only 15 per cent more hearth heat is developed by it, and the reasonable assumption is that if No. 2 had been given enough blast heat to increase the hearth heat per pound of coke to that of No. 1, *and if the distribution of the charge had been as good,* so that the furnace would take advantage of the increase, it would have done as good work as No. 1.

The clause in italics is very important. Cases are numerous enough in which a change in the stock distribution had produced an improvement of 30 per cent in fuel economy. The exact cause of the excess fuel required with bad distribution we do not know, and undoubtedly it varies in different cases, but broadly we may be sure that generally, if not always, it is *the result of having to do work in the hearth that should have been done in the shaft,* and this must necessitate the development of a surplus of hearth heat, precisely as it did at the charcoal furnace above cited, though in that case this condition was not due to bad filling.

It would seem well worth while in cases where the fuel economy is poor to make a brief analysis of the conditions and determine the amount of hearth heat developed per pound of iron. If it exceeds 1100 B.t.u. when making, say, 1200 lb. slag per ton of iron it is more than likely that the cause will be found in bad filling. In one case in my own experience the removal by better filling, without any other change whatever, of a cold core in the center of the furnace which was not properly heated and reduced by the gases in their ascent, resulted in a decrease of fuel consumption of 20 per cent and an increase in tonnage of 25 per cent.

In order to analyze the consumption of heat in detail in both hearth and shaft, let us assume that under average conditions the total heat consumed is 6500 B.t.u., and that of this the hearth heat is 1100 B.t.u., then the net heat used in the shaft is 5400 B.t.u. Let us assume that the slag volume is 1120 lb. per ton of iron (half the weight of the iron), and that the limestone charged is 1000 lb. per ton.

Our fundamental "second law" states that the heat above the critical temperature is supplied by the hearth heat, and the obvious corollary follows that the heat required below that temperature is derived from the shaft heat.

With this foundation we can make a subdivision of the gross heat consumption by remembering that only those portions of the charge which are discharged from the shaft down into the bosh take out any heat except that which passes out with the top gases, the volatile elements of the charge are heated to various temperatures in the shaft before they are detached from the non-volatile portion of the charge with which they enter, but the heat so absorbed is all given back to the charge again when they are ascending as a part of the gas column, excepting, of course, that heat which they take out as part of the top gas.

In other words, we have only to consider as credits to the shaft heat amounts which it imparts to the iron and the slag-forming materials in raising them to the critical temperature before delivering them into the bosh, and may disregard the temperature to which their gaseous components are heated when the latter are driven off, because the sensible heat so absorbed is restored to the stock column.

In considering the heat absorbed by the chemical reactions which take place in the shaft we do not need to consider the complex steps through which they pass, but only the final result, and from this point of view they are few and simple; the reduction of the iron ore, the decarbonation of the stone, the decomposition of the water vapor. In addition we have to evaporate the water of the charge and provide for the radiation loss. The shaft must supply the heat to raise to the critical temperature that portion of the coke which is burnt in the hearth, but the shaft recovers all this heat exactly as it does that expended on the volatile components of the charge. The quantities of heat required for these purposes are as follows:

Reduction of the Fe counting 95 per cent Fe in iron	2970
Decarbonation of stone	405
Heating slag forming materials to critical temperature	300
Heating Fe to critical temperature	480
Heating carbon in iron to critical temperature	45
Decomposition 0.1 lb. of H_2O from charge	580
Radiation deduced from Cornell and Mathesius	440
Evaporate moisture of charge (¼ lb.)	280
Total consumption in shaft	5500

But our original figures based in practice were 6400 total and 1100 hearth heat leaving 5300 shaft heat, an amount considerably below the actual requirements as above given.

In order to find the discrepancy let us consider next the utilization of the hearth heat. This is expended in reducing the silicon, in imparting to the iron and slag that portion of their total heat not imparted in the shaft, including the latent heat of fusion, supplying the heat lost by cooling water, radiation, and conduction through the bottom.

We know from Cornell's data the amount of the first loss 170 B.t.u. per pound and I have assumed that the other two would equal this amount which is probably a liberal assumption. I have assumed the silicon to be 1½ per cent and assumed the phosphorus and manganese to be included in this.

No attention is paid to the heat of formation of the slag and the carbide of iron since both those reactions *give out* heat in small quantities instead of absorbing it.

We have then the following consumption of heat in the hearth:

Reduction of silicon	180
Ht. of slag not imparted in shaft (900–600) ×½	150
Ht. of iron not imparted in shaft (600–480)	120
Cooling water	170
Radiation and conduction through bottom	170
	790

No allowance is made for the heat required to decompose the moisture of the blast because that has been taken care of by deducting it from the gross hearth heat.

Adding this figure to 5500 consumed in the shaft we have 6290 which is a very satisfactory check in the totals based in practice, but the distribution is obviously erroneous; we utilize in the shaft more than we produce there and in the hearth less.

Going over the matter carefully we see that the error can lie only in one place. We have assumed that *all* the reduction of iron was done in the shaft and none in the bosh, an assumption which, as we shall later see, is contrary to the observed facts of practice and to the indication of the equilibrium diagram in the last chapter which shows that the final traces of oxygen are only removed from iron oxide in an atmosphere almost free from CO_2 and at a very high temperature; conditions which are only obtained in the hearth.

We see, therefore, that a considerable percentage of the oxygen of the ore is only removed in the bosh of the furnace and from the consumption of hearth heat and the figures given above we can fairly estimate how much.

The data concerning the hearth heat are the most accurate, for the difference, which is a measure of the correction to be made, depends on the smaller number of items and the best established data.

The 790 B.t.u. accounted for, fall short of the 1100 we know to be consumed by 310 B.t.u., and as the total heat of reduction of the ore is 2970 B.t.u., this constitutes 10 per cent of the total, and we can thus feel reasonably well assured that under such conditions 10 per cent of the oxygen of the ore is removed in the bosh. This 300 B.t.u. subtracted from the original figure of 5500 consumed in the shaft leaves 5200 which is at least as good a check with the 5300 based on practice as we have any right to expect.

The high figure used for the total heat of slag is taken from the best sources obtainable and enables us to account for the facts of practice in regard to the effect of increased slag volume on coke consumption, something it is not possible to do in any other way. The heat imparted to the slag-forming materials up to the critical temperature as given in the table, 600 B.t.u., is obtained by adding the heats of the principal ingredients SiO_2, CaO, Al_2O_3, as taken from Richards' data, and is therefore fairly accurate. Deducting this from the total heat of the slag 900 we obtain a difference of 300 B.t.u., which must be imparted in the hearth by the hearth heat. The quantity of the latter per pound of coke charged (not that burned in the hearth only) is in ordinary practice about 1100 B.t.u. so that nearly 0.3 lb. of coke should be required per pound of slag. The figure commonly used is 0.25 lb., but my observation of practice in different districts where very different quantities of slag per ton of iron are made, leads me to believe that this figure is really about 0.33 lb. This is in good agreement with the figure just deduced on the basis of the critical temperature theory, but can not be squared with any other theory by any possibility. For instance, we see that the combustion of a pound of coke develops altogether under such conditions as we have been discussing about 6500 to 9000 B.t.u., taking even the smaller figure and the same high figure for the total heat of slag 900 B.t.u., 0.14 lb. of coke would be required per pound of slag, which has no relation whatever with practice.

I call particular attention to this in order to reiterate once more that the basis in which the critical temperature rests is not its reasonableness or agreement with accepted principle in other sciences but that it accounts *quantitatively* for the facts of practice, something which no other theory hitherto proposed can even attempt to do.

The shaft heat has so far been found merely by difference, subtracting from the total the hearth heat which we can calculate quite accurately and whose quantity so calculated checks well with fuel consumption over a wide range of practice, so that a number of furnacemen have come to have much confidence in the results so obtained. But while this is a small fraction of the total heat, to obtain the shaft heat merely by subtracting this small figure from the large one of total heat developed does not seem very convincing. We shall be able to show that the heat consumed in the shaft checks well with that imparted to that region; for this purpose we can use the results of calculations made for showing the results of solution loss which are given later on in this article.

There it will be seen that the heat developed and that brought into the shaft by the hot gases from the hearth supply enough for the requirements of the shaft with sufficient left over to heat the top gases to the temperature at which they are actually discharged in practice for those conditions. The radiation loss may have been assumed a little higher than it should and there are undoubtedly minor errors of constants used and assumptions made but it seems inconceivable that so involved a series of calculations could be made on the basis of authentic data and check so accurately as these do with themselves and with the conditions of practice unless they were substantially correct. Granting this we may surely say that here is a confirmation of the two-fold thermal balance of the furnace which cannot be denied since we see not only that the total heat must equal a certain quantity but that a certain portion cannot possibly be applied except above that temperature: also that the two quantities bear a definite ratio to each other depending upon the conditions of the operation.

The Determination of the Critical Temperature

The early work done for this purpose has been described in the quotation in the early part of this chapter and the critical temperature used in the coke-furnace calculations of this chapter is taken at 2750 deg., the same as the figure used for the early work, not for the sake of consistency but because the considerable amount of work done since seems to indicate that for the conditions of ordinary coke practice that figure is approximately correct.

In a valuable paper by F. E. Bachman before the American Iron & Steel Institute in October, 1914, he gives the results of pyrometric observations made by an expert from the Bureau of Standards which agree better than could have been expected with this figure taken as representing average condition of coke practice.

It is greatly to be hoped that more work will be done along this line, particularly on furnaces working under varying conditions, those making ferro-manganese, ferro-silicon and the like, as well as furnaces in different varieties of coke practice and in charcoal practice, both cold and warm blast.

When this is done we may have more correct figures for the various kinds of practice, but in the mean time 2750 deg. for most coke furnaces seems to be reasonably accurate, though on some rather lean slags the critical temperature is probably as much as 100 deg. lower.

(To be concluded.)

Solution of Smoke, Fume and Dust Problems by Electrical Precipitation*

BY LINN BRADLEY

A statement that the earth's atmosphere contains a practically unlimited supply of materials highly valued by civilized man probably would bring to mind the fact that nitrogen compounds are being extracted from the air and used as fertilizers, or perhaps in connection with the manufacture of explosives. On further reflection one might recall the publicity which has been given to the desirability of recovering certain values, among them ammonium sulphate, from the gases arising from bee-hive coke ovens. This is all very commendable, and more serious attention should be given to such recoveries.

But there are also being discharged into the atmosphere regularly many other materials, the aggregate value of which amounts to many thousands of dollars. An attempt will be made to give an outline of some of these latter problems in such a way as to promote and stimulate interest in them.

This is another field in which the recovery of valuable by-products already reflects credit upon the scientific achievements of the technical men of our country. It is indeed gratifying that in the application of electricity to the solution of such problems this country far outranks any other, a Californian, Dr. Frederick G. Cottrell, having done more to advance both the science and the art than any other individual. This special field of technical industry will be described more fully toward the end of this paper.

The terms "smoke problem," "dust problem," "fume problem" have different meanings to residents of various localities. For instance, "dust problem" has one meaning to the superintendent of a calcium carbide plant, another meaning to the foreman of an iron blast furnace, and still another to a resident of a California desert town. Each of these three little appreciates the other's problem and what it means to him.

"Fume problems" cover a great range, from garbage reduction works to sulphuric acid factories, including silver and gold refineries en route.

Even "smoke problem" is not a specific term always meaning the same thing, because some people are inclined to designate as smoke every gas which they can see. It may suffice for present purposes, however, to consider "smoke problems" as covering the gaseous products from burning carbonaceous material, carrying uncombined carbon particles in suspension in such quantities as to appear black, brown or gray, while "fume problems" cover gases carrying in suspension extremely finely divided particles which have resulted from quick condensation of vapors or gases, as, for example, arsenic trioxide.

"Dust problems" refer to fairly large solid particles suspended in gaseous bodies. The dividing line between "fume" and "dust" is not sharp, and oftentimes collected dust may be a mixture of "fume" particles and "dust" particles.

When the suspended particles are liquid, the term "mist" is generally used. Example: sulphuric acid mist, which contains minute drops of sulphuric acid of any strength. A "mist" is readily produced when saturated steam is suddenly mixed with cool, humid air. This "mist" is the so-called "visible steam." It may contain other water in the gaseous condition. Clouds and fogs are excellent examples of how readily these finely divided particles may be kept suspended in a gaseous body, and at the same time they indicate how futile it is to expect settling chambers to cause the deposition of all of the small particles carried through them by moving gases. Fogs are produced by two portions of the atmosphere, generally of different temperatures and humidities, commingling and producing a condition of supersaturation, the excess water being "fogged out."

The problems of removing from gases minute particles suspended therein are of great variety, and exist not only in thickly settled industrial communities but also in the sparsely settled States of the Middle West and Far West as well as the South. Requests for a solution of specific problems have been received from northeastern Canada, Cuba, Mexico, Hawaiian Islands, and far-away Alaska, to say nothing of inquiries from across the seas.

In New York City inquiries have ranged from the collection of diamond chips suspended in a small volume of air up to the collection of cinders and small pieces of coke from gases arising from boilers under which about 3000 tons of coal are burned every twenty-four hours. This volume of gas would fill the entire cubical space occupied by the Equitable Building in about three minutes. It is obvious that the saving of values was the object to be attained by collecting the diamond chips, while in the latter case the cinders and coke particles constituted a serious nuisance in the neighborhood.

Black smoke is so common that its origin needs no further reference than to say that practically every furnace fired with bituminous coal may occasionally offend, while some offend almost continuously due to the method of firing. Railroad locomotive engine-houses (roundhouses) are generally causes for complaint from residents of the neighborhood, as there are usually several fires being built or maintained in such manner as to produce large quantities of dense black smoke. Locomotives in rapid motion are not such direct offenders, but the accumulation in the atmosphere of smoke from several hundred such fires soon produces its effect throughout the district served.

Plants in which dry, finely divided materials are handled or grinding operations conducted generally have the problem of confining the dust either for saving values, or for sanitary reasons or for preventing nuisances. Sometimes dusts floating around a plant are very detrimental to rapidly moving machinery. Portland cement plants generally have severe dust problems as they feed finely ground materials into long cylindrical kilns near the point where large volumes of gas are rapidly emerging, and in such a manner that the gases pick up a large quantity of dust. Instances are known where the quantity of dust from a cement plant approaches from 200 to 400 tons per day. This dust is scattered broadcast over the district surrounding the plant.

At iron blast furnaces the finely divided ore is charged in such a way that dusting is facilitated. Reports have been obtained which show that the total amount of iron ore and coke lost in this manner amounts to a very large tonnage yearly, and when it is considered that this dust may be worth from $3 to $3.50 per ton the economic loss is better appreciated. The presence of this dust in the blast furnace gas is highly objectionable from other standpoints when the gas is to be used in gas engines for direct conversion into mechanical power, or burned in hot blast stoves or under boilers for conservation of the heat energy. Further, careful calculation has shown that by removing the particles from the gases from one iron blast furnace, without cooling the gases, the value of the conserved heat energy might amount to about $25,000 per annum. One corporation is said to control at least 100 furnaces. Therefore the saving in this way alone would approach $2,500,000 an-

*An address made before the First National Exposition of Chemical Industries in New York City.

nually. Now add to this the value of the ore recovered in a usable form, the value of the water used in wet-cleaning methods and the power for pumping it, the value due to better hot-blast stove operations, saving in stove and boiler brickwork, labor, etc., and the economic value of electrical precipitation in this one field of industry can easily be appreciated.

In the large smelteries of the Rocky Mountain States the fume and dust problems are of great importance, not alone because of the strife between the farmers and the smelting companies on account of crop damage but because of the huge economic waste occurring in the operations. It is true that other serious problems are to be met in addition to the collection of the suspended solids before the millenium is reached. Markets must be created or extended; transportation must be arranged; new metallurgical and chemical processes must be developed for separating the components of materials now considered valueless. It is true that rapid progress has been made, but much more remains to be accomplished.

While sulphur is being mined in Louisiana and prepared for the market as a distinct enterprise, and some sulphur and certain sulphur compounds are imported from foreign countries, yet the amount of sulphur being wasted in the smelting of valuable ores is extremely great. It is not unusual for a fair-sized smelter to waste 1000 tons of sulphur daily by discharging it into the atmosphere in the form of a gas sulphur dioxide. And this is being done notwithstanding the fact that sulphur is a very necessary commodity for members of a civilized nation. It is the most difficult to obtain of any of the constituents of sulphuric acid, the basis of chemical industry. Some smelting companies are manufacturing sulphuric acid from their previously waste gases. But there is a limit to the market for the grade of acid they produce.

It is evident that other remedies must be sought. Some serious efforts are being made to reduce the sulphur dioxide to elementary sulphur, as in this form it can be stored, shipped or used more universally than if converted directly into sulphuric acid, which is about three or four times as heavy as the sulphur contained, depending upon the acid's concentration. Where smelting operations are so situated as to prevent shipping acid to available markets, some sulphuric acid is being used to extract values from low grade ores which heretofore did not warrant treatment by older methods. Further progress will undoubtedly be made in the future.

Waste gases at smelteries and refineries also contain metals such as copper, lead, zinc, tin, gold, silver, nickel, and even less commonly known elements such as arsenic, bismuth, selenium, tellurium, palladium, antimony and various chemical compounds containing these. The recovery of these materials often would be warranted for the additional revenue which they would produce even under present circumstances; in others, it is desirable to develop processes for separating the constituents of the collected fume and dust. Investigations at one smeltery showed that metals having a gross value of approximately $4,000 per day were being discharged into the atmosphere. The expense of collecting, smelting, refining and marketing the valuable ingredients becomes an important item, and thus it behooves metallurgists, chemists and engineers to devise cheaper methods of handling such problems.

The arsenic which can be produced from the waste gases of one Western smeltery would much more than equal the entire United States consumption. In order to allow for placing all of this arsenic on the market further uses must be found for it, otherwise it must continue to settle upon the ground in the surrounding district or be collected and stored until a use is developed for it.

While discussing markets it may be well to state that price alone does not control the consumption of all product. At various copper refineries on the Atlantic Seaboard some selenium is produced, for example. In the elementary form this may sell for around $1 per pound, and yet, strange as it may seem, large quantities of it are being thrown into sewers. Contrary to the generally accepted theory, dropping the price to even 10 cents per pound would not find a market which would consume all that is now being wasted. This is because of the peculiar properties attached to this element. It can be used for but few things, and even for these in limited amounts only. When chemical research has discovered additional uses for selenium, and likewise for tellurium, this apparently paradoxical situation may be relieved.

The daily press has contained much in recent months concerning brass and the necessity for high-grade zinc. Extensive investigations in large brass foundries have shown that perhaps 3 per cent of all of the zinc charged into the crucibles is burned off or volatilized and then passes up stacks and is discharged into the atmosphere, thus constituting an economic loss aggregating many thousands of dollars per annum. Analyses of material collected from the stack gases showed a zinc content of about 55 to 60 per cent, mostly as zinc oxide. Small amounts of cadmium and other compounds are present, but it seems possible to convert all of this zinc heretofore wasted into high-grade zinc, and this would be a distinct and important gain from an economic standpoint as well as being a source of profit to the owners of the foundries.

In the production of metallic zinc from ore a considerable percentage of zinc is lost as fume. In the industry this is known as "ventilator loss," as all of this white fume passes through large stack-like openings in the building roof just over the bank of retorts. This loss amounts to many thousand dollars per annum.

In refining copper electrolytically, gold, silver and other materials are collected as slimes. When these latter are treated in a furnace for the recovery of the gold and silver considerable of these materials are lost as fume. In one plant near New York City these valuable fumes are being collected by electrical precipitation, and whereas previously the actual losses were several thousand dollars per annum, this has been so reduced that probably it does not now exceed $300 per annum.

There has been produced at this plant a situation which is interesting in showing how progress comes in stages. Prior to 1912 apparently little if any attention was given to the fumes, since their value was considered to be beyond recall and to be not great in any event. After their recovery had been proven it was considered a very serious matter to allow fumes to escape for more than a few minutes while repairs were being effected, those in charge saying that "it cost $1 for every minute the fumes were allowed to escape."

At a sulphuric acid plant where a large quantity of acid is concentrated in stills considerable mist is made which is considered a nuisance. Investigation showed that 2 to 3 tons of sulphuric acid were being wasted daily as mist. Here is an excellent example of a combined nuisance and value problem.

At another plant hydrochloric acid fumes had been killing vegetation in an adjacent park, but at present the trees and shrubs are thriving, as the acid fumes are being collected electrically. Fume and dust problems may exist within certain manufacturing operations, such as, for example, in the production of sulphuric acid

by the contact process. Sulphur either free or combined with other elements is burned in roasters, the object being to produce sulphur dioxide. These gases (primarily air plus 6 to 7 per cent sulphur dioxide) generally contain dust and fume and some sulphur trioxide, either free or combined with water, to form sulphuric acid. In order to further oxidize the sulphur dioxide to trioxide the gases are passed over a catalytic substance (ordinarily some form of platinum), and in order that the catalyzer be effective the dust should be removed from the gases and the cleaned gases brought to the catalyzer at a temperature of about 400 deg. C. Furthermore, all arsenic, selenium, antimony, lead, etc., and their compounds must be removed as must nearly all sulphuric acid and water vapor. After the conversion to trioxide has been accomplished the absorption of the product by concentrated acid is quite readily accomplished.

It will be seen, therefore, that the removal of dust and fume must be carried out completely and all other harmful impurities eliminated from the gases. Furthermore, the heat resulting from the combustion of the sulphur in the roaster should not be sacrificed. In this industry, therefore, there are some very important dust and fume problems, the importance of which is not based on values in the dusts nor upon neighborhood nuisances, but rather on the improvement of manufacturing operations. Similar problems exist in other industries.

In ventilating modern public buildings, and even up-to-date factory buildings, it is considered desirable to control the temperature and humidity of the air and remove all dust, bacteria, etc. In one recent installation it has been found that by circulating 50,000 cu. ft. of air per minute in a closed system, removing dust, etc., by electrical precipitation, the saving in steam which would be required for preheating this quantity of air in cold weather much more than pays a good return on the investment. Here it is noted that the primary object was conservation of steam for preheating ventilating air.

One of the most interesting problems in dust removal which has been brought up for consideration in conjunction with an ingenious suggestion pointing to its solution has been in connection with the cleaning and ventilation of the present subways. During the small hours of the night, specially equipped cars were to be operated from one end of the subway to the other, these cars to be provided with air-jets or blowers in front so as to stir up all of the dust on the floor, walls and ceilings. The rear of the car was to be equipped with apparatus for sucking in the air and contained dust. This air was to be subjected to electrical precipitation to remove the dust therefrom and thence discharged through the air-jets at the front. This whole arrangement might well be called a giant, portable vacuum cleaner. Perhaps the problem warrants some such equipment, but it would seem that the tracks should be separated by partitions if the scheme is to work satisfactorily.

Reference is hereby made to the article in the Annual Report of the Secretary of the Smithsonian Institution for 1913 by Dr. Frederick G. Cottrell, entitled "Problems in Smoke, Fume and Dust Abatement," and to an article by the author, entitled "Practical Application of Electrical Precipitation," appearing in the April, 1915, *Proceedings* of the A. I. E. E. These two papers give a more extended account of electrical precipitation and are accompanied by bibliographies, thus enabling anyone interested to obtain further details than are given in this paper.

The statement has already been made that the progress with this particular industry has far exceeded that in any other country. While a member of the faculty of the University of California, Dr. Cottrell conducted experiments in electrical precipitation, and as these were so successful the work was transferred to near-by smelteries and acid plants. To him must be given full credit for the ingenious and practical method which is used for getting the proper kind of electric field, and for developing rational hypotheses and working bases for solving all kinds of fume, dust and smoke problems by electricity. Dr. Cottrell and his associates, Messrs. Heller, Miller and O'Neill, also of California, generously donated their United States patent rights to the Research Corporation of New York City to be used as an endowment for scientific research. This corporation is controlled by a board of directors, each member of which is giving his time and energy gratis for the benefit of this public movement. This unique organization is described and its objects are fully set forth in a paper, entitled "The Research Corporation; an Experiment in the Public Administration of Patent Rights," which appeared in the records of the Eighth International Congress of Applied Chemistry.

The desire of Mr. R. B. Mellon of Pittsburgh to have the coal smoke nuisance in that vicinity eliminated was one of the motives leading to the establishment of the R. B. Mellon Smoke Fellowship of the University of Pittsburgh under the direction of the late Dr. Robert Kennedy Duncan. Partly as a result of the efforts of those engaged in this investigation, the Messrs. R. B. and Andrew Mellon have established the Mellon Institute of Industrial Research and School of Specific Industries, which has such an excellent mission to fulfill in advancing chemical progress. Mr. Mellon likewise has generously donated to the Research Corporation the results obtained by the Smoke Fellowship.

Consideration of the problems heretofore mentioned should suffice to show that some very interesting and valuable problems exist in which extremely finely divided particles must be separated and removed from gases of various kinds, temperatures and volumes.

It was pointed out that settling chambers do not and cannot adequately answer the purpose, since it is necessary to cause some force to act upon the particles in a readily controlled manner and in such a way that they will move away from the moving gas which serves to keep them suspended and separated. With a proper arrangement of pipes or plates and wires acting respectively as "collecting electrodes" and "discharge electrodes," it is possible to produce a discharge of electricity from the wires to the pipes or plates through gases present between them. For convenience the statement is made that this discharge consists of a number of units of electricity, the term being applied as one would use, say, pints of water.

When this discharge is taking place with sufficient rapidity (i.e., enough units of electricity are flowing through the gas in a unit of time), a beautiful violet light can be seen around the wires. It is true that ordinarily air and other gases are considered as unable to conduct electricity, but in electrical precipitation it is customary to employ very high voltages, such as, say, 75,000 to 100,000. With such voltages as these it is possible to subject a gas to such strains that it is changed from a non-conducting to a conducting medium. Of course, the conductivity is not of the first order of magnitude such as possessed by copper, nickel, etc. The discharge and collecting electrodes are not mechanically connected in any way, but on the contrary are necessarily kept spaced apart and insulated one from the other by high-voltage insulators. A large number of discharge electrodes may be connected by metallic wires or plates, and this is likewise true of the collecting electrodes, it being necessary only to keep these two kinds

of electrodes in proper relation with each other so that the units of electricity are compelled to flow through the air or other gases present between them.

To further explain the phenomenon of electrical precipitation, the suspended particles may be compared to a pith ball in an experiment on static electricity. Each of the particles of dust or fume collects a charge of one or more units of electricity of the same polarity as the discharge electrode. Now since two bodies charged with the same kind of electricity repel each other it would naturally be expected that the particles would be driven away from the wire and drawn toward the pipe or plate (collecting electrode). Enough units of electricity must be discharged from the wire or "discharge electrode" or otherwise produced to charge the particles suspended in the gas as it passes between the electrodes. The more units of electricity upon a particle the greater is the force acting upon it, therefore in practice a strong discharge is maintained. Furthermore, the greater the voltage between the electrodes the stronger is the precipitation force. This makes it desirable to operate at a voltage just below that where a spark or arc would form. Moving gases exert a force upon suspended particles, and the greater the velocity the greater is this force. Hence with a given precipitating apparatus there is an upper limit to the gas velocity at which the suspended particles may be completely removed.

If the polarity of the electrodes is too rapidly reversed, the particles will remain in suspension in the gases. For this reason direct current at high voltages is required, as alternating current at commercial frequencies is not suitable for this work. Large volumes of gases require, as a rule, more power than smaller volumes, but the power consumption is affected by other factors. Static machines do not furnish enough power for commercial installations and are not dependable. However, they give a desirable kind of current and potential for the work. In commercial installations the gases may pass between the electrodes in either a vertical or a horizontal direction. Ordinary black iron pipes about 12 in. or 18 in. in diameter by 15 ft. to 20 ft. long are in general use. These pipes may be connected to a gas chamber at each end in a manner similar to that in a tubular boiler. With this arrangement gases and suspended particles may readily be distributed to the various pipes and through them to another gas chamber having been cleaned during such passages. The cleaned gases may be conducted to other places as desired.

The precipitating apparatus may be designed for either hot or cold gases, and for corrosive or non-corrosive materials, and the product may be collected either wet or dry as conditions may indicate. In treating gases containing particles of acid held in suspension, materials such as lead or stoneware are employed to avoid serious corrosion. Heat-insulating materials may be employed in the apparatus to lessen the loss of heat energy when desired. The gases may be either forced or pulled through by fans or other mechanical means, or if the gases are sufficiently warm natural draft may be employed. When treating gases which are explosive when mixed with air, they are kept under a pressure at least slightly greater than atmosphere until they have been cleaned.

The high-voltage direct current is obtained by transforming low-voltage alternating current into high-voltage alternating current and then converting or rectifying the latter into an intermittent, high-voltage direct current. The amount of power required in commercial installations is relatively low, generally being much smaller than that necessary for any other gas-cleaning system.

A unique advantage of electrical precipitation is its ability to collect even the most minute particles. Another interesting feature is that components of gases of different volatilities may be separated by what has been termed "fractional precipitation." In this method the gases are treated while at a high temperature to remove those materials which are then either solid or liquid, and then after further cooling the gases subjecting them to another treatment in a separate precipitator. Arsenic trioxide of high purity has thus been separated from copper, iron, zinc and other materials. It would be possible to obtain water-free tar in gas plants by this means, and also it might be possible to collect tars of different compositions. This offers a fertile field for investigation at gas plants.

At foundries where old tin cans and other waste metals are melted and poured into sash weights, quite large tonnages of fumes high in tin, lead and zinc are being wasted into the atmosphere. While the gross value of this material may be, say, $100 daily, the fact that these elements are present in such proportions as to render their separation difficult and very expensive by present methods permits owners of these plants to continue such wastage. Research should disclose some practical and economical way of separating these constituents.

In smelting ores of certain districts for the production of copper, the contained lead is generally eliminated from the copper matte in the converters. This fume has heretofore been wasted, hence the lead in such ores was of no value in so far as it never reached a market. Now that this valuable fume can be recovered and the lead marketed, it should be good practice to charge more such ores into the furnaces instead of studiously avoiding them.

There is a large tonnage of galvanized sheet-iron scrap produced yearly, the zinc on which is generally wasted. In some plants this material is charged into open-hearth steel furnaces and the zinc driven off into the atmosphere as fume. By concentrating this material at certain locations, the recoverable zinc fumes should warrant its collection. A somewhat similar problem exists at some iron blast furnaces, the ore containing zinc in such quantities as to warrant its recovery from the blast furnace gases. An interesting situation has been found at other blast furnaces which indicates a nice research problem. It was noticed that there were white fumes in the gases from the boilers, these being heated by blast furnace gas, burned after being wet scrubbed. A study of these fume-laden gases showed a quite large tonnage of potash compounds which, if collected and properly treated, would make excellent fertilizer.

Many other instances could be given, but it is believed that these will be ample to convince that air and other gases contain values far beyond and of a greater variety than that which is generally understood. It is hoped that chemists, engineers and others will give more earnest consideration to smoke, fume and dust problems and endeavor to solve them, not only for the sake of better atmospheric conditions and for aesthetic reasons, but also for the values which are to be obtained when their solution is accomplished.

The Electric Arc in Vapors and Gases at Reduced Pressures*

BY W. A. DARRAH

Present commercial arc lamps operate with few exceptions in an atmosphere rich in oxygen or the oxide compounds of the electrodes. As a result the electrodes are oxidized as rapidly as they are vaporized (if not already composed of oxides as in the case of a magnetite arc), and as the oxides cannot be used again commercially it is necessary to provide means for disposing of them. This cycle of vaporization and oxidation of the electrodes naturally results in their comparative rapid consumption, which necessitates the trimming and cleaning of the arc lamp—one of the large factors of arc-lamp operation.

If it were possible to so design the lamp that the supply of material for the arc did not come from the electrodes but from a surrounding gas or vapor, and if in passing through the arc the vapor were not destroyed, it would then seem to be possible to construct an arc lamp which would not require trimming or materially more attention than an incandescent lamp. A lamp of this type, if it had a white light and good efficiency, might in some cases even occupy the field of the present incandescent lamp.

The research which is described in this paper was carried on to investigate the possibilities of accomplishing this object, and while the results are very promising from a practical standpoint, they are outlined here for their scientific value and should be considered only as a scientific research.

A study of the light efficiency of an arc from a chemical standpoint shows that there is a certain rather limited class of substances which when introduced into the arc in small quantities produce a very great increase in luminosity. Thus the addition of small quantities of cerium or calcium compounds to the carbon arc may increase its efficiency over 300 per cent, and the addition of titanium (preferably as an oxide) to the magnetite arc similarly produces an increased luminosity without a corresponding increase in energy consumption.

It is a peculiar coincidence that the addition of cerium or calcium to the magnetite arc, or titanium to the carbon arc does not result in approximately the same gain in efficiency. The chemical compounds in which the element appears is apparently of little importance.

A study of these facts led to the conception that perhaps an arc could be maintained in a closed vessel and supplied with these light-producing elements in the vapor form. On investigation this did not seem impractical, especially after a consideration of the liquid "inorganic" compounds shown in Table I, which contains some of the elements which produce highly luminous arcs. The table is discussed at length later on in this

TABLE 1—EFFECT OF VAPORS ON ARC

Substance	Boiling Point C°	Melting Point	Effect on Arc	Luminosity	Color
1. Carbon tetra chloride	77°	Liquid at ordinary temperature	Stable	Low	White
2. Stannic chloride	114°	Do.	Stable	Medium	Yellow white
3. Titanium tetra chloride	136°	Do.	Unstable Oscillatory Arc	Very high	White
4. Antimony trichloride	220°	Do.	Stable	High	Yellow white
5. Arsenic chloride	130°	Do.	Stable	Low	Purple
6. Silicon tetra chloride	57°	Do.	Unstable	High	White
7. Boron chloride	18°	Do.	Unstable	High	White
8. Phosphor trichloride	75°	Do.	Stable	Low	Pink and green
9. Aluminum trichloride	183°	Volatile	Do.	Low	Yellow
10. Cerium chloride	1400°	.....	Do.	Very high	White
11. Calcium chloride	1200°	780°	Do.	High	Strong yellow
12. Calcium iodide	1100°	740°	Do.	High	Yellow
13. Chromic chloride	White heat	.....	Unstable	Low	Green
14. Titanium chloro bromide	180°	.....	Very stable	Very high	White
15. Bromine	63°	7°	Very stable	Low (high absorption)	Yellow
16. Iodine	114°	Volatile	Unstable	Low	Blue
17. Chlorine	33°	102°	Stable	High	Yellow

*A paper read before the New York section of the American Electrochemical Society, in joint session with the Illuminating Engineering Society on November 11, 1915. Somewhat abstracted.

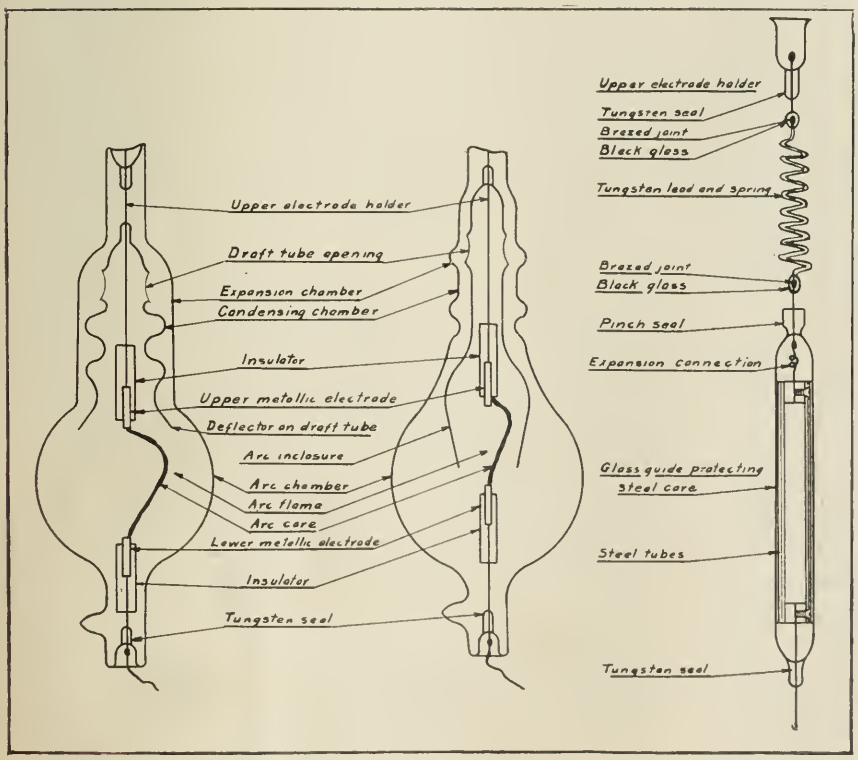

FIG. 1—LATEST CONSTRUCTION OF NEW ARC LAMP TYPE

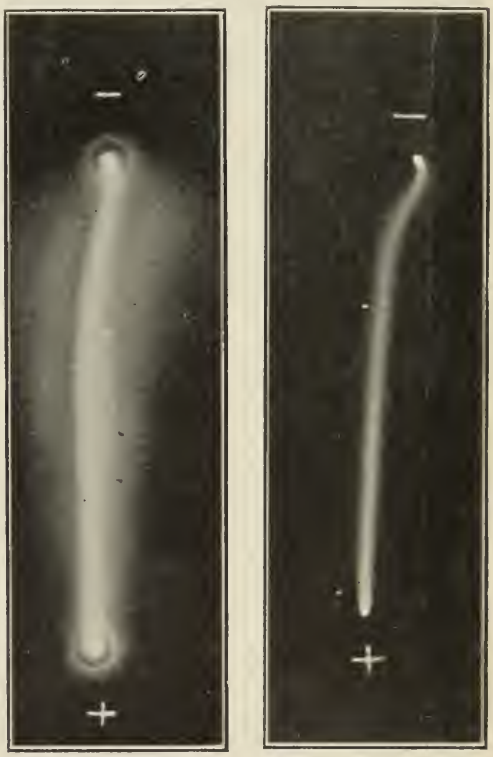

FIGS. 2 AND 3—VIEWS OF NEW TYPE OF ARC

paper, but it is interesting to note that titanium, tungsten and other elements which increase the luminous efficiency of an arc, may readily be secured in the form of volatile liquids.

Accordingly, a crude apparatus was arranged in which two hard carbon electrodes were placed vertically above each other in a tight glass vessel, and an arc drawn between the electrodes. As might be expected, this arc was non-luminous and very unstable. Accordingly, a small amount of carbon tetra chloride was poured into the vessel with a rather marked result. The arc then became stable and could be drawn out to several times the length which was previously possible, although its luminosity was not much increased. A flaky soot formed by the decomposition of the carbon tetra chloride also filled the glass chamber. A trial was next made with stannic chloride, with a similar increase both in stability and allowable arc length. In this case, also, the luminosity of the arc was much greater. The stannic chloride, however, was decomposed by the air and moisture present, forming a white insoluble powder upon the walls of the chamber, soon shutting out most of the light.

A more elaborate apparatus was therefore constructed in which the graphite electrodes were separated by an electro-magnet acting upon an iron core within a glass chamber.

The air was exhausted from the chamber, a small quantity of stannic chloride vapor at a pressure of from 3 to 4 centimeters was allowed to enter and the arc drawn. Under these conditions a stable arc 3 to 4 in. long could be produced with 6 to 7 amp. direct current, and 220 volts impressed. The arc was intensely white and so steady that it had the appearance of a thick incandescent filament slightly bowed and surrounded by a flame-like less luminous shell of yellow. The vapors from this arc, however, soon collected on the walls, forming a dense brown coat, which proved to be mainly tin carbide with a mixture of stannous chloride and other intermediate compounds.

These preliminary tests having indicated possibilities as well as having shown the difficulties to be overcome, additional smaller lamps were constructed along somewhat improved lines.

With these a detailed study was made of the effects of the various available electrode materials as well as the different vapors and lamp designs.

For convenience a hard glass (manufacturer's number G-702-P) was employed, as this permitted the sealing of tungsten wires and rods directly into the globe by the use of a flux of potassium nitrite and borax. This allowed the free use of heavy seals which were necessary for the tests. Fig. 1 shows the latest designs which have eliminated many of the difficulties encountered.

The shapes shown in Figs. 2 and 3 were found fairly satisfactory, while Fig. 5 shows some later designs which eliminated many of the difficulties eventually encountered.

The type of lamp shown consists essentially of an arc chamber at the center of which the arc is drawn between two tungsten electrodes about 3/16 in. in diameter. The electrodes are partly surrounded with a refractory insulator, designed to prevent the arc from moving far from the ends of the electrodes, as this allows the magnetic blow of the arc to continue to extend it, ultimately tending to rupture the arc. The refractory insulator also assists in maintaining the electrodes at a high temperature, thus increasing the efficiency of the lamp and the stability of the arc.

The upper electrode is fastened by means of a tungsten rod to an iron core, which is surrounded by a glass shell to protect the iron from corrosion, as the vapors used readily attack nearly all metal except tungsten, platinum, gold and a few other inert materials. A flexible tungsten spiral serves to conduct the current from the upper movable electrode to the upper seal.

It was found after a number of trials that a certain combination of gases to be described later gave a minimum amount of "soot" (decomposition products), which gradually collected upon the globe, thus reducing the amount of light radiated. In order to overcome this difficulty the arc chamber was extended somewhat above the upper electrode, thus forming a condensing chamber in which the soot could collect, allowing the walls to remain clean.

Further study developed that while this would remove a large quantity of the suspended soot a certain amount was still deposited on the glass walls adjacent to the arc. In order to eliminate this deposit, a draft tube was placed around the upper electrode in such a position that the heated gases from the arc would pass upward through the draft tube out into the condensing chamber and then back downward into the arc chamber for use again. The corrugations shown on the draft tube and condensing chamber has the effect of slightly compressing and expanding the gas as it passes from a chamber of small volume to one of large volume. The alternate expansion and compression of the gases, as well as the contact with the walls thus produced, was found to materially aid the condensation of the suspended matter.

The search for a satisfactory electrode material developed that carbon, either in the form of graphite or in the amorphous state, was unsatisfactory because of the disintegration by the action of the vapors and also the deposit of free carbon which it caused on the walls of the arc chamber apparently by direct radiation, as the draft tube and condensing chamber did not affect it as much as an increase of pressure of the gas around the arc.

It was demonstrated that practically all of the materials available (see Table I) formed carbides under the influence of the arc, and these carbides mixed with free

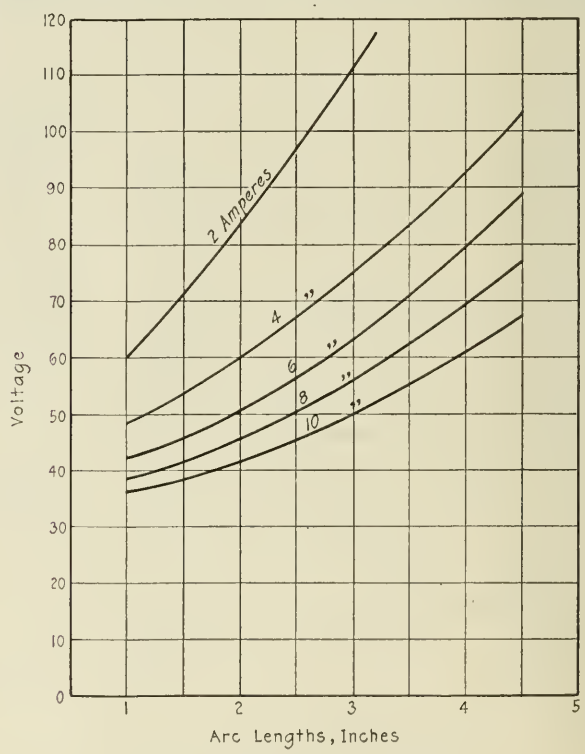

FIG. 4—PERFORMANCE CURVES

carbon formed so heavy a deposit on the walls of the arc chamber that it was decided to abandon carbon.

Chromium, titanium, molybdenum, nickel, iron, and silver were all tried without satisfactory results. Decomposition of the electrodes, decomposition of the surrounding gases and heavy deposits on the globe made the use of these materials impractical.

The substance which was found to be satisfactory in all respects was tungsten, which proved to be practically inert even at a white heat in the presence of the various vapors used. The tungsten terminals, moreover, did not melt or evaporate in the arc except at a very slow rate, which seemed to be comparable to the evaporation of the filament in an incandescent lamp. A rather interesting phenomena resulting from the gradual evaporation and deposition of the tungsten electrode was exhibited in the growth of a thin star-shaped fringe on the edges of the arc surfaces of the electrodes. This fringe was composed of points 2 or 3 millimeters long formed of small needle-like crystals of tungsten, and appears to be caused by the slow precipitation of free tungsten from the surrounding gases under the influence of temperature changes.

Having devised a satisfactory construction it was found that in order to introduce the gases and eliminate air and moisture special methods were required.

As all of the liquids employed are hygroscopic, and many of them readily decomposed by ordinary moist air, it became necessary to exhaust the air from the lamp, heat the lamp and electrodes while at a low pressure in order to remove the air films and then admit the liquids without opening the lamp chamber to the air. This was accomplished by means of a bottle sealed to the lower extremity of the lamp and provided with a ground stop cock connecting it with the lamp, as shown in the photographs. After the proper degree of exhaustion was reached, the desired liquid was carefully poured into the bottles and the stop cock opened slightly when atmospheric pressure forced the liquid into the lamp chamber.

The appearance of the arc in this lamp is quite different from other commercial arc lamps (see Figs. 2 and 3).

It is usually very stable, about ⅛ in. in diameter, tubular in form and varies from 2 to 5 in. in length with 110 volts direct current applied, the variations being due to differences in pressure, natures of the gases supplied, etc. A high pressure naturally increases the intrinsic brilliancy of the arc, but makes it necessary to operate at a shorter length as the gas currents due to temperature differences and arc reaction are correspondingly more violent. The diameter of the central luminous tube is also reduced with an increase in pressure.

Some of the arcs revolve very slowly, but as a rule the low pressure of the gases minimizes the motion of the arc and the general appearance is that of a thick intensely white incandescent filament slightly bent at the upper end. With some of the vapors, as, for example, the metaloid halogen compounds, antimony, phosphorus and arsenic chlorides, the central tubular portion is surrounded by a ragged flame, which is light pink in the case of arsenic and pale green in the case of phosphorus.

The flame portion acts somewhat as an absorbing screen, thus reducing the total useful radiation. It is a curious fact that this flame may exist for a short but appreciable time after the circuit has been interrupted, thus indicating that it probably does not have a part in the conduction of electricity through the vapor, but appears to be a zone in which the vapors after being dissociated by the heat and electrical effects of the arc recombine. The spectrum of the flame is usually quite different from the arc spectrum, and is characteristic of the elements involved, while the spectrum of the arc independent of the ends of the electrodes (which, of course, give a hot body spectrum) is usually a band spectrum and is practically continuous except for a few absorption lines.

A curious phenomenon noticed with an 8-amp., 220-volt arc at low pressure in the presence of cerium chloride was a separated arc which gathered into a glowing sphere at one corner of the chamber while the space between the electrodes through which a current of 8 amp. passed was entirely dark.

The complete paper contains typical performance curves which indicate the electrical characteristics of the antimony pentachloride lamp, which is illustrative but does not have as high an efficiency as the titanium tetra chloride or titanium bromo chloride lamp.

Fig. 4, plotted between arc length and voltage, shows the rate at which additional arc lengths require an increased voltage. The curve is also interesting as indicating that a 4-in. arc at 10 amp. requires no more voltage than a 1-in. arc at 2 amp. In other words, a 10-amp. arc is four times as long and therefore emits four times as much light as a 2-amp. arc. In addition its intrinsic brilliancy is about five times that of a 2-amp. arc. Accordingly, the light emitted by a 10-amp. arc *under these conditions* is twenty times that of a 2-amp. arc, and since the wattage of a 10-amp. arc is only about five times that of the 2-amp. arc, the efficiency is approximately four times that of the 2-amp. arc.

Efficiency curves indicate that 20 amp. is approximately the point of maximum efficiency of this particular antimony pentachloride lamp. It should be understood, however, that the current of maximum efficiency differs widely with differences in the nature and pressure of the gas as well as the volume and available radiating surface of the lamp, and very efficient titanium bromo chloride lamps have been constructed with a maximum efficiency of about 5 amp.

Regarding the efficiency secured, it is to be expected that these will vary widely with the condition and nature of the vapors used, and actual results range from 1 watt per mean spherical candle-power to less than one-quarter of the value. This performance may be secured with a white light which closely resembles afternoon daylight (north sky). An analysis of the color of the arc with the spectroscope as well as color-matching tests confirm this fact.

As a matter of interest, Table I shows some of the different compounds tested and some of the general results secured. These compounds may be roughly divided into three classes, as follows:

1. The illuminants, or those materials which give a high luminous efficiency. They usually produce unstable arcs if used alone.

2. The stabilizers, or those compounds which have a low luminous efficiency, but when introduced into an arc allow a very stable arc at relatively low voltages.

3. The "catalizers," or those compounds which are introduced to assist recombination in the flame zone, thus minimizing deposit.

Table I is interesting as it is the peculiar properties of the compounds, many of which are not very commonly used, that render possible a lamp of the kind described. The problem is to introduce as dense as possible an atmosphere of the various illuminants as titanium tetra chloride into an arc in such a form that it will not be permanently decomposed but may be used again and again. Some of the liquid halogen compounds shown in the table allow this. Some of those compounds (as, for example, those with the metaloids) which have a relatively slight affinity for a halogen are too readily

decomposed to be useful. Others, like stannic chloride, are too readily reduced to a less oxidized state, passing from a tetra chloride to the dichloride. Titanium tetra chloride is an example of this condition, but the addition of a small quantity of free bromide to the $TiCl_4$ (in which it is readily soluble) forms a compound (the bromo chloride) which readily recombines after dissociation.

Fortunately also, since the chloride and bromo-chloride of titanium dissociate at a higher temperature than tungsten chloride, and therefore recombine at a higher temperature than tungsten chloride, these vapors will not attack metallic tungsten even in the presence of the electric arc.

In order to avoid oxidation effects it was necessary to eliminate all oxides from Table I. More complex compounds such as sulphates, nitrates, could not be considered because of the tendency to dissociate and not recombine. Sulphides, nitrides, phosphides, etc., were eliminated because the chemical stability of these compounds in most cases was too slight to be satisfactory.

Chlorine was the halogen most generally used because of the stronger union of the chloride, and the reduced tendency of the dissociation products to attack the tungsten electrodes.

It would appear that an investigation along the lines here described opens up new possibilities in light production, but it cannot be too strongly emphasized that while the results set forth in this paper offer considerable promise from an applied, practical standpoint, yet they are not presented for consideration as representing a finished device, but merely a research in what seems to be a new and interesting field.

Mr. **Paul O. Abbe**, New York City, has issued a profusely illustrated catalog (A) describing his crushers, jar mills, pebble mills, mixers, disintegrators and various other classes of machinery.

The American Blower Co. of Detroit, Mich., has issued a bulletin describing Sirocco service in large hotels and office buildings.

Pyrometer Recorder—The Wilson-Maeulen Co., New York, has issued a catalog describing the Tapalog, a multi-record, multi-color pyrometer recorder. A description of this recorder was given in our issue of April, 1915, page 260.

Fuel Oil Engines—Messrs. Samuel L. Moore & Sons Corporation, Elizabeth, N. J., has issued a catalog describing its "Crescent" fuel oil engines for isolated stations. This engine operates on low grades of fuel oil, alcohol, hydrocarbon oil or kerosene.

The Richardson-Phenix Co., of Milwaukee, Wis., has sent us Bulletin No. 50 describing the Phenix force feed lubricator and a new type known as model "T," and Bulletin No. 60 containing information on the new model "M" lubricator.

The Yarnall-Waring Co. of Philadelphia, Pa., reports great activity in recent sales of "Lea" V-notch Recording Liquid Meters. Among the chemical and metallurgical companies using them are the American Smelting & Refining Co., the Atlantic Refining Co. and the Aluminum Co. of America.

Investigations of a Source of Potash—The United States Geological Survey in a report just issued (Bulletin 620-J) has suggested that a possible source of potash may exist in the tailings piled up at the concentrating mills of the big copper mines in the West. The potash, however, is combined in the form of silicate minerals, and its extraction has not yet been accomplished commercially, although for several years it has been the subject of much study.

The Development of Refined Tars for Use in Road Construction and Maintenance *

BY PHILIP P. SHARPLES

The year 1915 marks a decade in the application of refined tar to road treatment in the United States on any extensive scale. Experimental work had been done in desultory way before 1905, but the big influx of automobiles in 1905 made the problem of the maintenance of automobile-traveled surfaces acute and stimulated search after a remedy. For road work tar was first practically used in Nice in 1901 by Dr. Guglielminetti.

The problem of finding the most suitable tars for any given use in road work is not an easy one. The variables besides the tar are so many that it is often difficult to assign the exact causes of any success or failure. The observer in comparing different experiments must know not only the chemical and physical characteristics of the refined tar, but must have knowledge in a technical way of the engineering specifications under which the work was undertaken and an actual knowledge of the weather conditions under which the work was prosecuted with an intimate acquaintance with the climatic and traffic conditions imposed upon the road after completion.

The refining of the tar was the first step forward, and since 1905 practically only refined tars have been used in the United States for road purposes.

At the beginning of the decade, the intelligent study and testing of coal tars and coal-tar pitches for industrial uses had only begun. The rule of thumb was still the rule of the tar distiller and the manufacturer's chemist had presented to him not only the development of a new material but the development of methods of testing, the valuation of raw materials, the methods of factory control and the standardization of the finished product. The success attained has reacted on the whole tar distilling industry in the United States and now every plant of any size is equipped with a good chemical laboratory and one manufacturer even sustains a research laboratory unattached to any plant for investigating the scientific problems constantly arising in the industry.

The tar distiller is at the start confronted by a great diversity in raw materials. The tars may roughly be divided into two great groups, the coal tars and the water-gas tars, which differ essentially in chemical and physical characteristics. The coal tars form the basis for by far the larger percentage of the refined tar used for road purposes. The water-gas tars usually require modification by admixture with coal tars or with other bitumens to make them available for road purposes.

Coal tars are further divided for purposes of classification and manufacture into several groups based on their origin. The tars differ markedly one from another in physical properties. Their characteristics are shown in Table I to which is appended a sample of water-gas tar for the sake of comparison. Although the samples are typical of the groups, other tars in the same groups would show much variation in individual test.

Table I—Comparative Analyses of Tars

Tar From	Specific Gravity at 15.5° C.	Specific Viscosity Engler 100° C.	% Free Carbon	% Oil to Soft Pitch	% Tar Acids on Oil
Horizontal retort gas works, high heat	1.293	30.0	37.5	....	....
Horizontal retort gas works, low heat	1.267	21.8	28.9	13.2	14.0
Inclined retort gas works	1.238	14.9	24.3	14.3	21.0
Semet-Solvay coke oven plant	1.187	3.0	10.8	21.8	4.0
Vertical retort gas works	1.153	2.1	4.0	28.8	29.0
Water gas plant	1.074	1.6	0.3	45.1	0

*Presented at the First National Exposition of Chemical Industries, New York City, September, 1915.

The difference in specific gravity, specific viscosity and free carbon is marked and they vary directly. The amount of oils produced when the tars are distilled to a soft pitch varies inversely. Samples of other tars might not fall so regularly into the groups but the main comparison holds true. The tar acids, on the other hand, are much more irregular, though coke-oven tars usually contain lower percentages than gas-works tars. Oil tars, though usually containing no tar acids, may at times show traces or contain a small percentage of tar acids.

The deduction is easily drawn that with such a variation in raw materials, a uniform refined product is only possible with the command of considerable variety of tars and strict laboratory control. A study of pitches of uniform melting point made from these same tars still further accentuates the importance of selection and control, as shown in Table II.

TABLE II—COMPARATIVE ANALYSES OF PITCHES

From	Specific Gravity at 15.5° C.	Melting Point Cube Method in Water, ° F.	% Free Carbon	% Fixed Carbon	% Ash
Horizontal retort gas works (1)	1.357	127	46.1	51.5	0.14
Horizontal retort gas works (2)	1.306	131	33.5	42.0	0.21
Inclined retort gas works	1.284	130	30 4	37.9	0.10
Semet-Solvay coke oven plant	1.281	133	19.3	28.8	0.48
Vertical retort gas works	1.225	145	10.4	19 1	0.23
Water gas plant	1.190	139	1.1	23.8	0.06

The specific gravity, the free carbon and the fixed carbon advance in the same order as the raw tars. The ash, however, seems to be independent of the origin and is of little moment in the valuation of the tars. A more detailed examination of the pitches would still further develop these differences and would emphasize even more emphatically the importance of strict laboratory control of both the raw material and the finished product.

Refined tars for road purposes are divided into the following groups according to the use to be made of them:

1. Binders used in the construction of macadam roads.
2. Refined tars for use in road-blanket treatments.
3. Refined tars used in cold-surface treatments.
4. Pitches used as filler in block pavements.

The practice in regard to the specifications covering these materials has gradually crystallized and the following may be taken as typical of the grades:

Road Binder

The specific gravity shall not be less than 1.22 or more than 1.28 at 60 deg. Fahr. (15.5 deg. C.).

The material shall have a melting point, determined by the ½-in.-cube method in water of not less than 100 deg. Fahr (37.5 deg. C.), nor more than 110 deg. Fahr. (43 deg. C.).

On distilling 100 grams of the material, no distillate shall come over below 338 deg. Fahr. (170 deg. C.). On continuing the distillation to 600 deg. Fahr. (315 deg. C.) not more than 15 per cent of distillate shall come over and the specific gravity of the entire distillate shall be not less than 1.03 at 60 deg. Fahr. (15.5 deg. C.). The residue from the foregoing distillation shall have a melting point not greater than 165 deg. Fahr. (74 deg. C.).

The free carbon shall be not less than 12 per cent nor more than 25 per cent.

In making the foregoing tests the following methods shall be used:

Specific Gravity

The specific gravity shall be determined by the use of a Hubbard type specific gravity bottle. Approximately 10 grams of the melted material shall be placed in the weighing bottle and the weight taken after cooling. Freshly boiled distilled water shall be added and the bottle kept in a bath at 60 deg. Fahr. (15.5 deg. C.) until no further contraction takes place. The water shall then be adjusted to the mark and the bottle removed from the bath and weighed. The weight of the material, divided by the weight of the water displayed is the specific gravity.

Distillation

A 250-c.c. Engler flask shall be used and 100 grams of the material taken for distillation. The apparatus shall be set up and the distillation conducted as provided for in the tentative method proposed by the American Society for Testing Materials, Proceedings Vol. XI, 1911, page 241.

The distillate shall be collected in weighed flasks and fractions shall be determined by weight.

Receivers shall be changed when the thermometer records a temperature of 338 deg. Fahr. (170 deg. C.) and when the thermometer records a temperature of 600 deg. Fahr. (315 deg. C.) the flame shall be removed.

Melting Point

A clean-shaped ½-in. cube of the material shall be formed in the mold, placed on a hook of No. 12 (B. & S. gage) copper wire, and suspended in a 600-c.c. beaker so that the bottom of the cube shall be 1 in. above the bottom of the beaker (a sheet of paper placed on the bottom of the beaker, and conveniently weighted, will prevent the pitch from sticking to the beaker when it drops off). The cube shall remain five minutes in 400 c.c. of freshly distilled water kept at a temperature of 40 deg. Fahr. (4.5 deg. C.) before heat is applied. Heat shall be applied in such manner that the temperature of the water shall be raised 9 deg. Fahr. (5 deg. C.) each minute. The temperature recorded by the thermometer at the instant the material touches the bottom of the beaker shall be the melting point.

In determining the melting point of the residue after distillation, the initial temperature of the water shall be 60 deg. Fahr. (15.5 deg. C.) instead of 40 deg. Fahr. (4.5 deg. C.).

Free Carbon

The free carbon shall be determined by making a hot extraction of 5 to 10 grams of material with C. P. Toluol followed by C. P. Benzol, or C. P. Benzol followed by chloroform as solvents. The extraction shall be made in a Soxhlet, Knorr, Underwriters, or some other suitable extraction apparatus. The distillation of the solvent shall be continued until the washings run through practically colorless.

Refined Tar for Use in Road-Blanket Treatment

The specific gravity shall be not less than 1.20 or more than 1.26 at 60 deg. Fahr. (15.5 deg. C.).

The viscosity, tested by the standard Engler viscosimeter, shall be not less than 125 sec. nor more than 200 sec. for 100 c.c. at 212 deg. Fahr. (100 deg. C.).

On distilling 100 grams of the material, no distillate shall come over below 338 deg. Fahr. (170 deg. C.). On continuing the distillation to 600 deg. Fahr. (315 deg. C.) not more than 25 per cent of distillate shall come over. The specific gravity of the entire distillate shall not be less than 1.03 at 60 deg. Fahr. (15.5 deg. C.). The residue from the foregoing distillation shall have a melting point not greater than 165 deg. Fahr. (74 deg. C.).

The free carbon shall be not less than 12 per cent nor more than 22 per cent.

In making the tests, the methods already described shall be used. In determining the viscosity, the following method shall be employed:

Viscosity

The viscosity shall be determined in a standard Engler viscosimeter at 212 deg. Fahr. (100 deg. C.). Sufficient of the material shall be placed in the viscosimeter to bring the surface of the liquid to a level with the tops of the three levelling points. The time required to discharge 100 c.c. shall be recorded as the viscosity.

Refined Tar for Use in Cold-Surface Treatment

The specific gravity shall not be less than 1.14 nor more than 1.18 at 60 deg. Fahr. (15.5 deg. C.).

The viscosity tested by the standard Engler viscosimeter shall not be more than 250 sec. or less than 100 sec. for 100 c.c. at 104 deg. Fahr. (40 deg. C.).

On distilling 100 grams of the material to 338 deg. Fahr. (170 deg. C.) not more than 7 per cent shall distill over. On continuing the distillation to 600 deg. Fahr. (315 deg. C.) the residue shall be not less than 65 grams. This residue shall be a soft pitch at 60 deg. Fahr. (15.5 deg. C.). If the residue appears hard it shall be tested for melting point and the melting point shall not exceed 140 deg. Fahr. (60 deg. C.) by the ½-in.-cube method in water. The specific gravity of the entire distillate shall be not less than 1.01 at 60 deg. Fahr. (15.5 deg. C.).

The free carbon shall be not less than 4 per cent nor more than 12 per cent.

Pitch for Use in Stone Block with Fine Sand to Form a Mastic as Adopted by New York City

The coal-tar paving pitch shall be a straight-run residue obtained from the distillation of coal tar and shall comply with the following requirements:

(a) Melting point shall not be lower than 110 deg. Fahr. nor higher than 125 deg. Fahr.

(b) Free carbon shall not be less than 20 per cent nor more than 35 per cent.

(c) Specific gravity at 77 deg. Fahr. shall not be less than 1.22 nor more than 1.30.

(d) Specific gravity of the distillate to 670 deg. Fahr. shall not be less than 1.06 at 140 deg. Fahr., compared with water at the same temperature.

Pitch for Use in Wood Block as Adopted by New York City, 1914

The coal-tar paving pitch shall be a straight run residue obtained from the distillation of coal tar and shall comply with the following requirements:

(a) Melting point shall not be lower than 135 deg. Fahr. nor higher than 150 deg. Fahr. The contractor before beginning work on any contract shall obtain from the chief engineer in writing a statement as to the melting point desired for that particular contract and a variation of 5 deg. Fahr. either way will be permitted from this melting point, which, however, must be within the limits, as indicated above.

(b) Free carbon shall not be less than 22 per cent, nor more than 37 per cent.

(c) Specific gravity at 77 deg. Fahr. shall not be less than 1.24, nor more than 1.32.

(d) Specific gravity of the distillation to 670 deg. Fahr. shall not be less than 1.07 at 140 deg. Fahr. compared with water at the same temperature.

The tests governing the different elements are all closely interrelated and the attempt to change one without changing the others should not be made.

This is fully illustrated by Tables III and IV. Table III gives a series of refined tars made from the same raw tar, while Table IV gives three samples made from three tars of widely varying carbon content.

The tests used in these specifications and their significance have been given much study during the decade.

Table III

Sample No.	Free Carbon Percentages	Distillation Total to 315° C.	Melting Point, ° F.	Schutte Penetrometer, Sec. at ° F.		Viscosity Engler 100 c.c. at 100° C. Sec.	Float Test at 50° C Sec.
5	12.1	21.8	....	29	40	94	34
	12.0	19.2	....	108	40	127	38
8	14.0	16.4	....	114	50	159	58
9	14.4	14.9	86.9	85	60	208	75
10	17.2	12.7	99.7	90	70	335	110
11	18.2	10.4	108.7	88	80	431	170

Table IV—Relation of Viscosity to Carbon Content

Sample No.	Free Carbon Percentages	Melting Point, ° F.	Schutte Penetrometer at 80° F. Sec.	Engler 100 c.c. at 212° F. Sec.	Float Test at 212° F. Sec.
1	1.4	110	42.2	302	158
2	14.5	109	80.1	298	192
3	39.6	112	144.9	739	337

The specific gravity is of value as limiting to a certain extent the origin of the tar. The method used should be distinctly stated and the temperature at which the comparison with water is to be made should be given. Sixty degrees Fahrenheit is a usual temperature but many specifications call for 25 deg. C.

The viscosity or melting point is the most important test in the specification. It has nothing to do with the origin of the tar since any tar may be brought to a given viscosity or melting point above certain lower limits. It does, however, determine the way in which the material can be used and applied. In determining viscosity, the Engler viscosimeter is generally used for materials which are liquid at ordinary temperatures or which may be made fluid at the temperature of boiling water.

The float test or the Schutte penetrometer is often used for intermediate products while the melting point is generally specified for binders and fillers. Whatever method is used, the details must be specified in full.

The amount of free carbon desirable has been the occasion of much discussion. Practical experience in roofing and waterproofing work has shown indubitably the value of free carbon in pitches used for these purposes. In the case of road tars, it was argued that free carbon was an inert substance and could only be a diluent of the tar. A large number of experiments carried on to determine this point have seemed to indicate that tars very low in free carbon were too much affected by temperature and also more subject to change by weathering than tars which contain a fair amount of free carbon. At the same time an excess of free carbon is not desirable since it tends to make the material difficult to work. With cold surfacing materials, the free carbon must necessarily be kept lower, since its presence in considerable amount reduces the penetration of the material into the road surface.

The distillation test is important in defining the kinds of materials used in manufacture. It should always be coupled with a determination of the specific gravity of the distillate and the melting point of the residue.

The method of distillation should be specified with great detail. Unless this is done, the specification will be of little value since widely varying results may be obtained by different methods.

The development of suitable tars has gone hand in hand with the development of suitable specifications for their use and the development of suitable apparatus for their application to road surfaces.

The development of the whole industry has been a happy illustration of the importance of co-operation. The chemist, the civil engineer, the mechanical engineer and the manufacturer has each played his part. Any one, alone, could not have achieved the whole.

Society of Chemical Industry

Meeting of New York Section

The second meeting of the New York Section of the Society of Chemical Industry was held on Nov. 19 at Rumford Hall, Chemists' Building. Owing to the inclemency of the weather, the attendance was comparatively small, but in interest and liveliness of discussions the meeting was very successful.

Two papers on the program, by Dr. G. R. Fonda, on industrial argon and incandescent lamps, and by Dr. W. H. Walker, on chemical research in the iron and steel industry, had been withdrawn and a paper by Dr. Lewis, not on the program, had been substituted. This was first presented.

A FILING SYSTEM IN THE CHEMISTRY OF AMORPHOUS SUBSTANCES

The paper on this subject by Dr. **W. K. Lewis** of the Massachusetts Institute of Technology was of considerable interest and quite suggestive. This work is based upon the researches of the author as well as upon the researches of other chemists "on both sides of the water." All solids possessing desirable mechanical properties owe these properties to their amorphous condition. Such solids are plastic and can be molded without strain or fracture.

Thesis 1: All or nearly all amorphous solids are composed of large molecular aggregates.

Thesis 2: The molecular aggregates of most amorphous solids can be conceived as built up of a relatively small unit.

Thesis 3: Usually in an amorphous solid V_n the value of n is not fixed.

Thesis 4: The characteristic properties of all amorphous bodies are plasticity and relative inertness.

Thesis 5: The swelling of amorphous solids in solvents is due to the distension of an insoluble and impermeable residue by the osmotic pressure of a dissolved portion.

Thesis 6: Excessive mechanical manipulation of an amorphous solid ruptures the molecular aggregates.

Thesis 7: The utility of amorphous solids is due largely to their property of plasticity.

Numerous examples were cited to illustrate each one of the above seven theses. The author then took up methods of manipulation of plastics.

Method 1: By mechanical stress. The rigidity of the body is such that it will retain its molded shape without any further manipulation, *e.g.*, clay.

Method 2: Plasticity is secured by rise in temperature, rigidity is restored by cooling, *e.g.*, glass.

Method 3: Plasticity is secured by the action of a solvent, rigidity is restored by the removal of the solvent, *e.g.*, sugar.

Method 4: After manipulation of a plastic we may destroy the plasticity by chemical conversion into a new body less plastic, *e.g.*, ceramics, cement, plaster, etc.

Method 5: The plasticity may be lessened by increasing the size of the molecular aggregate produced by coprecipitation of two amorphous substances existing as colloidal solutions.

Method 6: In the complex V_n (amorphous solid) we can increase the size of the molecular aggregate by increasing n, *e.g.*, bakelite and all other condensation products.

Method 7: In the complex V_n we can increase the size of the molecular aggregate by increasing V, *e.g.*, rubber, linoxylin, oxycellulos, etc. In this case a small change in the unit V produces a great change in the plasticity and resistivity, *e.g.*, addition of sulphur to rubber (vulcanizing).

Those elements which do not combine chemically do not affect its plasticity. We also find that n in V_n decreases after rubber has been in solution, and more S is required to vulcanize rubber that has been in solution than the same rubber before it is dissolved.

Theories are a "filing system for facts," and in the manner sketched above many facts from the leather, starch and other industries may be explained.

In the discussion which followed, Dr. M. T. Bogert commented on the originality and novelty of the scheme proposed by Dr. Lewis.

RESEARCH IN CHEMICAL INDUSTRY

C. F. Burgess, president of the C. F. Burgess Laboratories of Madison, Wis., followed with a splendid paper, bringing out many fine points on a subject that some had thought had become somewhat stale for discussion —research in chemical industry. He started with a delightful little story of how his daughter had recently explained to an inquisitive elderly lady that "father used to be a professor in the University of Wisconsin, but two years ago he quit and got to work now."

Some of the points emphasized by Professor Burgess were as follows:

Twenty years ago the electrical engineering courses were most attractive to young men, but to-day chemistry gets their attention more and more.

Research work pays just as it pays to advertise.

Not all men are successful in research.

The research chemist and the manufacturer must ever be aware of the fact that there are more cases of disappointment than of success in research.

Many factories do not know how to conduct a research laboratory. Very often the laboratory becomes a mere adjunct to the sales department, and the unfortunate result is that the "research chemist" is eventually trained to get only such results in his tests, etc., as will boost the quality of the factory's product. Very often such results are far removed from scientific accuracy.

On the other hand, it is not advisable to separate the research laboratory from the sales department altogether. There ought to be an intimate contact between the two departments so that the research man will keep in touch with what is actually demanded.

The personality of the research man is a most important factor. Furthermore, proper training is essential; experience along mechanical lines is a great asset to the research chemist.

The manufacturer himself has to carry out the initial research work—when he selects the men for his research laboratory.

The average university graduate must give up some of his delusions, yet he must not lose his enthusiasm.

The problem of compensating a research chemist properly for his work is very important. To give a bonus to one man is often an injustice to another man. Further, the research worker must recognize the fact that there is a wide gap between research laboratory and factory when it comes to developing a process and putting it on a commercial basis. From his experience Professor Burgess concludes that when a product originally developed in the research department finally becomes a commercial product, the proportion of profits accruing from it which should be charged to the credit of the research department should usually be not more than 10 per cent. The other 90 per cent are due to members of the sales department and other departments. But a profit-sharing plan is difficult to work out.

The best way of taking care of the cost of equipment and maintenance of a research laboratory in a factory is to have a "development account" which might be entered as a fixed sum in the yearly budget.

ADMINISTRATION OF INDUSTRIAL RESEARCH LABORATORIES

Dr. **Raymond F. Bacon**, director of the Mellon Institute of Industrial Research, Pittsburgh, Pa., then presented in abstract an interesting paper of much originality on "some principles in the administration of industrial laboratories."

"Get your principles right, the rest is a matter of detail."

The proper selection of the director or controlling man is the real problem. He must be far-sighted and broad-minded, and must be of "peculiar normality." The direction of a research laboratory is very much like running a "zoo"—there are all kinds of animals with all kinds of tastes and habits.

In research work the unexpected results are often more important than those carefully planned and correctly predicted.

In a research man a pleasing personality is even more important than training or anything else. He must have "ginger and pep," and must be an "active optimist."

As regards the remuneration of the research man, this may be either a straight salary or it may be simply a bonus, or it may be a combination of salary and bonus. At the Mellon Institute the third scheme has been adopted. By bonus is meant a "small" cash bonus of, say, $2,000 to $5,000. Dr. Bacon does not believe in royalties or percentage bonuses.

A research man must be free from restraint and from petty annoyances. He ought not to hold an official position which does not permit him to devote his main energy and time to his research work. In the government institutions promotion to official positions is often a means of recognition, but this is a serious mistake.

Before starting a man upon a certain problem, the Mellon Institute makes it a practice to send the man to the factory which is interested in the problem, and there he remains until he is fully acquainted with the exact requirements of the problem.

The habit of reporting upon research work regularly once a week is very important. Not only do these reports form valuable records, but the man often realizes that he has not worked very hard during the past week. Accordingly, this system of reporting serves as a reminder and acts as a stimulus to do better work next week.

Dr. Bacon described at some length the remarkable equipment of the Mellon Institute. The methods of the Mellon Institute have met with great favor elsewhere, as the Royal Institute of Canada and the Sheffield Institute in England were modeled after the Mellon Institute.

GENERAL DISCUSSION ON RESEARCH

Dr. **A. M. Comey** of the Eastern Laboratory of the E. I. Du Pont Powder Company started the general discussion. He said that at their laboratory they find it absolutely necessary to keep routine work and research work separate and distinct. On the other hand, there is a real advantage in maintaining an amicable and intimate relation between the operating or manufacturing departments and the research laboratory.

In order to counteract any tendency of a feeling of jealousy to spring up among the members of the research laboratory they have found it necessary to make *one* man responsible for a certain problem or work.

The bonus system at the Du Pont laboratory has worked out very successfully. There are two kinds of bonuses:

Class A Bonus: For work that has brought material benefits.

Class B Bonus: For "zeal" where no direct material benefit accrues.

They train their own men at the laboratory by making them assistants or helpers, and they learn from their superiors. Sometimes it is found after a half a year or so that the man is not well suited for research work, and he is then transferred to one of the other departments, the analytical laboratory, the testing laboratory, etc.

When one of their men has made an improvement or an invention which is about to be carried out on a large scale in the factory, he is instructed to write up a detailed report and submit copies of this report—with his name attached—to various heads of the company. At times it is found advantageous to put the research man in charge of the process in the factory until it is fairly well established.

In a research chemist the combination of personality and common sense is more important than training. The man must be happy in his work and must not be hindered by time clocks and other strict regulations.

The remarks of Dr. Comey were heartily applauded. (The methods adopted by him and his company are usually conceded to be the nearest to the ideal. The laboratory has a splendid reputation.)

Dr. **C. G. Fink** of the Edison Lamp Works, Harrison, N. J., emphasized that an intimate relation between factory and laboratory is absolutely essential if the laboratory is to be of any direct value to the company. The head of the laboratory must realize at all times what the immediate and most urgent demands of the factory are and must be prepared at all times to render every assistance possible.

For example, when the European war deprived this country of potash and other raw material, it was necessary to find substitutes, and find them immediately. Thus soda glass was developed for potash glass for a certain special purpose. The factory usually cannot wait very long, and carefully planned research work covering periods of two, three or more years does not interest the factory. Many research men overlook this vital point in making an industrial laboratory an asset and a help. Give the factory "the next best" thing right off and then either improve upon it in the laboratory or find something better to take its place.

As to compensation, most factory heads do not appreciate the importance of giving the research men due recognition and credit for the work accomplished. "Usually a research man prefers proper recognition to an increase in salary or a bonus. He needs this recognition to keep up his enthusiasm. You cannot compensate a research man as you would compensate a salesman or a broker."

Dr. **A. D. Cushman**, director of the Institute of Industrial Research, Washington, D. C., said that they often find difficulty in getting sufficient financial assistance. "But on the whole we greatly enjoy our work. We look upon it as a most interesting game."

Dr. **J. B. F. Herreshoff** urged that in every laboratory there ought to be some men who have had business experience. Very often a young chemist will run into impractical lines. At their laboratories research has been going for very many years, only formerly instead of speaking of research they used to term it "improvements."

Prof. **M. T. Bogert** of Columbia University said that our industries must not overlook the importance of pure research work carried out at the universities. The investigation of new compounds and of complicated molecular reactions, etc., are problems fully as important as, if not more so, than the problems of the industrial laboratories. In this connection it is a source of gratification to learn of the establishment of the Willard Gibbs Professorship of Research in Pure Chemistry at the Mellon Institute. It is of vital importance to the

best interests of all that the industries assist the universities financially in carrying out research work in pure chemistry.

The meeting then adjourned.

The Physics of the Photographic Process*

BY C. E. KENNETH MEES

The unit of the photographic emulsion is the grain, and in order to study its properties we must study the properties of the individual grains. The grains are held in a sponge of gelatin, which is believed by Quincke to have a two-phase structure, one phase constituting the cell walls, and the other a solution filling the channels and cells themselves. Through these channels in the gelatin the migration of ions can take place at a velocity comparable with their diffusion rate in water, while penetration through the cell walls is a much slower and more difficult process.

Development consists of a reaction between an ion of the reducer and an ion of silver from the dissolved silver bromide, the silver ion being reduced to metallic silver in solution, which must then either precipitate or bring the reaction to an end. Precipitation can be induced only by the presence of a nucleus, and consequently in the absence of a nucleus for any grain, that grain will be undevelopable, the provision of the nucleus being the function of the "latent image." From a consideration of the energy required to produce a latent image in a high-speed photographic material it can be shown that the energy available per grain is of the same order as that required to ionize one molecule of a gas, and it is possible, therefore, that the latent image is composed of grains of silver bromide in each of which, on the average, one molecule has lost an electron by the action of light. The action of light on a photographic emulsion may, therefore, be classed as a photo-electric effect, and, as is the case with other photo-electric effects, the light must have a frequency above a certain critical value, the critical value depending upon the salt of silver employed, being about 400 $\mu\mu$ for silver chloride, and 480 $\mu\mu$ for silver bromide.

It seems probable that reversal is due to a slow decomposition of the silver bromide and liberation of bromine, which then attacks grains which had been exposed and contained a nucleus, rendering them undevelopable or, at any rate, less easily developable.

The size of the grain has several influences on the properties of photographic materials. In high-speed emulsions, if we assume that all the grains are equally sensitive, then the mass of silver produced for a given exposure will vary as the cube of the diameter of the grain, and the range of the sensitiveness experimentally found in high-speed emulsions can be accounted for by variation in the size of the grain without making any other assumptions.

It seems to be a fact that there is a qualitative difference between high-speed and low-speed emulsions, which must be due to the nature of the grains. If we start with a very fine-grained emulsion and cook it, the size of the grain and the sensitiveness will only increase to a certain limited extent, and in order to get a high-speed emulsion having larger grains and much greater sensitiveness, we must start in an entirely different manner, precipitating the silver of medium grain, which can then be increased in size with a concomitant increase of sensitiveness.

The difference may be that in the low-speed type the silver grains consist of a network of crystals containing gelatin, while in the high-speed emulsions the gelatin is distinctly separated from the crystals, so that in a low-speed emulsion each of the crystals forming part of the grain must be made developable by the action of the light, while the large grain of the high-speed emulsion requires action only at one point to make it entirely developable, the energy required to form a latent image in a high-speed emulsion being only that necessary for the liberation of one electron per grain, while in the low-speed emulsion several electrons for each grain may be necessary. Inasmuch as the grains of high-speed emulsions are not homogeneous in size, the sensitiveness will depend on the distribution of the grains of different size, and so also will the shape of the plate curve.

With a homogeneous emulsion we should have a simple curve with short over and under-exposure portion, but if the size of the grains varies more about the mean, then a curve having a longer straight line can be obtained, while any special distribution of the grains will be accompanied by a corresponding change in the shape of the plate curve.

The resolving power of an emulsion represents its ability to give sharp images and depends upon the side spreading of the light in the emulsion itself. It can be examined by printing images of the edge of a steel blade on the emulsion by parallel light, the distribution of the image inside of the shadow of the blade being afterwards investigated. It has been shown that there are three factors in the resolving powers: (1) The scattering power of the emulsion for light, (2) the absorption of scattered light by the emulsion, and (3) the photographic factor, which covers the reproduction of the light distribution as density distribution in the developed plate.

The distance between the two lines which will just be separated with a given emulsion will be extremely small for extremely small sizes of grain, because such sizes of grain far below the wave-length of light will scatter very little light; that is, the turbidity will be negligible. As the size of grain rises, however, the turbidity increases very rapidly, and with it the distance necessary to separate two lines, until with a grain diameter a little less than 1 μ the turbidity is high and the opacity still low, so that the necessary separation of the lines is a maximum, and then, as the grain still grows, the opacity grows faster than the turbidity and the lines to be separated can be somewhat closer together. Then, again, with the increasing diameter of the grains the actual space factor comes in, the size of the grains themselves and the distance between them becoming comparable with the distance between the separated lines, and with increasing size of grain this distance must again increase steadily.

Recent Chemical and Metallurgical Patents

Tungsten and Zirconium

Treatment of Tungsten Ores.—A method of treating scheelite and its concentrates for the removal of phosphorus is disclosed in a patent recently granted to FREDERICK M. BECKET of Niagara Falls, N. Y. A representative sample of scheelite was found to contain 54.60 per cent WO_3, 3.45 per cent FeO and 0.212 per cent P. The ratio of tungsten to phosphorus was about 204. It is impracticable to eliminate this phosphorus by treating the ore with dilute acids without entailing serious loss of tungsten. The inventor has discovered, however, that if the ore is treated at red heat with concentrated sulphuric acid, the phosphorus is soluble while the tungsten is rendered nearly insoluble. The mixture of ore and acid is allowed to stand for some hours.

when the residue is washed until approximately free of sulphuric acid. By this treatment the tungsten-phosphorus ratio was increased from 204 to 3093 with a loss of less than 1 per cent of the total tungsten. The resulting product can be reduced by silicon to tungsten metal in the electric furnace; or it can be converted into ferro-tungsten by mixing with an ore of the iron-tungstate type, such as wolframite or ferberite, the mixture being proportioned to contain iron and tungsten in the ratio necessary to produce the desired alloy. This mixture is then reduced by silicon in the electric furnace. Thus the purified scheelite acts as a diluent of the less pure ores of the iron-tungstate type, and renders the latter available for the manufacture of low-phosphorus ferro-tungsten. (1,153,594, Sept. 14, 1915.)

Preparation of Tungsten for Lamp Filaments.—A method of treating metallic tungsten so that it will be specially suitable for the manufacture of lamp filaments is patented by Gottlieb Gmür-Zehnder of Aarau, Switzerland. The patentee has discovered that if tungsten is fused to a perfectly liquid condition in an electric furnace and then cooled rapidly it will be exceedingly fine in granular structure and perfectly malleable and ductile. The furnace is of the resistance type and the tungsten is heated by radiation. The cooling is accomplished by a blast of cold compressed air. (1,150,670, Aug. 17, 1915.)

Zirconium-Iron Alloy for Lamp Filaments.—Attempts hitherto made to produce commercially useful alloys of zirconium have not been very successful, as the brittleness of the metal has characterized its alloys. Moreover, it has been found extremely difficult to produce alloys of the metal by direct combination with other metals. According to a patent granted to John L. Brown of Baltimore, Md., however, it has been found possible to produce satisfactory alloys of zirconium and iron and other metals by reducing mixtures of compounds containing these metals. The alloys thus produced are of a type hitherto unknown among metallic zirconium combinations. They exhibit little tendency to oxidize and are resistant to most chemical reagents. They are also tough, malleable and ductile. The value of these alloys for lamp filaments is that they have the property of selective radiation and possess a remarkably high degree of luminescence at relatively low filament temperatures. The presence of titanium, aluminium, tantalum, and columbium give alloys that offer certain advantages for special purposes. (1,151,160, Aug. 24, 1915.)

Gold and Silver

Agitator.—A type of mechanical agitator for slime pulps is shown in Fig. 1, being the patented invention of Albert E. Vandercook of Alameda, Cal. In this agitator the pulp is circulated by means of a centrifugal pump 32 through a vertical stationary pipe 2 and radial movable arms 17, the intake to the pump being by way of pipe 31. The principal feature of the agitator is the construction of the gland 13, which forms the rotatable part of the bearing, whereby pulp is prevented from finding its way into the ball race. As the movement of the radial arms, due to the discharge of pulp through the nozzles 18, is not visible, an indicating rod 27 is attached to a boss on the gland, thus indicating the motion of the rotating element. (1,156,946, Oct. 19, 1915.)

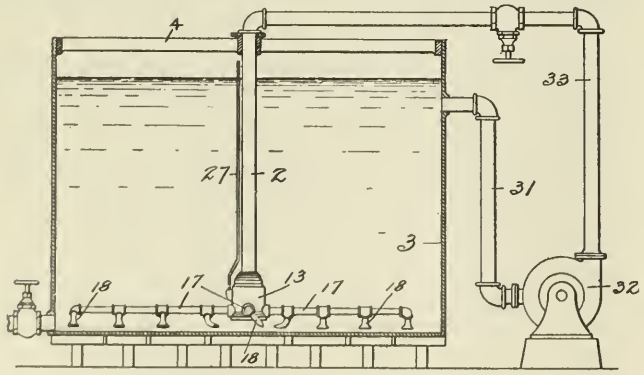

FIG. 1—AGITATOR

Copper

Copper Converter.—In the ordinary type of converter construction the gases are discharged through a throat in the upper side of the shell; and since the hood which directs the gases to the flue is stationary, it has an unduly large opening in order to cover the range of the converter when it is set at varying angles. This arrangement permits the entrainment of a great amount of air into the flue, from two to three times the quantity of gases discharged from the converter. As an improvement on this construction, William H. Howard of Garfield, Utah, has patented a form of converter

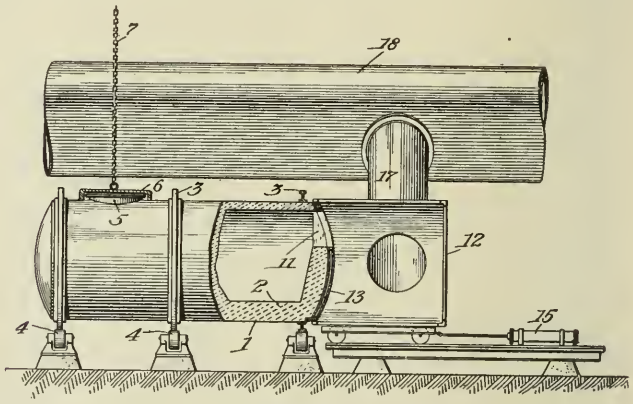

FIG. 2—COPPER CONVERTER

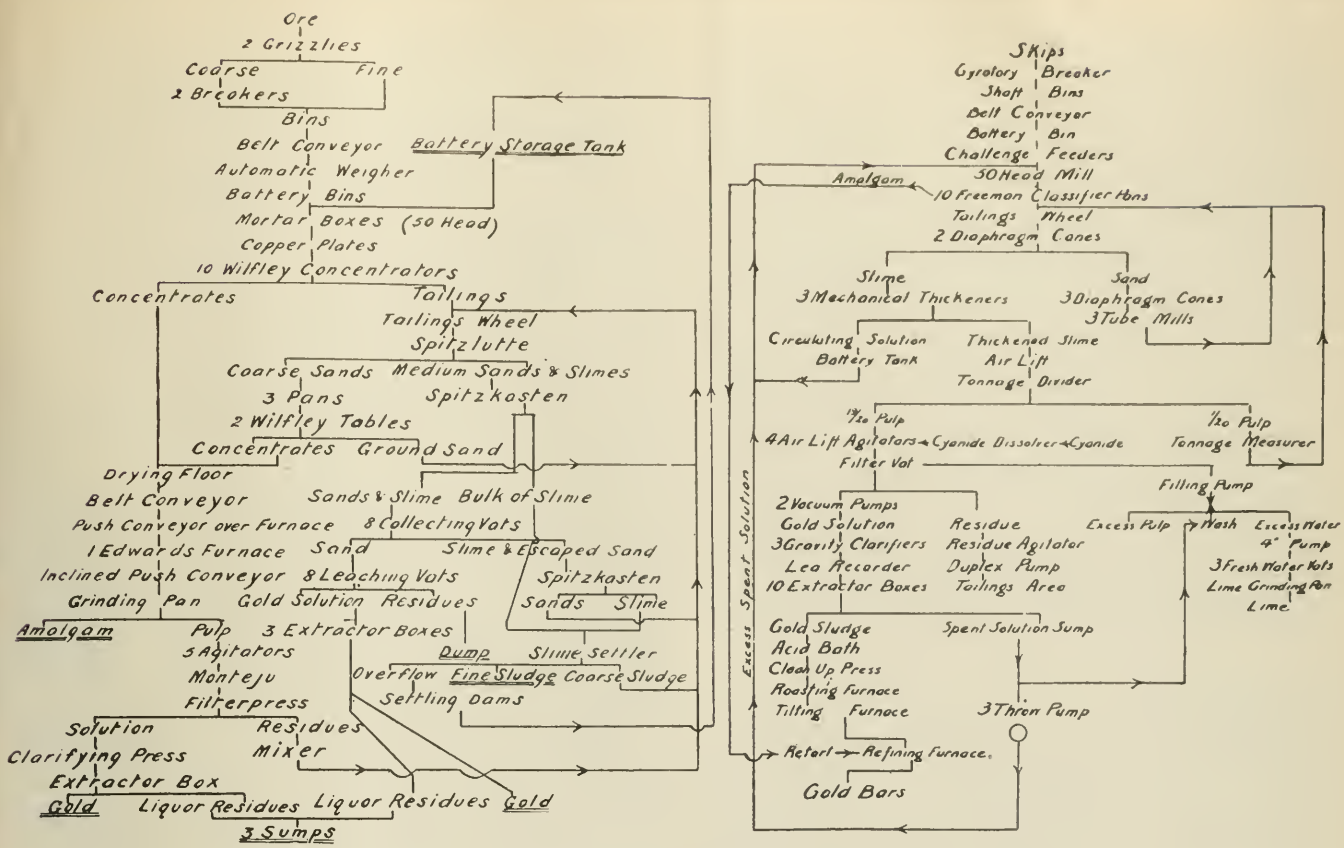
with adjacent stationary hood, as shown in Fig. 2. The converter has its discharge opening at one end and is combined with a stationary hood concentric with the shell of the converter and telescoping that end in which the discharge opening is placed. By this construction the exit for gases is always within the hood, regardless of the position of the converter shell. In Fig. 5 the converter is shown with a lining 2, a covered opening 5 for introduction of matte, waterjacketed end 13, and exit for gases at 11 into the hood 12, which communicates with the flue 18 by pipe 17. Spouts for pouring slag and metal and tuyeres are not shown. A practically tight connection is maintained between the converter and the hood, thus insuring the delivery into the flue of substantially undiluted gases. (1,153,921, Sept. 21, 1915.)

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Wood-Burning Assay Furnaces.—By the substitution of wood for coke and charcoal, and the reconstruction of the assay furnaces to give conditions suitable to burning wood, H. R. Edmands effected a saving of about £12 or nearly $60 per month. The furnace is illustrated and described in the monthly *Journal* of the Chamber of Mines of Western Australia for May, 1915.

The furnace used for fusions is a reverberatory of the type described by McArthur Johnson in "Rand Metallurgical Practice." The firebox is 19 in. wide, 28 in. high and 30 in. deep. The hearth behind the bridge takes the place of the ordinary muffle, and is covered



FIGS. 1 AND 2—FLOW-SHEETS OF 1906 (AT LEFT) AND 1914 (AT RIGHT)

with sand to absorb any slag that may boil over from the crucibles placed thereon. The hearth is covered by a firebrick arch, and an opening at the side is used for placing and removing crucibles. For cupellation a wood-burning muffle furnace is used. The average life of crucibles and muffles is much greater in these wood-burning furnaces than in either coke or charcoal furnaces. Fuel consumption for both furnaces is about 6 tons of wood per month, costing £3 6s. Previous cost of coke and charcoal for the same work was £13 11s., or a saving of £10 5s. per month, to which must be added the saving in crucibles and muffles, amounting to about 35s., or a total saving of £12.

Cyaniding at the Sons of Gwalia, Australia.—The accompanying flow-sheets, Figs. 1 and 2, taken from the monthly *Journal* of the Chamber of Mines of Western Australia, illustrate the simplification of cyanide treatment at the Sons of Gwalia mine. Explanatory data are contributed by Mr. A. WAUCHOPE. The former system consisted in wet crushing, amalgamation in mortar boxes, followed by pan grinding, table concentration, vacuum filtration of slime and leaching of sand. Experiments having demonstrated that all-sliming would be as effective as double treatment, the mill was remodeled on that basis, as shown in Fig. 2.

In the present scheme no amalgamation is done in mortars or on plates, but in 5-ft. Forwood Down grinding pans with Freeman selective pipe discharge. About 20 per cent of the gold is recovered here, with a mercury consumption of 0.23 oz. per ton of ore crushed. Tube-mills have corrugated hard-iron liners, with flint pebbles as the grinding medium. The pebble load for each 18-ft. by 4½-ft. tube is 7 tons, and the consumption is about 1.5 lb. per ton of ore crushed. The slime product contains about 10 per cent of material coarser than 150 mesh. Continuous mechanical thickeners discharge a pulp of 45 per cent moisture which is agitated continuously by combination mechanical and pneumatic agitators. The filter is of the Cassell type, with forty-four leaves each 9 ft. by 5½ ft. The cotton-duck cloths have a life of about six months, the long service being attributed to a softening of all water taken into the plant. The softening process prevents a precipitation of magnesia when water is mixed with plant solutions. Wet vacuum pumps maintain a vacuum of about 25 in. during filtration and 7 in. during pulp transfer. The elevation is 1400 ft. above sea level. In order to prevent cracking and falling of cakes during changes of pulp and wash solutions, a number of sprays drench the cakes with atomized solution which not only washes the sides of the tank and prevents salting of the following wash, but also reduces loss of dissolved metals. Solution tonnage is measured by means of a Lea V-notch recording meter, which has proved satisfactory over a period of eight months and has permitted close regulation of operations. Solution is precipitated on zinc shavings in boxes having a capacity of 0.8 cu. ft. per ton of solution per day. One and a half tons of solutions is precipitated per ton of ore crushed. The gold-zinc slime is acid-treated, filter-pressed, roasted in a wood-fired reverberatory furnace, and smelted in a tilting, coke-fired furnace. The consumption of chemicals per ton of ore is: KCN, 0.45 lb.; Zn, 0.37; CaO, 3.4; H_2SO_4, 0.2.

Metallurgical Practice on the Rand, South Africa.—A review of the development of gold metallurgy in South Africa was given in a paper before the American Institute of Mining Engineers at San Francisco by F. L. BOSQUI, covering two periods, that preceding the use of cyanidation on a commercial scale in 1890, and the twenty-four years subsequent to that important event. Cyanidation was introduced as a result of trials at the Salisbury battery in 1890 by the Cassel Gold Extraction Co. The first application on a commercial scale was in the same year, when the Gold Recovery Syndicate treated by contract 10,000 tons of tailing on the prop-

erty of the Robinson Gold Mining Co. The Siemens-Halske electrolytic method of gold precipitation was introduced in 1894 at the Worcester mine and was adopted at several other properties, but never won general acceptance owing to the delicacy of the process and the formation of troublesome by-products. It was finally abandoned in 1898 in favor of zinc. With the reversion to the use of zinc, Rand metallurgy may be said to have crystallized into a general scheme of milling and of separate treatment of sand and slime by cyanide. Even the introduction of tube mills in 1904 did not seriously modify the main features, the tube becoming an accessory to the stamp. The vacuum filter was introduced in 1909. The fact that local practice has not adopted numerous processes found feasible elsewhere is not a reflection on the lack of enterprise of Rand metallurgists, but rather of their knowledge of local conditions requiring simplicity in operation, low maintenance and treatment cost, and high efficiency. The ore is low-grade, ranging from 4½ to 9 dwt. gold per ton, up to 70 per cent of which is amalgamable. The author gives the following tabulation of variations in local practice as adopted at different mills:

Step in Treatment	Variations
I. Ore sorting and breaking.	(a) Ore washed in trommels or in stationary chutes.
	(b) Ore sorted on slowly moving belts or on revolving tables.
	(c) Ore broken in two types of crusher, those in common use being the Blake swinging jaw type and the Gate gyratory.
II. Stamp-milling	(a) A range in weight of stamps from 1,150 to 2,000 lb.
	(b) Considerable variation in details of battery construction; also variation in mesh of battery screen dependent chiefly upon tube-mill facilities.
III. Amalgamation	(a) Use of battery plates, and so-called tube-mill plates for secondary amalgamation after tube milling.
	(b) No battery plates; all amalgamation done after tube milling.
	(c) Tube-mill plates, shaking and stationary.
	(d) Considerable variation in ratio of area of plates to tonnage.
IV. Tube milling	(a) Tube mills of varying dimensions.
	(b) Varying ratio of number of tube mills to stamps.
	(c) Devices for thickening pulp and feeding tube mills.
	(d) Kinds of "liner" in use.
V. Classification of pulp	(a) Coarse sand separated out and sent to tube mills.
	(b) Separation of sand from slime.
	(c) Classification in spitzkasten or hydraulic cones.
VI. Treatment of sand	
1. Collecting	(a) Collecting tanks superimposed on treatment tanks, or on ground level, and fed by (1) movable hose, (2) Butters and Mein distributors.
	(b) Collecting tanks filled direct from classifiers or with solution-borne pulp from Caldecott sand-filter tables.
2. Treatment	(a) Sand dropped from superimposed collectors into treatment tanks.
	(b) Sand transferred by belt conveyor from collectors on ground level.
	(c) Sand collected and treated in the same tank from Caldecott sand-filter tables.
	(d) Sand residue trammed to dump in trucks.
	(e) Sand sent to dump by aerial bucket conveyor.
VII. Treatment of slime	(a) By circulation with pumps and decantation.
	(b) By agitation in Pachuca tanks, followed by filtration with Butters vacuum filter.
VIII. Gold precipitation	(a) On zinc shavings.
	(b) On zinc dust in Merrill presses.
IX. Smelting methods	(a) In Travener lead furnaces, with cupellation.
	(b) Direct smelting in pots.

Speaking of the introduction of the Nissen single stamp, the author says that, pound for pound of dropping weight, the Nissen stamp will crush about 30 per cent more rock per day with an increased efficiency of 35 per cent over the ordinary stamp. He sums up the distinct advantages of the single-stamp principles as follows:

1. Owing to the mortar being circular, the screen can be extended around the stamp for the greater part of the circumference of the mortar, so that it is equally distant from the stamp throughout its full length. The screen is therefore always at right angles to the direct splash of the pulp, in the most advantageous position.

2. At each blow of the stamp the pulp is forced radially against the screen, so that all particles sufficiently reduced are discharged. Owing to the mortar box being circular, each time the stamp is raised all the material in the mortar flushes to the center, to be struck by the falling stamp. It follows, therefore, that the uncrushed ore is automatically returned to the crushing zone, so that the best conditions of feed are maintained.

3. The blow being always received in the vertical axis of the box, the mortar remains rigid on its foundation. This is noticeable in the case of the Nissen stamps at the City Deep, where, after three years of use, the box is apparently as rigid on its base as on the day it was fixed in position.

4. One of the important features of the Nissen box is that it can be cast with a minimum likelihood of shrinkage strains, which are so destructive to ordinary 5-stamp mortars. The foundation bolts give no trouble, not being subject to undue strains.

5. Another advantage of the unit principle is the more continuous operation and flexibility of the entire plan, as each stamp can be put out of commission independently.

6. An interesting feature of this type of stamp is the comparatively even and flat wear of the dies, which results from the return wash of the ore to the center of the mortar with each stroke of the stamp, and from the increased number of rotations of the stamp due to wider cam and tappet faces.

With regard to tube milling, it is now generally accepted that a battery product through a screen of 0.272-in. aperture is about the economic limit of size for tube-mill feed. Beyond this limit the tube encroaches on the domain of the stamp. The proper ratio of tubes to stamps is variable, but in recent practice the tendency is to have a ratio of one 22-ft. 6-in by 5-ft. 6-in. tube to ten 2000-lb. stamps, or one tube to 200 to 250 tons per day of product of the size given above.

Referring to the development of the principle of peripheral discharge from tube mills, the author gives the following conclusions deduced from tests:

1. That when maintaining the pebble load at the center mark with feeds ranging from 250 to 400 tons per 24 hr., a 25 per cent increase in crushing efficiency could be obtained, but with proportionately increased power consumption.

2. That within certain limits of feed, the weight of the pebble load can be decreased by 25 per cent without affecting the crushing efficiency, with about a 10 per cent decrease in power consumption, the mechanical efficiency showing a corresponding increase.

3. That the wear on the crushing load is increased 300 to 400 per cent.

4. That by decreasing the effective radius of the scoop from the maximum possible (about 29 in. in a 5 ft. 6 in. mill) to the ordinary trunnion discharge, a steady decrease in crushing efficiency is accompanied by a proportionate decrease in power consumption.

Vacuum filtration is now generally conceded to be applicable where it is desired to extend a decantation plant of inadequate capacity or obsolete design; where difficulty in settlement makes it impracticable to use decantation without prohibitive extension of plant, and in all new plants.

Zinc dust precipitation has been adopted at some mines, and offers some distinct advantages over zinc shavings. The following details cover three months' operation at the Brakpan.

	Tons Precipitated (Average per Day)	Gold Content of Dwt.	Gold Content of Dwt.	KCN Content Inflow, per Cent	KCN Content Outflow, per Cent	Alkalinity (CaO) Inflow, per Cent	Alkalinity (CaO) Outflow, per Cent
Sand solution	269	3.952	0.045	0.070	0.036	0.023	0.027
Medium sand solution	769	1.548	0.056	0.017	0.009	0.0146	0.015
Slime solution	1791	1.271	0.048	0.010	0.007	0.0149	0.015

The consumption of zinc in the Merrill presses is approximately 1/10 lb. less than in boxes. At Johannesburg zinc shavings cost 4.2d. per pound and zinc dust 3.93d. ($0.084 and $0.0786 respectively). The lower cost of dust is offset by the greater strength of cyanide solutions required for good precipitation. The general opinion is that the zinc dust method is effecting economies in zinc consumption and labor and in affording a complete clean-up of gold.

Percentage extraction has increased from 60 per cent in 1890 to a maximum of 96 per cent in 1914. The cost of reduction of Rand ores ranges from $0.68 to $1.20 per ton milled. Figures for the Modderfontein B are given below:

COST OF TREATMENT AT MODDERFONTEIN B.—NOVEMBER, 1914. 42,000 TONS MILLED

	Per Ton Milled, Cents
Ore sorting and breaking	5.3
Transport from crusher station to mill bins	0.7
Stamp milling	17.5
Tube milling	12.5
Amalgamation	3.6
Cyaniding	29 0
Total	68 6

Amalgamation Tests.—A discussion of the various proposed methods for estimating the gold content of ores by amalgamation, together with a proposed standard method by the author, W. J. SHARWOOD, formed the subject of a paper at the meeting of the American Institute of Mining Engineers in San Francisco. Twenty-six published methods are reviewed and the following standard amalgamation test suggested:

Equipment Required for Systematic Amalgamation Tests

Agitator. A shaking box, stoutly built, with twenty-four or more compartments, each 3 in. square and 6 in. deep, driven from a shaft running about 250 r.p.m., giving a horizontal travel of about 2 in. The entire bottom, or each section, should be covered with heavy belting or linoleum.

Twenty-four "citrate magnesia" bottles, with spring clamps and rubber washers. These have a capacity about 350 to 370 cc.

Twenty-four Griffin beakers, capacity about 250 cc.

Two enameled-iron pans, rectangular, with straight sides, to hold twelve beakers each.

Filtering rack with twelve 2¾-in. funnels and twelve extra beakers.

Hot plate.

Glass-stoppered burette for pure mercury, standing over an enameled pan.

Robervahl scale, turning with ½ g.

Cylinder, graduated to 100, 150, and 200 cc.

Weighing scoop and steep-sided copper funnel or hopper for charging ore into bottles.

Six-inch funnel for water.

A few porcelain dishes about 3 in. diameter, and some enameled pans about 8 in. diameter and about 2 in. deep.

Filter paper, 12.5 cm., S. and S. No. 595 or similar quality.

Scorifiers, 2 in. or less in diameter; these may be used repeatedly and are best glazed before first using.

Washbottle.

Test lead.

Nitric acid, diluted with about double its volume of water.

Mercury, pure or previously assayed.

Silver foil, cut in pieces of about ½ g. each.

Routine Method for Gold Only

One hundred grams of crushed ore or tailing are weighed out, charged into a bottle by means of the metal funnel, 150 cc. of water added, then 1.5 to 2 cc. of pure mercury from a burette. The stopper is then clamped, the bottle folded in a thick piece of cloth or flannel and put into the moving "shaker" for 2 hr. It is then removed, opened, covered with the thumb, shaken and inverted over a 3-in. porcelain dish, and as much as possible of the clean mercury allowed to run out. It is then shaken again for a moment, and if necessary a little more water is added, and more mercury allowed to run out into a second dish, and so on, as long as any mercury comes out. If not floured the mercury is nearly all removed in two operations. The clean mercury thus obtained is transferred to a beaker. The bottle is again shaken well and inverted so as to let a little sand run out into the dish; this is then panned into an enamel dish. Usually only a few globules are obtained; if much is found the whole charge must be panned. If "floured" a small globule of liquid sodium amalgam should be added at this point.

To the mercury, after collecting in a 250-cc. beaker, is added ½ g. of pure silver foil. If this has been carefully prepared and cleaned by treating with cyanide solution or weak nitric acid, or by slightly amalgamating the surface, it may be used to pick up the small globules of mercury obtained in panning. About 150 cc. of nitric acid (sp. gr. 1.14 or 1.15) previously warmed to about 70 deg. C. is now poured into the beaker; all the beakers are set together in a pan, which is placed on the hot plate and left until all the mercury has dissolved. If not too hot it is unnecessary to use covers. As soon as the mercury disappears the liquid is filtered, the residue is rinsed on to the paper, washed once or twice with very dilute nitric acid (not over 5 per cent) and once with water. The paper is then sprinkled with test lead, folded, and placed in a small glazed scorifier, and covered with lead enough to make up the total to 15 or 20 g. Enough pure silver is added to insure ready parting, and 2 or 3 g. of borax glass. The scorifiers are then charged into a muffle, the paper carefully burned, the lead scorified a few minutes, poured, and cupelled. The cupel buttons are parted in porcelain cups, and the gold annealed and weighed.

A correction is subtracted for gold contained in the silver and mercury.

Using a 100-g. sample, each milligram of gold represents 0.29166 oz., or $6.03 amalgamable gold per ton.

The author suggests that if assay tons are used, each milligram indicates exactly 0.25 troy ounce, or 120.5 g./ when each milligram indicates exactly $5 per ton. The ore should be ground quite fine, 100-mesh being found suitable.

A Rule Governing Cupellation Losses.—A paper by W. J. SHARWOOD giving an empiric rule by which cupellation losses of silver or gold can be calculated and a correction applied. The rule is thus stated:

When a given amount of silver (or of gold) is cupelled with a given amount of lead, under a fixed set of conditions as to temperature, etc., the apparent loss of weight sustained by the precious metals is directly proportional to the surface of the button of fine metal remaining.

If the above is true the following also must be true:

The loss of weight varies as the 2/3 power of the weight, or as the square of the diameter of the button.

The percentage loss varies inversely as the diameter of the button, or inversely as the cube root of the weight.

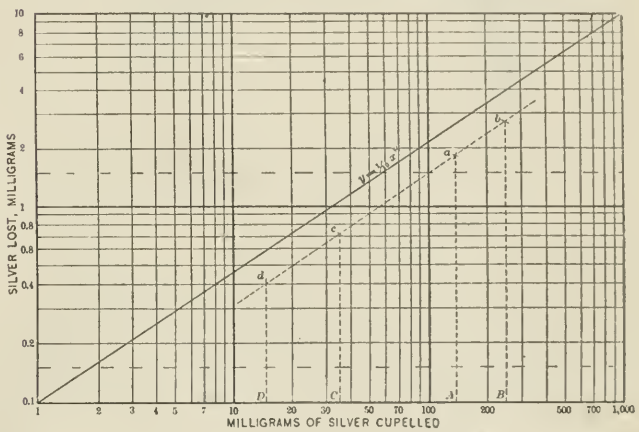


FIG. 3—CUPELLATION DIAGRAM

The author states that the examination of a large number of experimental results proves the last statement to be a close approximation to the truth, and therefore proof of the others.

"The readiest proof of the rule, which avoids all calculation, is by the aid of logarithmic paper—that is, paper on which the co-ordinates are plotted on a scale like that of a slide rule. In place of using the ruled paper the distances may be actually laid off by means of a slide-rule scale.

"As to the possible application of this rule: An approximate correction may be obtained for an ore or the like, if one proof, as near the expected weight as possible, is cupelled in each row, and its exact loss noted. The corresponding point is plotted on the diagram (*a* in Fig. 3, *A* representing the final weight), and a straightedge is placed on the diagram, or a line drawn through *a*, parallel to the guide line, $y = x^{2/3}$. Noting the points on the line or straightedge corresponding to the weights *B*, *C*, *D*, of other buttons weighed, the correction for each is read at once from the scale. In the example plotted in Fig. 3, a button of 140 mg. weight has lost 1.8 mg.; from this it appears that other buttons of 250, 35, and 15 mg. will respectively have lost about 2.85, 0.72, and 0.40 mg."

Improved Apparatus for Photomicrography of Metals

The chief characteristics of an efficient photomicrographic apparatus are rigidity, firmness, compactness, brilliant and uniform illumination, accuracy of detail in the photograph of the structure under examination, quickness and ease of manipulation.

These essentials are embodied in the improved photomicrographic apparatus, illustrated in Fig. 1 and designed and supplied by Sauveur and Boylston, Metallurgical Engineers, Cambridge, Mass.

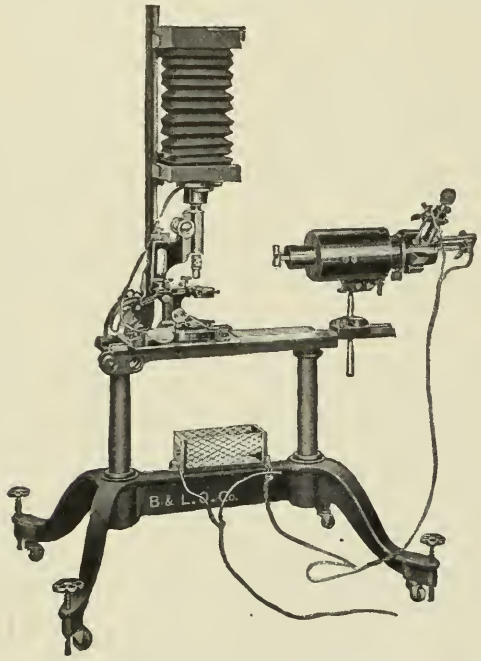

FIG. 1—STANDARD PHOTOMICROGRAPHIC APPARATUS; ABOUT 1/20 ACTUAL SIZE

Rigidity.—In many works laboratories vibrations are present from one cause or another. The different parts of the apparatus described here are rigidly clamped together so that the apparatus vibrates as a whole thus obviating the fuzzy or blurred detail so often obtained with other instruments especially at high magnifications.

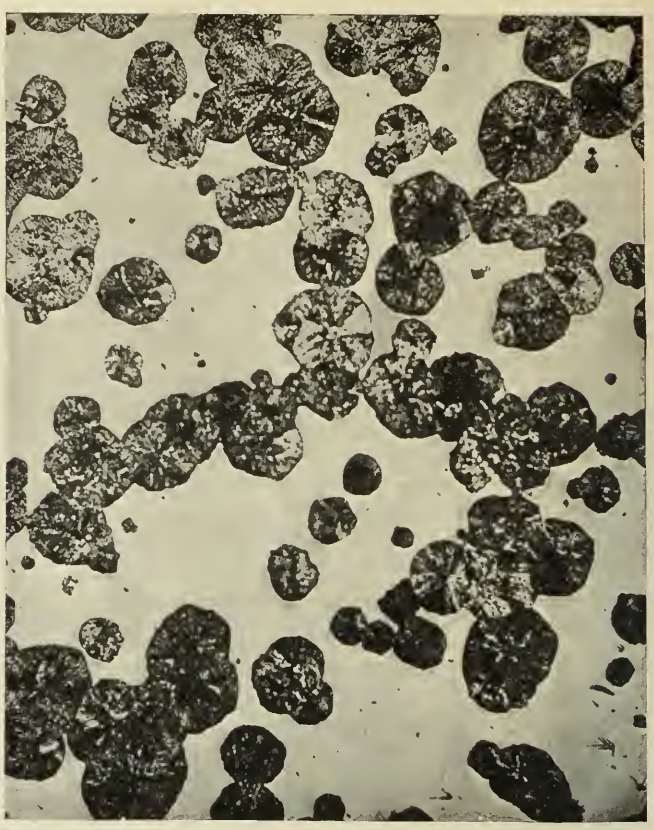

FIG. 4—MICROSTRUCTURE OF QUENCHED HIGH-CARBON STEEL (ROSETTE OF TROOSTITE ON LIGHT BACKGROUND OF MARTENSITE MAGNIFIED 150X) TAKEN WITH APPARATUS ILLUSTRATED IN FIG. 1

Firmness.—The heavy construction of all parts of this apparatus makes for firmness, which in turn means simplicity in adjustment of parts such as the microscope, camera, and arc lamp adjustments.

Compactness.—One of the chief faults of older types of instruments of this sort and of some recent types is a tendency to spread out the apparatus over a large floor space. In this instrument the carbon adjustments and those of the condenser are easily accessible to the operator who is seated in front of the microscope for visual work (see Fig. 2). When taking a photograph the operator simply rises and without moving from the spot can focus the image on the ground glass of the camera in a standing position as shown in Fig. 3. This feature will be readily appreciated by those who have worked with the less convenient or larger apparatus.

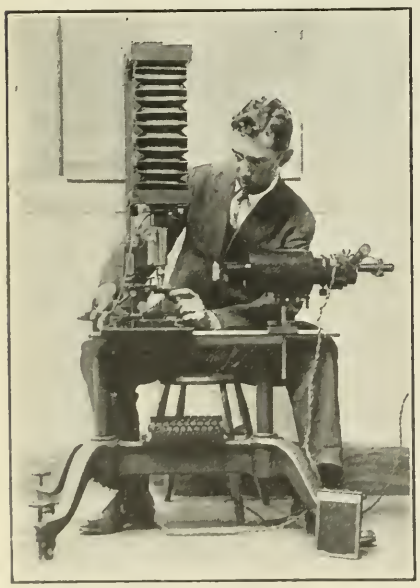

FIG. 2—PHOTOMICROGRAPHIC APPARATUS WITH OPERATOR SEATED

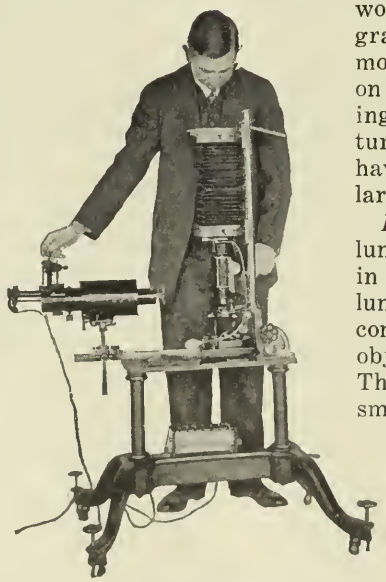

FIG. 3—PHOTOMICROGRAPHIC APPARATUS WITH OPERATOR IN POSITION FOR FOCUSING IMAGE AT CAMERA

Illumination.—Brilliant and uniform illumination of the specimen is brought about in the usual way by the use of a vertical illuminator of the plain glass reflector type in combination with long-mounted achromatic objectives of Bausch & Lomb manufacture. The source of illumination may be either a small arc lamp consuming 4.5 amp. or a 250-watt nitrogen-filled Mazda lamp of special design in light-tight lamp box with the necessary lateral and vertical adjustments for the lamp as a whole. Either lamp may be used on an ordinary house circuit.

Accuracy of Results.—Photomicrographs shown in Figs. 4 and 5 magnified 150 and 400 diameters respectively will give some indication of the accuracy

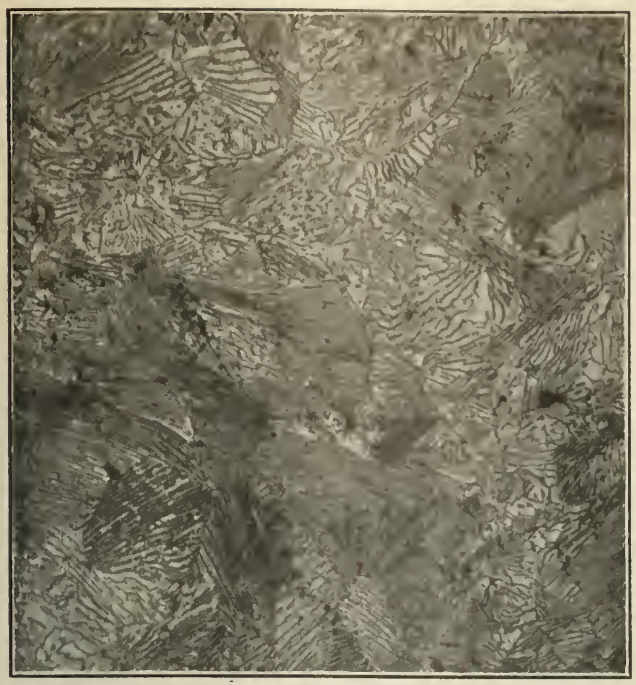

FIG. 5—MICROSTRUCTURE OF PEARLITE (MAGNIFIED 400X) TAKEN WITH APPARATUS ILLUSTRATED IN FIG. 1

of detail in the structures photographed with this apparatus. These photomicrographs were obtained with the aid of a green monochromatic ray filter regularly supplied with the apparatus together with orthochromatic plates. The use of this screen and plate in combination with achromatic objectives of great flatness of field such as are furnished with this outfit renders the use of expensive and fragile apochromatic objectives of doubtful value.

Speed of Working.—With the green ray filter, orthochromatic plates, and achromatic objectives used in connection with the 4.5 amp. arc lamp on an alternating-current circuit the photographic exposures necessary range from seven to twelve seconds at 100 diameters and from thirty to sixty seconds at 1000 diameters depending upon the contrast in the structure of the specimen. With direct current these exposures are reduced about 30 per cent while with the Mazda lamp the figures given above should be multiplied by 1½ or 2. As many as eighty photomicrographs at 100X have been taken, developed, and fixed in an eight-hour day by one operator using one of these instruments.

The Microscope.—This part of the apparatus is the same in general design as that used by Professor Sauveur as far back as 1892, but with improvements in the mechanical and optical details from time to time which have brought it up to its present standard. The microscope as now furnished includes Sauveur vertically-movable stage for coarse adjustment with the latest Bausch & Lomb lever fine adjustment and mechanical stage. An improved form of magnetic specimen holder* has bevelled edges, which allow the close approach of a high power objective to a specimen without the necessity of a templet or other auxiliary device. Specimens measuring from ⅛ in. or less in diameter up to 1 in. in diameter can be easily examined by the use of this magnetic holder, which is illustrated in Fig. 6, or by means of the bridge type of specimen holder designed by Sauveur in 1892 and illustrated also in Fig. 6. The microscope has a body tube of 1½ in. diameter, which increases its usefulness when very low power photomicrographs are being taken and the new construction of the stand gives a very long working distance between the objective and the stage. For the examination of very large specimens, such as rail sections, etc., an auxiliary tube is provided, the specimen being placed across the horseshoe base of the microscope.

The Camera.—This is generally furnished to take 5 x 7 plates or smaller, and a 4 x 5 camera can be supplied if desired. The camera is fitted with automatic shutter with Iris diaphragm.

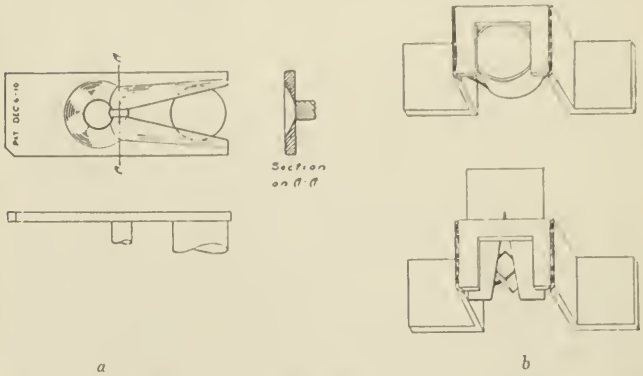

FIG. 6—*a*, MAGNETIC SPECIMEN HOLDER WITH LARGE AND SMALL SPECIMENS; *b*, NON-MAGNETIC SPECIMEN HOLDER WITH LARGE AND SMALL SPECIMENS

Range of Usefulness.—This apparatus may be used not only for the photomicrography of all kinds of metals and alloys, but also in the case of other opaque objects such as ores, rocks, concrete, slags, wood, leather, paints and varnishes, rubber, etc. The lamp may also be tilted at an angle for use with oblique illumination for opaque specimens, including core and molding sands, and with transmitted light for the examination and photomicrography of transparent sections.

The apparatus is wholly American-made and of moderate price.

*Patented Dec. 6, 1910.

Thermit Welding of Camshafts

Experience with thermit welding of camshafts at the Belmont mill, Tonapah, is given by the superintendent, A. H. Jones, in his paper read at the meeting of the A. I. M. E. at San Francisco. Two shafts were welded at the following cost per shaft:

Labor	$16.00
85 lb. thermit	21.60
Iron punchings	0.38
Wax	1.75
Gasoline (preheat)	2.80
Total	$42.53

The first shaft repaired was put into service July 1, 1914, and broke, in the weld, Aug. 8, 1914. The second was put into service Aug. 8, 1914, and broke, in the weld, on Sept. 13, 1914. These two shafts were welded at the break, necessitating their being turned down to original size, which is against the advice of the "thermit" manufacturers. On April 6, 1915, another shaft was welded from two long, discarded ends, sawed so that the weld would come in the middle box, and a boss ½ in. high and 4 in. wide left, which was taken care of in babbitting the center bearing. This shaft is still in service and may show a life really worth while. Figuring 8.88 tons per stamp day, the 30-day service from the first two shafts welded would cost about 2c. per ton of ore stamped, which, in case of breakage with no spare at hand, would be better than having ten stamps out of commission for any length of time, and therefore thermit supplies are kept on hand for this and other emergencies.

New Flotation Testing Machine

The widespread interest that has been aroused in the flotation process of concentration has created a demand for simple and efficient means of making tests on small lots of ore with different oils and oil mixtures. To meet this demand the Denver Fire Clay Company of Denver, Col., has designed the flotation testing unit illustrated in Fig. 1. Neat in appearance, compact and well constructed, it presents a marked contrast to the home-made testing apparatus with which many investigators have had to content themselves.

The Case machine consists of a single aluminium casting comprising the agitation cell and spitzkasten, mounted on a heavy board which also carries a bracket for the support of the propeller shaft and a shelf for the motor. Connection between the bottom of the spitzkasten and the agitation cell, for circulation of pulp, is made of rubber tubing which is readily removed for cleaning the apparatus. The propeller blade is made of aluminium, while the steel shaft is coated with lead in order to resist the attack of the acid that may be used in the process. The motor is a $\frac{1}{8}$-hp. Westinghouse machine operated from a 110-volt circuit at 1800 r.p.m. Variable speed of the flotation propeller is provided for by a three-speed pulley which will give approximately 1800, 1600 and 1400 r.p.m.

The entire apparatus stands about 4 ft. high and can be attached to the wall or other support convenient to a water supply. Accessory apparatus has been prepared for use with the machine, in the form of a metal hoe or scraper for removing the froth as it forms, and ground-glass-stoppered dropping bottles for measuring the quantity of oil used. The machine will prove a timely and welcome addition to the laboratory of the metallurgical investigator. A recent modification of the type shown in the illustration has only a single-speed pulley on the driving shaft and a variable-speed motor. This combination is thought to offer some advantages.

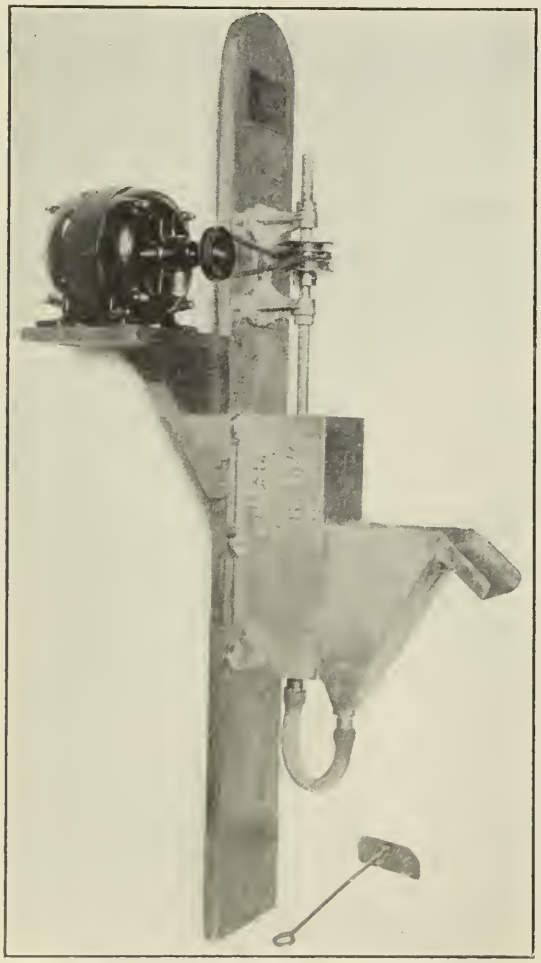

FIG. 1—FLOTATION TESTING MACHINE

Sampling Lead Bullion

The methods of sampling lead bullion at Salida, Col., and El Paso, Tex., are given in the following extracts from papers appearing in Bulletins of the A. I. M. E.

According to Mr. F. D. Weeks, an early method of sampling at Salida was to take a dip from the lead well of the furnace, but this was not satisfactory. The present management built drossing kettles in which the bullion is stirred by compressed air, skimmed into a Howard press, stirred by hand and siphoned out into bars for shipment, after sampling by dipping "gum-drops," approximately $\frac{1}{2}$ assay ton in weight. For some time the results were unsatisfactory. Although the copper had been reduced to 0.06 per cent, the bullion had a dirty appearance, and "gum-drops" of the same dip would not check with each other, especially as gold content. Consultation with men versed in the subject did not help. A remedy was finally found when the temperatures were determined by a pyrometer and the difficulties overcome by the following procedure: Take off heavy dross at 900 deg. Fahr.; blow until temperature reaches 680 deg. Fahr., skimming from time to time; raise the heat to 720 deg. Fahr. for sampling, and mold at 800 deg. Fahr. Since this method was adopted, little trouble has been encountered.

A plan to eliminate the personal equation in bullion assaying has been carried out for some years, with good results. The "gum-drops," weighing about $\frac{1}{2}$ assay ton each, are weighed without trimming, cupelled, and parted; the weights of the "gum-drops" in decimals of an assay ton, of the gold and silver together and of the gold alone, in milligrams, are reported by the assayer. The calculations are then made in the office on a machine. In this way the assayer is not tempted to make his results check, because until they are figured he does not know whether they will check or not. The excellent results obtained are sufficient reason for following the plan.

The method used at El Paso is described by H. F. Easter, as follows: Whether drossed at the blast furnace or at the remelting furnace, the bullion is sampled in the same manner, as follows: The bullion is tapped into a cast-iron cooling pot. The dross is skimmed off carefully and thoroughly. Before the final skimming the contents of the kettle are well stirred with the skimmer and the dross thereby raised is taken off completely. After skimming, the contents of the cooler are stirred again and, while the lead is still in motion, "gum-drop" samples are dipped. A few more gum-drops are taken than it is expected to make bars of lead, to insure having a gum-drop for each bar of lead. The bullion is ladled into molds, and after the pot is empty all extra gum-drops over the number of bars produced are thrown out. These gum-drops are held and delivered to the assay office whenever the bullion corresponding to them is removed.

A shipping lot consists of 780 bars (about 42 tons), and, when complete, the 780 gum-drops corresponding are placed in a graphite crucible and melted at as low a temperature as will give a homogeneous mass from which to dip the final gum-drop samples, upon which the actual assay of the lot is made. Great care is taken not to get the sample hot enough to oxidize the lead during the process.

The gum-drops, which weigh about 40 g. each, are assayed without clipping and the gold and silver calculated to an assay-ton basis.

A New Die Casting Metal

A new alloy which has recently been placed on the market under the name of "Ampco bronze" is unlike any other bronze in that it contains neither zinc, tin, lead or phosphorus. This new bronze was developed to supply the demand for a strong die-casting metal to be used in places where white metal die-castings were too weak and porous. Great difficulties have attended the attempts to form suitable die-casting copper-base alloys, as usually they melted at too high a temperature and attacked the dies when containing zinc and tin.

Ampco bronze is the result of ten years of research work, and is a 90 per cent copper-base alloy. It can be die-cast in permanent steel molds to finished dimensions and has great strength at high temperatures. This enables this metal to overcome the strains set up in the castings in the die molds while the metal is cooling and shrinking in the die.

This bronze is produced in several grades, differing slightly in composition, but considerably in physical properties. They have a range of tensile strengths of from 50,000 lb. per square inch to 100,000 lb. per square inch; elastic limit of 25,000 lb. per square inch to 45,000 lb. per square inch; elongation of 50 to 6 per cent; hardness of 70 to 280.

The metal is non-corrodible by acids, malleable, ductile, and can be forged, hammered, rolled or drawn. The tests given above are for sand castings. The forged, rolled and drawn metal has a tensile strength up to 150,000 lb. per square inch.

It is manufactured by the American Metal Products Company, Milwaukee, Wis.

Personal

Mr. **W. R. Cox** has been appointed professor of mining and metallurgy in the Oregon School of Mines, vice G. Montague Butler, resigned.

Mr. **A. C. Dart** has returned to Denver after an absence of several years and has again entered the professional field as a mining and metallurgical engineer.

Mr. **John Gross** has returned to Denver from Central America and opened his office as metallurgical engineer at 523 McPhee Building.

Mr. **P. Kranefeld** has removed from Montreal, Canada, where he was representing the Krupp concern, to Denver, Col., and will continue to specialize in crushing and grinding apparatus.

Mr. **Phillip J. Krell** will become manager of the new plant of the International Oxygen Company in the course of erection at Verona, Pa.

Mr. **J. P. Mooney**, formerly with the B. F. Goodrich Co., Akron, Ohio, has been appointed sales manager of the commercial department of the Hyatt Roller Bearing Co., Newark, N. J.

Mr. **James J. Ormsbee**, recently with the Tacoma and Hayden Smelters of the A. S. & R. Co., is spending a short time in New York.

Mr. **W. Acheson Smith**, general manager of the International Acheson Graphite Co., was elected on Nov. 2 one of the commissioners of the new commission government of Niagara Falls.

Dr. **Walter O. Snelling** of Pittsburgh, Pa., will erect an extensive laboratory in Long Island City, N. Y.

Dr. **Charles P. Steinmetz** was elected president of the common council of Schenectady, N. Y., on the socialistic ticket, on Nov. 2.

Mr. **W. R. Thurston** has been appointed manager of the Mine & Smelter Supply Co.'s Salt Lake City branch.

Mr. **Howard H. Utley** is local manager for the River Smelting & Refining Co., a new concern which is remodeling the old pyritic smelting plant at Florence, Col., to suit the requirements of proposed operations. **L. V. Emanuel** is superintendent and **George B. Clark** chemist.

Mr. **H. P. Zeller** has resigned his position as assistant superintendent of the coke plant of the Republic Iron Steel Company and has become superintendent of the new by-product plant of the Toledo Products Company.

Obituary

Abraham Van Winkle, president of the Hanson & Van Winkle Company, Newark, N. J., died on Sept. 30. He had been active in the electroplating trade for over forty years, and his untiring energy had made him a commanding figure. Born in Pompton, N. J., he was first interested in the drug business in Newark, N. J., but in 1870 went into the plating field. He was interested with Dr. Edward Weston in the first low-voltage dynamo made in this country. This dynamo was exhibited in Philadelphia in 1876. Mr. Van Winkle was also connected at one time with the Brush Electric Company, and his successes were instrumental in the forming of the U. S. Electric Lighting Company. He manifested at all times a great interest in all the affairs of the electroplating trade as well as in electrochemistry in general. His loss is keenly felt by all who knew him.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath Apparatus

(*Continued*)

225,571, March 16, 1880, Patrick Concannon of Wallingford, Conn.

Relates to a rack for holding spoons and the like which are subjected to unequal wear, the spoons being held at the points of least wear. The holding clamp is mounted on a small shaft provided with a pinion which engages a movable toothed rack to oscillate the pinion, thereby dipping first the bottom of the bowl of the spoon in the electrolyte, then the underside of the handle, these portions receiving the greater amount of wearing use. Several spoon-holders are arranged in one frame to operate simultaneously. The device may be used for replating worn spoons.

234,775, Nov. 23, 1880, Robert B. Herskell of Wallingford, Conn., assignor to Simpson, Hall, Miller & Co. of same place.

Relates to a holder to support spoons and the like to be electroplated, and which are subjected to unequal wear. On opposite sides of the plating tank are arranged two uprights which support a cross-bar between them, the height of the cross-bar being adjustable. Upon this bar are fastened brackets to hold the spoons, the latter may therefore be immersed in the plating solution to any desired depth. Upon the remaining sides of the tank are arranged shelves supporting contact plates, the spoons resting on the contact plates and

the edge of the tank and extending into the solution, the outside of the bowl of the spoon dipping slightly in the solution so as to receive a deposit over a limited area.

245,206, Aug. 2, 1881, Hans J. Müller, of New York, N. Y., assignor to himself and Alexander Levett of same place.

Relates to protecting plating baths from reversing the polarity of the field magnets of a plating machine, and refers to his prior patent, No. 241,053, dated May 3, 1881, for a dynamo, which should be consulted with this for an understanding of the invention, which consists broadly in providing an extra circuit, using a carbon cathode, through which enough current is flowing to keep the fields excited.

248,436, Oct. 18, 1881, Thomas A. Edison, of Menlo Park, N. J., assignor to the Edison Electric Light Company, of New York, N. Y.

Relates to cells for depositing copper or the like upon the joints between the carbon filament and leading-in wires of an incandescent lamp. The cell consists of a tubular shaped body having a flared opening at the bottom, to receive a rubber stopper. The stopper is perforated to receive the glass tube of the lamp-stem supporting the leading-in wires, the stem being adjustable in the perforation to bring the joint just below the surface of the electrolyte. Instead of a cell consisting of a single tube, it may be a larger vessel having a plurality of openings in its bottom to receive stoppers. In the plating operation, the leading-in wires are connected as cathode, a suitable anode or anodes being suspended in the electrolyte. The electrolyte is drawn off when the plating operation is completed.

258,214, May 23, 1882, Alexander Brinckmann, of Astoria, assignor to himself and George H. Wooster of New York, N. Y.

Relates to supporting frames for small articles like "plate-pins" used in piano-fortes, and the like, such articles being too small to be held in any of the usual clamps. The supporting frames consist of one or more sheets of metal, preferably a plurality, the sheets being secured in parallel planes by metal supports at the corners, the bottom sheet having a plurality of small irregularly shaped perforations too small for the pin to fall through and making contact at points; the upper sheets being perforated with registering holes larger than the pin, to allow circulation of the electrolyte around the pin. In use pins are inserted in the alined holes, and the frame immersed by wires or rods in the electrolyte, and connected as cathode.

297,669, April 29, 1884, Charles F. Brush of Cleveland, Ohio.

Relates to apparatus for electroplating carbons for arc lighting, etc., and refers to his prior patent No. 196,425, which relates to the advantages of electroplated carbons. The present apparatus consists of a plurality of individual depositing cells connected in series, each to receive one carbon connected as cathode, and having a tubular anode. A tube to supply compressed air is also inserted in each cell, the compressed air stirring the electrolyte. The inventor finds it necessary to connect the cells in series, using a high potential current to supply the current necessary for plating, on account of the irregularities in individual carbons, these irregularities causing uneven and irregular deposits when the carbons are connected in parallel as usual.

310,146, Dec. 30, 1884, Arthur Murphy of Taunton, Mass., assignor to himself and Charles Minchew.

Relates to baskets and the like made of glazed earthenware, etc., and having perforated sides and bottom. Attached to the bottom are a plurality of metallic buttons electrically connected to each other and to a metallic suspending hook attached to the bail or handle of the basket. The apparatus is for electroplating tacks and other small articles.

331,609, Dec. 1, 1885, Herman R. Boissier of New York, N. Y.

Relates to methods of connecting the electroplating tanks to a dynamo. With a series dynamo, a small quantity of work in the plating bath does not permit enough current to pass to supply the field magnets, consequently the plating operation is exceedingly slow. The inventor provides an extra tank connected across the brushes of the dynamo, the extra tank containing an anode and cathode, and may be used for quick work; when not thus used it serves to produce electrolyte by the solution of the anode. The field magnet coils are provided with several shunts which may be used to vary the current flowing through the fields when the principal plating tank is filled with work.

369,457, Sept. 6, 1887, Morris H. Levett of New York, N. Y., assignor of one-third to Louis Levett.

Relates to electroplating tanks, and is for a folding removable inner cell made of fabric supported by wire mesh sides and bottom. The fabric cell is so made that its sides may be folded inward and entirely cover the bottom. In use, a plating tank accumulates a lot of scum and sediment, which renders the solution turbid. This sediment settles on the fabric bottom; the fabric sides are then folded down to inclose it, the fabric cell then lifted from the tank and cleaned. The inner cell thus serves to maintain a clean electrolyte.

Book Reviews

The Analysis of Non-Ferrous Alloys. By **F. Ibbotson** and **L. Aitchison.** Octavo, 230 pages, 19 illus. Price, $2.25. London and New York: Longmans, Green & Company.

This is intended for laboratory instruction as well as for use by the works' chemist. It is admirably adapted for both purposes, being keenly analytical in its method of presentation, explaining clearly the *why* and *wherefore* and the scientific basis for the methods described. It is up to date, as seen by it describing the analysis of the new high-speed tool alloy "stellite." It is, however, limited to the determination of lead, copper, bismuth, antimony, tin, arsenic, aluminium, chromium, nickel, cobalt, manganese (iron) and zinc. The other non-ferrous metals and non-metals occurring in alloys (such as cerium, silicon, phosphorus, titanium, molybdenum, etc.) are not considered. Within the limits treated it is a most admirable book.

Principles of Physical Chemistry.—By **Edward W. Washburn.** Octavo, 445 pages, 61 illustrations. Price $3.50. New York: McGraw-Hill Book Company, Inc.

The sub-title states that the treatment is from the standpoint of modern atomistics and thermodynamics, and that it is intended for students intending to enter physics or chemistry as a profession. It is not a laboratory manual, but a thorough discussion based on first principles, most admirably planned and very skillfully executed. The mastery of the author over every phase and topic is in evidence throughout the book, giving to the reader a sense of confidence in the information and lending a charm to the reading which is as refreshing as it is unusual. The book pre-supposes a knowledge of general chemistry and physics, and in mathematics the elements of differential and integral calculus. Anyone with this equipment will find this book probably the best help he can get in print to a thorough acquaintance with and a working knowledge of the principles of physical chemistry.

Alumina in Steel

The article by Mr. G. F. Comstock in our issue of December 1 has apparently a bearing on the problem of steel failures. It seems to be recognized that many failures are caused by the inclusion and segregation of non-metallic impurities. These have been clearly shown by metallographic examination and it has been a general custom to designate them as "slag" inclusions. By some it has been maintained that many so-called "slag" inclusions are really alumina derived from the oxidation of aluminium additions to the steel during the process of manufacture and that these alumina particles show a particularly objectionable tendency to segregate. This, however, could only be regarded as an hypothesis unless some trustworthy method for detecting and distinguishing these as alumina could be devised. Mr. Comstock's paper apparently shows that this can be done and paves the way for reasonable discussion.

The brief letter by Mr. F. A. J. FitzGerald, which we publish in the present issue with respect to Mr. Comstock's article, is refreshing in its frankness and a particularly interesting illustration of what metallographic examinations can reveal.

Lake Superior Iron Ore Prices

An annual event of no little importance in the iron trade occurred on Dec. 8, Lake Superior iron ore prices for the season of 1916 being announced by the merchant ore interests. The prices named represent, broadly speaking, an advance of 75 cents a ton from the schedule that obtained for the 1915 season, that schedule being practically identical with the schedules obtaining in 1912 and 1914, and the lowest since 1904. The 1916 prices are about 50 cents a ton under the schedule ruling in 1907 and 1910, the highest since 1900. The new prices are: Old range Bessemer, $4.45; old range non-Bessemer, $3.70; Mesaba Bessemer, $4.20; Mesaba non-Bessemer, $3.55, per gross ton, on Lake Erie docks.

Unlike contracts in many branches of the finished steel trade, iron ore contracts are rigidly adhered to. The tonnage sold must be taken. A unique feature of the trade is that instead of payment being made according to delivery the payments are in twelve equal monthly installments, May 1 to April 1, whereas the deliveries, being subject to lake navigation, are chiefly from May 1 to Dec. 1. An interesting feature of the ore contract is that the buyer is given a guaranty that the seller will not sell others at a lower price. Nominally, this is a protection merely given the buyer; practically, it is a safeguard the seller throws around himself.

Improved practice at blast furnaces in recent years in the use of the dusty ores of the Mesaba range is

shown in the decreased price differential between Mesaba and old range ores of non-Bessemer grade. The differential is now well established at 15 cents. From 1905 to 1911 the differential was 20 cents, while in 1902 and 1903 it had been 40 cents. In previous years the differential was apparently less, but in actual fact the dustier Mesaba ores then had no vogue at all. The present 15-cent differential comes about from the desire of the old range producers, not the Mesaba producers. It is not that the Mesaba producer desires to keep his price up, but that the old range producer desires to hold his down, as otherwise he would suffer in the competition by not finding a broad enough market for his product.

High-Grade Spelter "Not Quite So Valuable as Diamonds"

The war has affected all metals and chemicals to a greater or less degree, but one metal indeed erratically. That is the "unusual" metal zinc. The impelling cause lies in the vast amount of spelter used for cartridges both for artillery and small-arms in form of a brass of a mixture 70 per cent copper and 30 per cent zinc suitable for rolling into strips or "discs." The constituent metals of this alloy must have and give peculiar physical and chemical properties, or otherwise cracks, seams and splits occur in the "flowing" and drawing of the metal. Any lack of homogeneity or ductility causes defects. Oxides, sulphides or an excess of lead are specific malignant impurities, although care in casting, rolling and annealing will lessen their effect. A certain number of "rejects" will be made and the cost of manufacture increased. What grade of spelter to use depends largely on the difference in prices, although small-arms cartridges are practically all made from 99.90 per cent spelter. For such class of work as condenser tubes, etc., high-grade spelter is also needed.

For years the production of high-grade spelter has been in the hands of the New Jersey Zinc Co., one of the aristocrats of the metallurgical world, but the "spread" between high-grade and "Prime Western" spelter is so great that several new producers have entered the field for small lots of high-grade which has sold as high as 52 cents, while even now the market is from 30 to 35 cents. The electrolytic zinc works, chief of which are those at Trail and Anaconda, are making a zinc of high purity. The American Zinc Lead and Smelting Co. and the Grasselli Chemical Co. are both producers of spelter analyzing over 99.85 per cent zinc and cadmium. There are others producing a strictly intermediate or 99.75 per cent. The "American" standard "high-grade" calls for 99.90 per cent, Fe 0.03 per cent, Pb 0.07 per cent, Cd trace. Metal like this is produced by the American Smelting and Refining Co. at its Pueblo plant, and by the American Spelter Corporation with works at Kusa, Okla., the latter company being sponsored by Messrs. J. L. de Saulles and G. M. Heckscher.

Whether or not such metal, though made by a process once used at Bertha, will prove equal to Bertha or Horse Head is open for debate. We are inclined to think that though it is an excellent substitute it will not surpass it, especially for the finest galvanizing. We judge this to be due to what might be termed "geologic individuality." The elements often behave as though they varied with the locality. Arsenious oxide when dissolved in the solvent and precipitated as Paris green, will give under the same conditions products of different properties when from different mines. Fake copper, certain steels, also show evidence of "geologic individuality of the atom," although sometimes the difference comes from minute impurities. Of course, in the case of spelter rare elements like gallium and indium may account for the difference, but "we hae ours doots." However that may be, the pure race of high-grade zinc commands a premium. Saith the buyer to the zinc salesman, "You are trying to sell me something not quite so valuable as diamonds."

How the Steel Market Is Made

Not since 1899 have finished-steel prices displayed such a strongly advancing tendency. The movement of that year cannot be regarded as a precedent or as an illustration, extreme or otherwise, of a market movement in the steel trade, for the steel industry was just finding itself. The period of industrial depression which according to common standards embraced the five years 1893 to 1898 inclusive may be said to have begun earlier in the case of the iron industry, for the pig-iron output of 1890 was not equalled in immediately following years, and during 1890 there was a rapid and extensive fall in pig-iron prices with no substantial recovery in immediately following years. Assuming then that in the iron industry at large the depression began in 1890, the industry entered the depression with wrought iron the dominant product and emerged from it with mild steel as the dominant product. During the depression the change from wrought iron to steel was effected. Some manufacturers, the Carnegie interest being a prominent example, were able to finance the change from wrought iron to mild steel. Others were not. Their plants became effete and dropped out of the reckoning. When demand for the wrought product reached normal, or perhaps slighting supernormal, proportions, the capacity was not available and a veritable boom in prices resulted. General industrial and financial conditions such as obtained in 1899 might recur at any time, but the conditions then existing in the steel industry could not recur, for the steel industry was then for the first time finding its place.

There have been many movements in the steel market since 1899, major movements of which this is the fifth. It is interesting to analyze the conditions that have developed in these movements and attempt to trace the reactions that produced the conditions. In such a study one finds reactions that suggest the catalytic agents as often active in chemical reactions.

Demand and supply are elements in trade which produce reactions, not as chemical elements do through chemical affinity, but through one or the other preponderating. If demand exceeds supply, prices tend to rise. The physical conditions obtaining in the manufacture, distribution and use of steel products are such

that in most finished-steel products it is the jobber or manufacturing consumer who carries the stocks, not the producer. The course of the steel market from year to year has often been strongly suggestive of an underlying trade law, that the carrying of stocks by the producer tends to stabilize prices while the carrying of stocks by the buyer tends to promote fluctuations. One must distinguish between actual ultimate consumptive demand and market demand. The period of prosperity which began early in 1901 and quietly disappeared in 1903 was one of strong consumptive demand. The period extending from late in 1904 to late in 1907 was a similar one, but with the prosperity still more marked. In each case the increase in actual consumptive demand was so marked as to lead to the addition of much productive capacity.

The next two steel-market movements, centering in 1909 and 1912 respectively, were different in extent from their two predecessors, but they were different also in character, in that the demand which causes prices to advance, by being in excess of the offerings, was a market demand not based wholly upon an increased consumptive demand. In each case the inception of the movement found stocks of steel in the hands of jobbers and manufacturing consumers at an extremely low ebb, while later on at the point at which the shipments of mills began to decrease these stocks were much larger, the result of the demand having been partly a market demand and not wholly a consumptive demand. The market demand was created by the fact that prices advanced from time to time and buyers were allowed to place contracts for specification and shipment in future periods. Such contracts would prove profitable to buyers as long as prices should advance.

The extremely heavy consumptive demand in 1905, 1906 and a large part of 1907 prompted the addition of much new productive capacity, and the almost complete collapse in demand that occurred late in 1907 found the steel industry not only with a large capacity, but with much new construction work in progress. Realization of the condition gave the industry a chill from which it did not recover for years, if indeed it is fully recovered even now. New construction has been undertaken with relative timidity since 1907. The market movements of 1909 and 1912 did not produce great waves of new construction. To-day the steel industry finds itself with a smaller increase in capacity over that in existence in 1907 or definitely under construction, than has occurred in any corresponding period in the past.

Given a restoration, or even partial restoration of normal consumptive demand, in keeping with the growth of the country, and an adventitious demand for steel for war purposes abroad, to the extent of a very few million tons a year, the steel industry was at the beginning of this year ripe for another major market movement. The extreme tightness of money late in 1914, coupled with an industrial depression and a continued decline in steel prices, produced the condition that stocks of steel in the hands of jobbers and manufacturing consumers were, in proportion to the size of the steel industry, easily the smallest on record. Conditions were precisely ripe for a market movement, and one based not necessarily upon greatly increased consumptive demand, for the market demand would of itself do much toward carrying a movement along. The steel mills evidently recognized the fact that a market demand could be developed. In several products they followed the policy of naming one price for material if specified once, and another price a dollar a ton higher on a contract that would permit specifying in some later period. For several months the market carried itself along nicely, with this market demand as the chief foundation. Gradually the "war orders" were found to constitute an important tonnage, and actual consumption at home began to increase. Important freight-car orders were placed in May, after many months of practically no railroad buying.

To make a long story short, with increased exports, increased domestic consumption, and a strong market demand due to jobbers and manufacturing consumers being willing to contract ahead, and also if necessary store material in their warehouses, the steel mills eventually found themselves crowded with work.

In analyzing the present condition itself, and the conduct of the market in the past two months, one discovers evidences of catalytic influences already referred to. They do not directly increase or decrease the consumptive demand for steel, or the productive capacity by a single ton, but they affect profoundly the flux of the market. The first is the legal situation, and the mental attitude of sellers of steel, produced by the suit of the government against the United States Steel Corporation, settled in the United States District Court June 3, 1915. The suit developed the fact that sellers of steel should not agree upon market policies. Previously their minds had met at times in an effort to prevent prices from falling, and they had also met at other times to prevent the market's own advancing tendency from carrying prices to a level that might later prove unsafe. The circumstances of the steel suit indicated that such policies ought not to be followed in future and the mental attitude of the steel trade became that it would be just as well, or better, to allow prices to advance as much as they would.

The second catalytic action was the war, and the effects it has produced in trade generally. Spectacular advances have occurred in various commodities. Some of the non-ferrous metals, and many chemicals, are selling at multiples of their former prices. Men's minds are open. Unprecedented advances are regarded as distinct possibilities when everything is so upset. Buyers give countenance to price advances that would be looked askance under normal world conditions.

The catalytic influence of these two elements is beyond question very important in the reactions that are making the steel market. The developments to date are remarkable, and no one knows how much may still occur. From the lowest level since the fore part of 1899 steel prices have risen in a twelvemonth to the highest level since 1907, and yet the prices used for comparison are practically nominal, for the mills accept but a small part of the tonnage offered them.

What Metallography Can Show

To the Editor of Metallurgical & Chemical Engineering:

SIR:—An incident in the course of the work reported by Mr. Comstock in his article on "Alumina in Steel" in your issue of Dec. 1 may be of interest as showing the trustworthiness of the conclusions drawn from his micrographic investigations.

The 10-lb. steel ingots used for confirmatory tests were made at the FitzGerald Laboratories by melting the special steel, mentioned by Mr. Comstock, in crucibles made from 6-in. Acheson graphite electrodes and lined with electrically sintered magnesia prepared by the Norton Company. The crucibles were heated in an electric furnace of the kind illustrated in *Electrochemical and Metallurgical Industry*, Vol. III, page 56, Fig. 6, and a new crucible used for every heat unless the melt poured so as to leave the crucible perfectly clean, free from any skull or slag sticking to the lining.

In preparing the ingots treated respectively with aluminium and titanium three heats were made. Of these the first and third were with additions of 0.2 per cent of aluminium, the second with 0.2 per cent titanium in the form of ferro-carbon titanium, but in marking the ingots the sample from the second heat was labeled "No. 3 Titanium," while that from the third was marked "No. 2 Aluminium."

Now in all the experiments the same crucible was used, for the metal poured so cleanly that in no case was an appreciable residue left in the crucible. However, a few days after the sample ingots had been sent to Mr. Comstock an inquiry was received as to whether Sample 2 had not been made *after* Sample 3 and the same crucible used in both cases, because in addition to the alumina found in Sample 2 a small quantity of titanium nitride was detected in the metal, and this was the only hypothesis to explain its presence.

"While You Learn from Mistakes, Make Your Mistakes on a Small Scale"

To the Editor of Metallurgical & Chemical Engineering:

SIR:—In your issue of Nov. 15 I note an editorial entitled "Make Your Mistakes on a Small Scale." The following anecdote illustrating the wisdom of your editorial may interest your readers. It was told me by an old Jew, well versed in the Talmud and in Hebrew lore.

A certain nobleman in Hamburg, Germany, who had inherited title and wealth and had spent his time in the manner of the idle rich, determined quite late in life to speculate on the Hamburg Exchange. His ventures all went wrong. One morning on the floor of the Exchange, he accosted Mr. Moses, an old successful Jewish speculator. "Mr. Moses," he said, "Why is it that in the year I have been a member of this Exchange I have lost money on everything I have touched, and you seem to be making it? It does not seem to me that I am so much less intelligent than you are. Will you not tell me the secret of your success?"

"Oh, yes," said Mr. Moses, "I will be glad to tell you what I think is the reason. When I was a youngster of 13 years of age my father told me that he could not afford to send me to school any longer, and that I must make my own living. He sent me away from the little village where we lived with one dollar, and said, 'My boy, go out and see whether you cannot make a little money with this dollar.' I left the village and passed an old woman, leaning on the gate of a farm, and I asked her whether she did not have something to sell. She said that she had an old copper kettle for sale. Before purchasing it I went and inquired the price of copper from a junk man and returned to the old woman and asked her to weigh the copper kettle. She did so and I figured that I could make a little money according to the market price of copper and bought the kettle. When I came to sell it, the junk man, to my consternation, would not pay me the price I expected. His reason was a very good one; the copper kettle had a wooden handle, which I had not noticed. I returned to my father in tears, and he consoled me and gave me another dollar. I again went out and purchased a hide. When I came to sell the hide I could not get the price expected, because the hide had no tail, and those special hides without the tail did not command the full price, and again I returned to my father in tears. In this way I paid for my apprenticeship when I was very young *and in small amounts*. I buy no more copper kettles with wooden handles, nor hides without tails."

Thus spake Mr. Moses and walked away, leaving Mr. Nobleman to reflect on the aptness of the story.

L. HEYNEMANN.

Efficiency of Preparedness in Business

To the Editor of Metallurgical & Chemical Engineering:

SIR:—I was much interested to read the editorial in your issue of Nov. 15 on the process of inception in invention.

A month ago I spoke before the Efficiency Society in New York on the inception of business and engineering ideas in a lecture on "Efficiency of Preparedness in Business." This lecture, which follows, may be of interest to your readers.

The fact that a thing works proves that it is effective, but it may be far from efficient. The difficulty in measuring efficiency in preparedness increases steadily as we work back from performance and production to forecast and vision. I leave to others more competent the subject of economic laws governing all business ventures, and confine myself to inceptions not ruled out on this score.

Preparedness is a large topic, but to most business men it has a very limited significance. To some it means merely the enlargement of export business; to others a more or less organized readiness to take advantage of new opportunities at home; still others regard it as a call to greater efficiency in the tasks already in hand and in statistical analyses to that end. Some think of it as chiefly concerning campaigns of advertising, sales and distribution, and the anticipation of needs and styles, while others are wholly engrossed in producing commodities, and what they have not heard in the last few years about their shortcomings would hardly be worth listening to. The fact is that efficient preparedness is demanded nowadays at every stage in business, if we are to lead in the procession. It must be in evidence from the earliest thought regarding a promising idea or a generalization of value down to the elaborate formulation of specific plans to realize these ideas and to a host of precautions for launching them safely on the sea of experience and ensuring a successful voyage.

The efficient conducting of present business in its

many aspects is the matter upon which the Efficiency Society exercises most of its thought, but "preparedness" is essentially concerned with things more or less indefinite which are yet to arrive. I will, therefore, avoid covering the well-traveled road of "the art of getting things done," and dwell upon the qualities demanded for business "preparedness" in three relations, viz., *inception, organization* and *operation.*

I know of just three ways for attaining wisdom, and thereby efficiency and preparedness on anything, whether it be business or baseball, motors or morals. These are *thinking, imitation* and *experience.* Thinking is the finest way, imitation is the easiest way, and experience the most difficult way.

A preparedness attained solely by experience is apt to be laborious and long delayed. Reached by imitation alone it adds to our experience, but fails to develop self-reliance; whereas a wise provision attained by a well-disciplined mind concentrating on a problem is the best of all, for it is the earnest of more successes of the same kind.

Efficient preparedness in business is the result of the interplay of these three factors combined with the industry necessary to intensify them. Such preparedness, however, in the matter of inceptions cannot be always measured by the result of the project for many other elements enter into performance and enhance or nullify the original conception. It is for this reason that good ideas poorly supported are apt to be overlooked and that efficient support of a poor scheme is so often a thankless task. Proprietors are too little given to analyses of their failures, and bookkeeping rarely explains anything about poor inceptions.

INCEPTIONS

Consider first the nature of the mental processes that lead to the initiative and originality characteristic of preparedness. The thorough co-operation of the three wisdom factors I have named and the quality of the minds engaged are the sole factors conditioning the birth of new business ideas. Mental grasp and imaginative power exercised upon the real facts of the problem are paramount here.

Obviously if the inception of a policy or plan is insufficient, inaccurate, and, therefore, inefficient, it matters little what may be done later by good organization and operation to support it. The best thing that can happen to the many inefficient inceptions is that they should never see the light or that they should be submitted to the test of intelligent and fearless criticism.

Unforunately many of them reach the rank and file in business with executive indorsement, if not also with executive origination, and are *not* open to challenge. Thereby hang not a few sad tales about rainbow chasing. Actual business occurrences show that lack of thought, lack of imitation and observation, and lack of knowledge of scientific and industrial principles are to be found in men who have inceptions of the highest importance in their control. Good business is the art of selecting probabilities and poor business is the result of taking chances on possibilities merely.

Sound concepts, visions, forecasts of coming events or needs, or estimates of conditions by leaders in finance, commerce and industry are fundamentals in business preparedness, and in my experience those concerns have been most successful and stable where the fewest things, external or internal, "just happened." Lack of preparedness is always rooted in lack of provision or inaccurate estimates, and we do not know how many bad guesses at the future are made on the average by our professional forecasters or the men at the masthead of business. One authority says 10 per cent is the minimum, and that 30 per cent more just escape failure. It is quite certain, however, that in our modern civilization, with its international business relations, acquaintance with other people and their conditions, is not widespread, and planning, preparedness and clear thinking are none too prominent. The gambler's chance in this land of promise and of quick recoveries is all too common, but its days are numbered.

We need in both our home and foreign business outlooks more statesman-like qualities, for we are destined, if we accept the nomination, to lead the world's markets. We are at present the great creditor nation; whether we shall remain so depends upon a strict attention to preparedness not yet in evidence. It is very important, therefore, to start right with the elementary ideas of projects, and many of our business inceptions fail right here, though, unfortunately, the failure is sometimes concealed from the onlooker until capital has been irretrievably wasted upon the project, and then various more obvious but secondary reasons are advanced for the collapse.

There have been no more striking instances of this than in the adventures of some of our own men of finance in the realm of industry. Their failure and surprise at being unable to juggle with matter and men after the skillful fashion of the world of figures and speculation has been instructive. Again and again financiers of the keenest intelligence and success in their own special spheres have been fooled, not through the operation of the law of average but by inceptions and projects inherently uneconomical and needing no wizard to discover this. For any efficient preparedness in such cases we look in vain. Apparently they could not resist the attractive terms either offered or possibly conceded for their capital and they swallowed the bait whole, with the reservation that any resulting burdens could be fastened on the backs of others. The first element in efficient business preparedness is to start right, trusting to no adventitious aid from capital or influence to attain that for which we have not laid secure foundations.

In the matter of the inception of great business ideas the lack of the trained mind in the adult is almost beyond remedy. But even trained minds will fail here if they lack imagination. So far as my experience goes, nearly every good idea in business, embodied finally in a project, arose from trained minds carrying thought past all verified phenomena and experiences into the realm of intuition. In other words, the step attained by what is really the scientific use of the imagination was a step beyond the last solid ground. Imagination played with and around ideas and ultimately flamed into consciousness of that which was yet to be proved. All the great originators testify to this, and our ordinary minds operate in the same way. It was thus that Newton took the stupendous leap from a falling apple to a falling moon, and it is a true saying that "science only gives us *hints* of what by a higher method we come to know."

But with our imagination among the stars, our feet must be firmly planted on the ground, for we are not dreaming here; we are consciously cerebrating, and so long as we think correctly we must think of things as they *are.* The state of mind within us must correspond to the state of things without us whenever a call comes for comparing them. Some people are intellectually dishonest, and in inceptions decline to see what they do not want to see. It is as if a man relished cheating himself at solitaire. In all preparedness, therefore, a passion for facts should rule and we should be willing to go far afield to get all relevant experiences. The mind also should be a nimble one for immediate

decisions may be demanded. But given a clear, clean, intellectual start the originator of business and industrial ideas should launch out boldly in mental speculation; open-minded, struggling against preconceptions of ideas and of people; ready to correct imperfect estimates of things and of character, and to welcome any new truth when it has proved its title, despite its impact upon cherished beliefs.

Such thinking and brooding over facts, always fortified by personal experience, keen observation and resourcefulness, is the secret of power and of efficiency in business preparedness. It gives a man the ability to acquire, to marshall, to master ideas and to forge from them a weapon to conquer men, or commerce, or adverse circumstance. Such subjects as the search for new markets, the stimulation of old ones, new products, improved merchandise, reduction of the present huge cost of distribution and selling, the influence of tariffs, the present trend of these in our own and foreign countries, the demands of the export customer, his banking needs, not to speak of the purely internal problems of a business, these and a score of others should keep our inception departments working overtime at this momentous epoch in our commercial career when the shrewdest analysis is necessary to forecast the economic result to each business of the present waste of men and capital abroad.

I have devoted most time to inceptions, to the preparedness which sets to work, for fruitful ideas, the right quality of mind, with the appropriate experience, upon the external and internal problems of the near and distant future of a business. This is not arm-chair work by any means. It may and often does call for travel and contact with all sorts and conditions of men. A few of our great corporations with international connections are highly efficient in their preparedness, but the average American concern does little to develop preparedness for foreign opportunities. Fortunately, our Department of Commerce is steadily increasing its consular service in this particular and improving its methods of circulating information, but the benefits will not be reaped by our commerce until we go after this trade in earnest and take great preliminary pains.

ORGANIZATION

I will deal very briefly with preparedness in the later stages of business. What is the next stage in order of importance? System says one; capital says another; credits say others, and so forth. The second essential in my opinion is efficient *organization*. Here again the triple discipline of thinking, imitation, experience, must be brought to bear upon the issue. One of Kipling's characters explains the failure of a cherished project by saying, "Now I saw so clearly what things needed to be done that I forgot that things are only accomplished by means of *men*." He was a big man himself but he had failed to organize.

In these days organization is receiving much attention. It can never get too much, but I think a word of caution is needed. That organization is not necessarily best considered that is represented by the most imposing chart. It is quality not quantity that counts for most in the executive circle, and the wise selection of the brains of a business is all-important. Not only so, but the task is not done once for all. I do not mean by this that fussy interference every few months with a stabilized staff is desirable—that is simply evidence of incompetence higher up. But men change, or fail to develop; their characters deteriorate or we make a mistake in our early choice. Hence for preparedness we must revise from time to time our selections of the human factors in business, and always with the sincere desire to take the square man out of the round hole and put him where he fits.

Preparedness calls for truer discrimination of suitability than at present and, at the initial stages, more use of the science of character-reading and of the psychology and physiology of business aptitudes in which notable progress has been made in the past five years. The employment department is coming into its own. Under competent administration it is no longer a mere laborer's registry. It classifies aptitudes competently, and even the higher salaried men are no longer engaged upon chance impressions of their personalities.

OPERATION

I close with a few words on preparedness in the operating departments of business, which present the largest field. The new leaven which has been fermenting in business in the last ten years has worked chiefly in industry. Management has been struggling from an art toward a science, and, while I do not think it has attained that goal, the machinery of management, namely, system, has been evolving rapidly. Whether too rapidly or too completely we will not inquire here. The question before us is what is the essence of preparedness in the operating department; in its mills and plants and stores; in sales and distribution of products and in the office, clerical and recording functions of all of these?

The new element in preparedness is the use of the "scientific method" in attacking problems. The scientific method, however, is not any particular system nor is it a tool that you can keep handy on the shelf for occasional use only. It is as old as Socrates and the dawn of science, but in its conscious application to business it is as new as to-day. It is essentially an attitude of the mind which influences our business conduct, plans and decisions, and causes us habitually to observe, describe, analyze and classify with accuracy the phenomena which recur in our daily round.

The result is that we apply these analyses and experiences to regulate later affairs and shape all our records so that they are interpretive and constructive. At the same time all this is confined solely to the problems where it is *economically justified*. Many men of outstanding ability in inception do all of these analyses by mind and memory, but in the operating departments we need store houses for facts and conveyors for our decisions, and the real question of system economy is, What kind and how many? It is the possession of adequate discrimination in this matter that distinguishes the mere statistician from the efficiency business planner and forecaster.

Finally let me refer to the great importance of preparedness in labor management. Do not attend to all else and give the human problem "absent treatment." More and more society in this favored land is becoming just "all-of-us," and the capitalist or executive who does not want to belong is quite unfitted for the new industrial age. When times are tranquil and relations are harmonious, get acquainted with your people and let them become acquainted with you. Let trust and confidence be sown and you will not reap distrust and suspicion. Do not let the sowers of good-will be accompanied by a brass band or attempt to hasten the capitulation of the doubter by paternalistic policies which he cannot appreciate. Some one in all our large plants and organizations should be charged with this sort of preparedness; the sensing of the inarticulate but none the less real misconceptions—often grotesque—grievances and trivial grudges which, massed in time in narrow minds, are formidable obstacles to progress. Every business must meet the impact of troubles of outside

as well as inside origin but, if you know your people and they know you, you will not have to wake up in surprise and chagrin at the number of things you felt comfortably sure of, which turn out to be *not so*.

Here, then, is the conclusion of the whole matter of business preparedness. It is simply the concentration on the inceptions in every department of the best minds we have and the provision for systematically widening and recording experience. Behind every method, every practice, every custom in business and society alike lies an idea or group of ideas—a theory—a reason. Hence, the only practical things in life are ideas; the only *practical* man, the man of ideas, the man who *knows*, not merely the man who *does*. Behind our individual practice, whether we are conscious of it or not, lies the theory and only he who knows it possesses the rule of the higher practice and can take the next step wisely.

It is thus, on the last analysis, to the man of sound theory and of efficient mentality we must ever look for preparedness at its best, for better ways of doing the world's work, for progress and efficiency.

JOHN CALDER.

Lexington, Mass.

Perkin Medal Award to Dr. Baekeland

The Perkin Medal Committee, consisting of representatives of the different chemical societies of this country, has awarded the Perkin medal for 1916 to Dr. L. H. Baekeland.

According to established custom the presentation of the Perkin medal to Dr. Baekeland will be made at the January meeting of the Society of Chemical Industry in joint session with the American Chemical Society and the American Electrochemical Society.

The University and the Chemical Industry

Mass. Tech. Night at Meeting of New York Section of American Chemical Society

At the meeting of the New York Section of the American Chemical Society on Friday, Dec. 10, in joint session with the American Electrochemical Society and the Society of Chemical Industry, the symposium on "The Universities and the Chemical Industry" was continued. This was Mass. Tech. night, while for the preceding meeting (see our issue of Dec. 1, p. 885) Columbia University had provided the speakers, and in his introductory remarks the chairman, Dr. **T. B. Wagner,** stated that in a third meeting later in the season representatives of the chemical industry would have the floor.

President **Richard C. Maclaurin** of the Massachusetts Institute of Technology was the first speaker. The Massachusetts Institute is a university in everything but name. The industries of this country will never rise to what they ought to be until they become imbued with the spirit of the university, the scientific spirit. On the other hand, the universities will never rise to their true level until they become permeated with the spirit of industries. The growth of the chemical industries is reflected by the fact that at Mass. Tech. the study of chemistry has grown threefold in the last decade; to-day one-fifth of its total student body, or 350 students, take courses in chemistry or electrochemistry.

The function of the university is to help to organize industries on a scientific basis. Three essentials the university can give to the student: a knowledge of fundamentals in science, an appreciation of the methods of science and their application to industry, and the spirit of science, the spirit of research.

The real question is: Are the universities doing enough? They are limited by the available funds. The salaries of the professors should be raised—if only to one-tenth of what they might expect to earn in the practice of their professions. To attract better students to the study of chemistry the prevalent opinion that chemists are poorly paid must be overcome. The professors should be in closer contact with the industries; in this respect we should take a leaf out of Germany's book. The professor of pure chemistry must not be overlooked. The problem of America is to organize all available knowledge. A lot is stored up in the professors of pure chemistry, and even in textbooks. Perhaps our greatest problem is not so much to break new ground, but to make use of what we have. Germany became rich in peace by believing in the obvious, by having faith in the obvious. This America has still to learn, to believe in the organization of science for the industry. The universities want to help. They are imbued with the desire of rendering service, if only the industries will say what they want.

Dr. **Henry P. Talbot,** professor of inorganic chemistry at Mass. Tech. was the next speaker. The Carnegie Foundations for the Advancement of Teaching has recently undertaken an exhaustive study of the present status of engineering education, and Prof. C. R. Mann has sent out many letters of inquiry to many members of engineering societies. From the replies received it appears that what is considered most vital for professional success, are such personal traits as character, personality, innate ability, perseverance, temperament, leadership, aims—for self or work. But these are exactly the factors over which the universities have the least influence. Then there are traits which are largely God-given but can be fostered by universities—integrity and honesty, tact, ability to co-operate, resourcefulness, power of expression, ability to understand and deal with men, and cultivation of engineering spirit. The university may and should catalyze the latent powers which Nature has bestowed (using due care to avoid negative catalysis, which is far more likely to occur in the educational than in the chemical field), but the university is practically unable to create such powers.

There still remains a serious criticism—that the graduates from our educational institutions fail to catch what may be termed the engineer's viewpoint, as applied to chemical industries. In the opinion of their employers they lack constructive imagination; they do not appreciate how diversified are the factors which enter into commercial operations nor the complexity of the human relationships and agencies involved; they have little business sense.

I can point out one particular in which it seems to me that our institutions are at fault: that they have not sufficiently required or even encouraged those of their staff who claim that they are fitting men for the industries to take adequate pains to acquaint themselves with the conditions under which those industries exist and prosper. It has been aptly said that the efficient teacher must have his knowledge in the "contagious form." It must be at least as true that the instructor who is capable of equipping his pupils to grapple with industrial problems in the broad sense, must have acquired the engineer's viewpoint, before he can impart it. I believe that we can only attain the best results when *every* instructor concerned with undergraduate courses has made such an acquisition, not merely *one or two* members of a staff whose particular business it happens to be to give courses labeled Industrial Chemistry or Chemical Engineering. The effect must be cumulative. . . . On the part of a teacher who has had some industrial experience, there is an increase of resourcefulness, especially in the matter of illustration of principles, which vitalizes his instruction. It surely need not commercialize his instruction; it does tend to enrich it and to give to the more academic phases of it, which must always be the backbone of the training, greater vitality. . . .

One of the most frequent criticisms of the young graduate relates to his inability to understand or make himself understood by other men; to his failures to co-operate with others or to direct the work of others, even though the latter are less intelligent than himself. It is quite possible that our schemes of instructions for the chemists and chemical engineers, as they have actually taken form, do tend toward more individualism, and less of concerted action than is true in the case of other engineering professions, where students are much more likely to work in squads. This matter deserves and is receiving some consideration.

Dr. Talbot thought it would be a great help if students could obtain even simple employment in manufacturing plants in summer. As to the instructors the universities should put a premium upon or, when practicable, demand of its instructing staff some sort of real contact with industrial processes. Even a round of visits among operating plants, of a fortnight's duration, is a wonderful education.

Undoubtedly the greatest service which the universities could render the industries in the training of young men would be to increase the proportion of large-minded, mature teachers. Unhappily, those entrusted with administrative duties realize that it is increasingly difficult (especially in chemistry to-day) to attract and hold such men (especially young men) in competition with the attractions in the technical field. This not alone because of the increased emolument which they offer; it is quite as much because of the opportunities for tangible achievement. It is, of course, too much to ask of the industries that they should refrain from securing the services of such men, but it seems very desirable to make an effort to devise some plan of co-operation which will, in a considerable number of cases, permit able men to serve the industries, without severing their connections with the educational institutions.

Dr. **William H. Walker,** professor of chemical engineering at Mass. Tech., followed. The university is not in that active co-operation with the industrial life of the country which makes for the greatest national efficiency and prosperity. In which respects have the industries failed to take their full part in meeting this demand for more efficient co-operation? The first criticism of the industries is their failure to make known to the university what their troubles and their problems are. This proposition is simple in its statement, but fundamental in its importance and far-reaching in its results.

One reason for this condition of things is that the industries have too little faith in the university as a source of help. A manufacturer consults the professional man and soon discovers that he does not know the details of his plant or his process or his product. He at once concludes that however able and learned the professor may be, he is too ignorant of the subject in hand to be of service. Here is where the manufacturer goes wrong. It is not only unnecessary, but as a rule undesirable, that the university professor should know the detail of the problem which is so familiar to the manufacturer. Co-operation signifies the combined striving of two people toward the same end. When the manufacturer contributes the practical details of the problem, and to this the university man adds a broad knowledge of the facts and principles of science, with a training and experience in the application of these facts and principles, there is created a team which will produce results to satisfy the most exacting. This is what co-operation means; and it is this combination of science and industry that has made Germany the power she is to-day.

A second reason is, that there is a lack of frankness and a want of confidence on the part of the industries when dealing with the University man, which so far as I know is not merited by him, and which too often makes efficient co-operation impossible. The university man . . . can aid efficiently and intelligently only when he is in possession of all the facts. If the scientist is not worthy of being intrusted with the whole story, he is a dangerous man to be in possession of any part of it. Nothing is more discouraging to the university man than to expend a lot of time and energy on a problem only to later find that he was kept in ignorance of conditions which made the results of his earlier work useless. If the scientific man cannot be a confidential man, his usefulness to the manufacturer has vanished.

The next matter in which the industries are at fault, is in not assuming a more liberal attitude toward the publication of the results of research work done for the industries by the universities and their graduates. There is a feeling on the part of the president or manager of the company that if the university man be generously reimbursed for his time and trouble that he should be satisfied. No scientific man should be, and few scientific men are, satisfied with a purely monetary return for their labor. They appreciate that they are under an obligation to contribute their share toward the development of their science. . . . In every piece of research work there are results which could be published in a perfectly impersonal way, so to speak, that would enrich science, and do the industries no harm. . . .

The unfortunate use of the words "pure" and "applied" research has led to the almost unconscious assumption that the only motive behind pure research is to enrich science, while the sole motive actuating applied research is to enrich the investigator or the organization financing the investigation. This latter assumption is unwarranted. Because an investigation is to be utilized, is no reason why the work should not be done with that thoroughness and accuracy which produces the best of scientific results. . . . Consider the splendid research carried on by Whitney and Langmuir on the behavior of gases at very high temperatures. It is immaterial whether you consider this the finest type of pure research from which the commercially valuable gas-filled tungsten lamp resulted, or an exceedingly profitable piece of industrial research in which purely scientific results of great value and interest were obtained, and given to the world. The goal toward which we should strive is to conduct our investigations so that the only distinction which can be drawn between pure and applied research, is the interval which will probably elapse between the time when the results are obtained, and the time when they become of service to the community.

A fundamental difficulty which presents itself when we in America attempt to introduce science into industry as compared to the ease with which the same thing is done in Germany, is occasioned by the absence of the equivalent of the equivalent of the German "technical director." . . . The average directing head of an American organization may have all the training necessary to be the son of the owner, or the representative of the majority stockholders, or of the banking syndicate which financed the industry; but he lacks the training which enables him to appreciate the atmosphere which must surround research work or in fact scientific work of any kind if it is to be successful. The infinite patience of the German investigator is made possible and profitable only by a corresponding infinite appreciation and sympathy on the part of the managing director. We may talk until the crack of doom about the miraculous results of Germany; but so long as we continue to draw the technical directors of our industries, the men on whom decision as to development work depends, from the purely commercial side of the organization rather than from those men with a scientific training, just so long shall we continue, notwithstanding our great natural resources, to cry for a protective tariff, more favorable patent laws, and other wholly temporary and superficial aids.

Finally we come to that factor in which the industries are most woefully lacking, and to remedy which the university has done almost nothing, namely the absence of intelligent foremen. . . . While science forced into an organization from on top is most helpful, some science introduced at the bottom is also necessary. . . . Here is a golden opportunity for the university, using this term always in the broad sense already stated, and the industries, to co-operate as they have never done before. All through the long summer the industrial and chemical engineering laboratories of our large institutions are empty. Why should this expensive equipment be idle when there are so many anxious to use it? Time does not suffice to outline in detail a plan which we are developing at the Institute of Technology, to present to young foremen and superintendents the principles of physics and chemistry on which their chosen industry depends. We propose to assemble each summer in our chemical engineering laboratory apparatus designed to present one specific industry. We shall invite that industry to send to us their more promising and ambitious men, in order that they may learn the scientific principles upon which the control of the raw materials, the process and the product depend. There are grave difficulties in such a plan, I admit, but co-operation can solve them. The objection met most frequently is that the industries cannot spare a good foreman for so long a time as six weeks. I can only say, that the foreman does not exist who may not at any time be taken out of the factory for six weeks by pneumonia, or typhoid fever, and yet the factory would not stop, nor the foreman loose his position. No more promising field exists, nor one fraught with greater possibilities for the industrial progress of this country than the opportunity which this

problem presents for co-operation between the university and industry. The foremen are anxious to learn; the industries are anxious to have them know; the universities are anxious to teach: Let's get together.

Mr. Arthur D. Little, in closest touch with the industry as president of Arthur D. Little, Inc., and in equally close touch with the Mass. Tech. as a member of its Corporation, made the final speech of the symposium. He pointed out that the part which science plays in furthering industrial development is not sufficiently appreciated by bankers, capitalists, men of affairs, and directors of industry, nor by superintendents, foremen, work people and the public generally. The directors of industry frequently ignore science. The attitude of superintendents and foremen and industrial workers generally to the innovation and betterments proposed by science is far too commonly one of militant scepticism or hostile suspicion.

Now all these individuals are social units who, with many other interdependent and mutually reacting units, together constitute the public at large. One may therefore fairly claim that our universities, great technical schools and colleges cannot serve business better than by directing some considerable part of their immense collective resources and influence toward creating in the public mind the mental atmosphere in which only business can truly flourish.

The first great necessity of business, as it seems to me, is a wiser, less recklessly extravagant and more generally efficient government of nation, State and municipality, and, as a corollary, a higher respect for law in the community. The second urgent need of business is that of establishing in the public mind as axioms the broad facts and principles without such general acceptance of which business cannot be carried on at high efficiency anywhere.

Business for example suffers much from the notion prevalent in certain quarters that all wealth is produced by labor and none by brains. It is likely to suffer still more from the idea that the productive capacity of all should be limited by that of the least capable. So, again, is business hampered by the general ignorance of workers and superintendents as to what research is and what it can do for them. . . .

The University of Wisconsin has done much to raise the standard of government in Wisconsin. Other universities everywhere are doing something, but could do much more, to combat the influence of pernicious ideas and enlighten obstructive ignorance.

To those of us who come in contact in considerable numbers with recent university graduates, one of the most shocking defects in the educational system of which they are the product is found in the pitiful lack of decision exhibited by the majority of these young men concerning the work and place in the world for which they are best fitted. One gains the impression that all too often the educational processes to which they have been subjected have been akin to the Strassburg process of stuffing by which geese are fattened. Or, they have been taught as Dr. Johnson said books were made, as an apothecary puts up a prescription, by pouring a little from many large bottles into one small bottle. It is not surprising that both the Strassburg process and that of the apothecary should have failed to draw out and develop the native capacities and latent possibilities of the student or that they should leave him with no well defined directive impulse.

Such a state of affairs is happily not true of our technical schools and it ought not to be true of our universities. . . .

Those of us who have received the benefit of any sort of scientific training are constantly amazed at the ignorance of cultivated men and women, business men and work people, regarding the simplest phenomena by which they are surrounded. To a deplorably large proportion of the community the striking of a match, the lighting of a fire, the freezing of water, the fall of snow, the sending of a telegram or a talk by telephone, the operation of a steam engine, or the turning on of an electric light, involve mysteries as far beyond their range of thought as the cause of gravitation or the rotation of the nebulae.

Since business involves at every point contact with natural phenomena and since the proper understanding of these phenomena, or at least some realization of what underlies them, often determines the measure of success attained in business, the university might well establish a compulsory elementary course in general science. This should be designed to give the student at least a rudimentary knowledge of the field covered by the different sciences, the relation of their subject matter to natural phenomena in the affairs of everyday life and those of business, the interdependence of the sciences, and, above all, a clear idea of the scientific method. Such a course could not fail to prove an immense stimulus to any intelligent mind. It would open out new horizons for thought and put an altogether different and more interesting aspect on the world in which we live and in which we must do business.

The business man seldom has at his disposal any more potentially efficient tool than the English language, but in his hands it is a tool which is often rusty and very seldom so keen and highly tempered as to be capable of rendering its highest service. The fault for this is largely with our universities, and the remedy, so far at least as their own students are concerned, is in their hands. Our great institutions of learning are every day disgraced by the inability of their recent graduates to make a concise and convincing oral statement of a series of facts, to prepare a well organized and adequate report, or even to write a graceful and informing letter.

There is finally a very definite field in which our smaller colleges can do much for business, and that is by offering specialized courses in the science and technology of particular industries which are highly developed in their locality. Ohio State University, for example, has for years specialized in this way regarding coal, and the University of Maine is now instituting courses in paper making. Other colleges and universities are favorably situated as to particular industries, in such numbers and with such variety of opportunity that, were these opportunities utilized in even moderate measure, the young man who desired to prepare himself for any line of industrial activity would have within his reach the means of realizing his ambition.

The result would be the constant accession to the ranks of business of annual quotas of young men not blindly groping into an unknown world like the modern graduate, but advancing eagerly with open eyes toward responsibilities which they know that they can meet.

This closed the symposium on "university and industry." Dr. L. H. Baekeland then presented his address on the Naval Consulting Board which is printed in full on page 943 of this issue. Dr. W. R. Whitney, also a member of the Naval Consulting Board, added a few humorous remarks, and the meeting adjourned.

The Iron and Steel Market

Prices on Lake Superior iron ore for the coming season were announced Nov. 8 by the Cleveland ore interests. The schedule will probably be as follows: Old range Bessemer, $4.45; old range non-Bessemer, $3.70; Mesabi Bessemer, $4.20; Mesabi non-Bessemer, $3.55, per gross ton on Lake Erie dock. The standard or base ore contains 55 per cent iron in the case of Bessemer and 51.50 per cent iron in the case of non-Bessemer, natural state. For ores whose iron content is near that of the base settlement is made on a straight unit basis, in proportion to the actual iron content, but in case of considerable departure the system of computation is more complicated. In Bessemer there are phosphorus premiums and penalties, in accordance with departures from a base of 0.045 per cent phosphorus content. Generally speaking, the 1916 schedule is about 75 cents a ton above the prices of 1912, 1914 and 1915, the lowest since 1904, and 50 cents under the prices of 1907 and 1910, the highest since 1900. The entire advance of 75 cents for 1916 does not go to the ore producer, as vessel rates were recently established at 10 cents advance over the rate for 1915, and further advances are likely. The Steel Corporation set the 10-cent advance recently by chartering vessels to the extent of a 10,000,000-ton movement, and since then owners of vessels have been chary about contracting at all.

Shipments of ore down the lakes in the season just closed total 46,318,804 tons, against 32,021,900 tons in 1914 and 49,070,478 tons in 1913, the banner year. Besides the lake shipments about 750,000 tons of ore is usually moved by all-rail routes. The forecast is that 60,000,000 tons or more will be required next year, but doubt is expressed whether as much ore can be carried

by the vessels. There would be no difficulty about mining the tonnage, in all probability.

The steel market has come almost to a standstill as to the booking of strictly new orders, for a heavy tonnage continues to pour into the mills in the form of specifications on existing contracts. The mills will accept specific orders, at a price, for almost any delivery they can make, when it appears that the steel will be needed for a definite purpose, but the deliveries are such that buyers are but little interested. What many buyers would like to secure is protection for third quarter and later deliveries by open contracts, subject to later specification, but the mills are indisposed to commit themselves so far ahead.

The steel market is likely to be quiet, generally speaking, for two or three months while the mills straighten out their obligations. So heavy has been the specifying, and so rapidly have obligations piled up on mill books, that a great many arrangements have to be made with buyers. Often it occurs that a buyer will request that an earlier delivery be made on a specification filed later than another.

Emphasis should be laid upon the fact that the war demand is now a relatively minor factor in steel trade activity, domestic demand having increased so sharply in recent months. An illuminating comparison can be made. The last period of full activity in the steel industry extended from early in 1912 until late in 1913. The outputs in the calendar year 1913 may be taken as representing about 90 per cent as great a tonnage as would have been produced if the activity of the first nine months had been continued throughout the year. Dividing the outputs reported for 1913 by this factor we have: Pig iron, 34,500,000 tons; steel ingots, 33,600,000 tons; steel castings, 1,100,000 tons; finished rolled steel, 25,500,000 tons; finished rolled iron, 1,850,000 tons. Exports of steel products in 1913 amounted to about 2,300,000 tons. At the present time production is at the following estimated rates: Pig iron, 38,000,000 tons; steel ingots, 38,000,000 tons; steel castings, 1,000,000 tons; finished rolled steel, 28,000,000 tons, finished rolled iron, 1,500,000 tons. Direct and indirect exports probably represent about 7,000,000 tons of rolled steel, and more likely less than more than this quantity. Thus during the active portion of 1913 finished steel appears to have been delivered to the domestic trade at the rate of about 23,200,000 tons, while at present the rate seems to be about 21,000,000 tons, perhaps somewhat more. In most directions the domestic demand is much heavier than in 1913, for in 1913 there was more than 3,000,000 tons of rails produced for use in the United States, while the present production of rails is extremely light. There was also much more structural material consumed than is being consumed at present. Deducting for these two items, the domestic demand remaining appears to exceed quite materially that of 1913, the heaviest domestic demand that had been experienced up to this movement. The alignment is one that has been established but recently, and it is one that is perhaps not universally recognized even now.

Pig Iron

Pig iron has been advancing fully as rapidly since Dec. 1 as it did during November, the rate then, averaging various grades in the different markets, being between 35 and 40 cents per ton per week. The pig iron market has shown a very interesting reversal in its conduct as to prices. During the first six months of the year prices did not advance, although demand continually increased. Idle furnaces blew in from time to time and forestalled advances. In July, August and September demand increased further and moderate price advances occurred. In the past thirty days there has been little increase in the rate of consumption, and the tonnage demand in the market has been relatively light, yet prices have advanced very sharply, and evidently because the limit of productive capacity has been reached or closely approached. It is not demand alone, but the relation between demand and supply, that makes prices. The most spectacular performance has been by Bessemer pig iron in the valleys, which was quoted at $17.50 to $18, valley, in our last report, in the closing days of November. Early this month sales of 3500 tons were reported at $18, fixing the market at that as minimum, but within a few days sales of 1100 tons were made at $18.50, followed by sales of about 1500 tons at $19. There may have been other sales, but if so the trade at large did not hear of them. Never before had Bessemer thus advanced on such an extremely light turnover. We quote: No. 2 foundry iron, delivered Philadelphia, $18.25 to $18.75; f.o.b. furnace, Buffalo, $17.50 to $18; delivered Cleveland, $18.30; f.o.b. furnace, Chicago, $18 to $18.25; f.o.b. Birmingham, $14 to $14.50; at valley furnaces, 95 cents higher delivered Pittsburgh; Bessemer, $19 to $20; basic, $17.50 to $18; No. 2 foundry and malleable, $18 to $18.50, and gray forge, $17.50 to $18.

Steel

There is no regular open market for billets and sheet bars. The mills are very short of steel and prefer to take care of their regular finished steel trade together with their regular billet and sheet bar customers, leaving nothing to be offered in the open market for such deliveries as the mills would care to consider. Based partly upon private settlements in the trade the market is regarded as nominally quotable at about $30 for Bessemer billets and sheet bars and about $31 for open-hearth, f.o.b. maker's mill, Pittsburgh or Youngstown. Forging billets are quoted at about $52, with a small turnover, and rods at about $40.

Finished Steel

Prices of some of the steel products have become largely nominal. In bars, plates and shapes the large mills have a minimum of 1.70 cents, which they seem about to advance to 1.80 cents, for shipment at mill convenience, no early delivery being possible, while the smaller mills, able to make earlier deliveries, are securing premiums.

Prices quoted are f.o.b. Pittsburgh unless otherwise noted:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.70 cents to 2.10 cents, base.

Shapes, 1.70 cents to 1.80 cents.

Steel bars and bands, 1.70 cents to 1.90 cents base; steel hoops, 1.90 cents, base.

Iron bars, 1.859 cents to 1.959 cents, Philadelphia; 1.60 cents to 1.70 cents, Chicago; 1.85 cents to 1.90 cents, Pittsburgh.

Plain wire, 1.85 cents, base; wire nails, $2 per keg, base; galvanized wire, 2.55 cents; painted barb wire, 2.15 cents; galvanized barb wire, 2.85 cents.

Sheets, blue annealed, 10 gage, 2.25 cents; black, 28 gage, 2.50 cents to 2.70 cents; galvanized, 28 gage, 4.75 cents to 5.00 cents; painted corrugated, 28 gage, 2.70 cents to 2.90 cents; galvanized corrugated, 28 gage, 4.80 cents to 5.05 cents.

Tin plate, $3.60 for 100-lb. cokes.

Steel pipe, ¾ to 3-in., black, 78 per cent off list; galvanized, 73½ per cent off list.

Boiler tubes (less than carloads), 68 per cent off list.

Structural rivets, 2.50 cents; boiler rivets, 2.60 cents.

The Naval Consulting Board of the United States*

BY DR. L. H. BAEKELAND
Member of the Board

Modern war, whether it be for robbing, plundering and subjugating other nations, or for legitimate self-defense, has become primarily dependent upon exact knowledge, good scientific engineering, and to a large extent, applied chemistry.

Napoleon used to say that the Lord was on the side of the armies with the biggest artillery and the best ammunition; if this seemed true in his time, it sounds almost like an axiom to-day, when physical training, personal valor, bravery, or courage, appear to count for little if efficient technical equipment, based on sound scientific knowledge, is lacking.

Germany, with her enormous and well-drilled army, with her 42-centimeter guns, and other formidable equipment, would be hopelessly paralyzed did she not find in modern chemical processes of synthetic nitric acid from the air, the source of supply of this indispensable chemical. How otherwise, could she manufacture smokeless powder and explosives, since England succeeded in shutting her off from the general source of supply of nitrates from Chili?

THE NAVAL CONSULTING BOARD

Secretary Daniels seemed to be imbued with these facts, when by organizing the Naval Consulting Board of the United States, he desired to give to our Navy the benefit of the scientific and technical talent of this country.

Since then his example has been followed by the French Republic, who in her hour of danger, has organized a similar civilian board and has even raised it to the dignity of a ministry: "Le Ministère des Inventions."

Great Britain also has enlisted the services of a board of civilian scientists and technologists for her present war operations.

As to Germany, we know that long ago she has abundantly availed herself in her war plans of the advice and co-operation of her scientists, inventors and engineers.

Although general information about the Naval Consulting Board has been more or less available through the daily press, there seems to be a very hazy conception in the mind of the public as to its work and plans. Unfortunately, some published criticisms, emanating mostly from persons who neither seem to have the desire nor the tact to first obtain correct information, have caused a very misleading interpretation of the work of this board.

A BOARD WITHOUT "POLITICS"

To those whose limits of imagination do not go beyond petty political considerations, it may be well to point out that in the formation of this board, politics has not had even the most remote influence. Secretary Daniels appointed America's best known inventor, Edison, as chairman, and by the latter's advice, applied afterward to different engineering and scientific societies of the United States, so that each of them should designate two representatives best qualified to serve on the board, through which our Secretary of the Navy would try, as he expressed it, "to mobilize the inventors and engineering talent of the country in the service of the United States."

Until now, Mr. Daniels does not know whether there are any democrats, republicans or progressives on this board—nor does he care to know. He relieved himself of the responsibility of selecting the members of this board by putting the matter up to the representative engineering societies of the United States. If any of those societies did not make the best possible selection, they alone should bear the blame. In the meantime, it matters little as long as the majority of the board are men of such ability and personality that they cannot fail to impress their attitude and talent upon the work of the board.

IS THE BOARD TOO CUMBERSOME?

At first it seemed as if a board of twenty-two men was to be much hampered by cumbersomeness and by long deliberations; but this fear vanished after our first meetings. If any member felt inclined to use unnecessary oratory or rhetoric, he soon changed his mind after he noticed how the other members displayed mutual respect for each other's valuable time, how discussions of secondary importance were eliminated, and how this board proceeded with unusual directness toward matters of immediate importance.

THE TRIP ON THE MAYFLOWER

When the announcement was made that on the first day of our meetings we were to board the yacht of the President to proceed to the Indian Head Proving Ground, some of us were inclined to think that formalities and social affairs might interfere with the efficient distribution of our time. But this idea also was soon dispelled, as during this entire trip, the time was taken up with the discussion of subjects directly related to our work, while becoming acquainted with the other members of the Naval Consulting Board, as well as with the chiefs of the different departments of the Navy.

So little time was given to formalities that even a regular lunch was dispensed with, beyond the distribution of a few sandwiches, while discussing various matters. Our visit to Indian Head gave us an excellent opportunity to get some direct practical information upon matters of ordnance and ammunition.

We landed back in Washington after dark, but at half-past eight that same evening, we were to continue our meeting at Secretary Daniels' office. Although this left us scarcely a few minutes to swallow some supper, none of the members of the board failed to appear at the appointed time.

A JOINT MEETING WITH THE CHIEFS OF THE NAVY

It is not generally known that the Navy had, in itself, an advisory board which is made up as follows: Hon. Franklin D. Roosevelt, Assistant Secretary of the Navy; Rear-Admiral W. S. Benson, Chief of Naval Operations; Rear-Admiral Victor Blue, Chief of Bureau of Navigation; Rear-Admiral Joseph Strauss, Chief of Bureau of Ordnance; Rear-Admiral R. S. Griffin, Chief of Bureau of Steam Engineering; Chief Constructor D. W. Taylor, Chief of Bureau of Construction and Repair; Civil Engineer H. R. Stanford, Chief of Bureau of Yards and Docks; Paymaster-General Samuel McGowan, Chief of Bureau of Supplies and Accounts; Surgeon-General W. C. Braisted, Chief of Bureau of Medicine and Surgery; Major-General George Barnett, Commandant of the Marine Corps, and Captain Ridley McLean, Judge-Advocate-General of the Navy.

All of us were impressed with the concise and business-like way in which each one of these gentlemen described his various responsibilities and presented the details of the subjects on which he desired the advice and assistance of the members of our board.

*An address made at the joint meeting of the New York Sections of American Chemical Society, American Electrochemical Society, and Society of Chemical Industry, Dec. 10, 1915.

Not only did they give us the convincing impression that they were sincerely glad to discuss their problems with us, but in doing so, they made us forget that they were the chief officers of the Navy; they appeared to us like so many engineering or business men who in a simple and direct way, wanted to discuss questions on which they felt their grave responsibilities. To anyone who is acquainted with all the pose and overbearing attitude of European military caste, and who might fear that this nation might bear the incubus of militarism, direct acquaintance with men like these would soon dispel this apprehension.

Nor did we see, anywhere among them, nor at the Army and Navy Club, nor at the Department of the Navy, as much as one single uniform, except, of course, on board the Mayflower, where the yacht's officers and crew were in uniform.

Notwithstanding the fact that no time was lost for unnecessary purposes, it was after midnight when the first day's meeting adjourned.

NO TIME GIVEN TO UNNECESSARY DISCUSSION

Early next morning we met again, this time at the library of the Navy, and then and there the board was organized for its future work. Here again, no time was spent upon side matters; everything was transacted in a practical direct way. For instance, when the rules of procedure for further meetings had to be discussed, a sub-committee was immediately organized with instructions to leave the room and report "not later than thirty minutes," so as not to impede other deliberations which were going on; the result was that when at noon we gathered for lunch, all questions of organization and subcommittees had been discussed, sifted and settled until future conditions may make it desirable to introduce any needed changes.

But even at lunch, the business meeting went on, and some of us had to interrupt our lunch, and go to a next room to deliberate further in a subcommittee, until a report could be submitted on some matters relating to this particular committee. So when at the end of this second day, the Naval Consulting Board adjourned, a good deal of work had been disposed of.

Shortly afterward another meeting was held in New York, where the organization of the subcommittees was completed, and where the different chairmen of the subcommittees were appointed.

A BOARD THAT RECEIVES NO PAY AND PROVIDES FOR ALL ITS OWN EXPENSES

For those who are accustomed to consider the United States Government as a big "milking cow" for salaries and remunerations, it may be of interest to know that no member of the Naval Consulting Board draws any salary, nor gets any remuneration from the Government.

We all pay our own traveling and hotel expenses and each member feels that if he can give his time, free of charge, to the Government, he can still better afford to pay his own expenses.

This program is carried out so scrupulously that even the cash for the purchase of stationery and printing is furnished by the members of the board, who are monthly assessed among themselves.

A "SHORT-CUT" BETWEEN THE NAVY AND THE INVENTORS OF THE COUNTRY

The general opinion of the members of the board is that its scope of usefulness can best be fulfilled by acting as a "go-between" or a "short-cut" to information between the heads of departments of the Navy, and any individual member of the different societies they represent. This carries into practice the idea of "mobilization of inventors and engineering talent" of Mr. Daniels.

The board mainly puts its services at the disposal of the chief officers of the Navy, as fast as the latter feel the necessity of co-operation or advice.

For instance, a subject relating to improvements in the manufacture or the composition of a certain explosive, would be referred to the subcommittee on chemistry and physics, as well as to the subcommittee on ordnance and explosives; the matter is discussed in these two committees and the members of these two committees decide whom to select among their fellow members of the chemical or engineering societies who are best qualified to help them in this task, and who, at the same time, are willing to co-operate without any other compensation than the feeling that they are working for the good and the security of our republic.

It is obvious that in handling all these matters, tact and discretion are just as indispensable qualifications as talent or knowledge, and this involves quite some responsibility for the members of the Consulting Board in selecting suitable collaborators.

As a matter of fact, several important pending problems are now actively before the subcommittees, and, notwithstanding the short time which has elapsed since the first meeting of the board, some of these questions are already in an encouraging phase toward successful solution.

THE SO-CALLED "FIVE-MILLION LABORATORY" OF THE NAVAL CONSULTING BOARD

The so-called "five-million laboratory," proposed by the Naval Consulting Board, has been the favorite subject of varied and picturesque criticisms which, as usual, originated more through lack of information than by ill-will.

Secretary Daniels requested each member to address to him his personal opinion on the advisability of the creation of a research laboratory where urgent technical matters relating to the needs of our Navy could be studied successfully.

At the second meeting a special committee was appointed to submit a joint report. On this committee were, besides Mr. Edison, four other members. One of the other members of the committee is a man who has earned a national reputation in organizing and developing one of our largest mechanical industries. The second member is at the head of perhaps the largest and best endowed scientific research institution of the world; another is the chief of one of the most successful chemical and physical industrial research laboratories of this country; the fifth has devoted much of his life to private chemical research.

VARIOUS OPINIONS OF HOW RESEARCH SHOULD BE CONDUCTED

It was interesting to follow how the five members grouped themselves in accordance with their own point of view, dictated by their daily scope of action: The chemical or purely scientific members of this committee agreed pretty well on the kind of research laboratory they had in view, and although their suggestions had been written independently without consulting each other, their general recommendations as to the organization, equipment, and needed expenditures were fairly similar and relatively modest.

But their recommendations were mainly limited to a chemical and physical laboratory; they did not include the study of elaborate mechanical and technical problems which go far beyond the questions which are usually dealt with in chemical and physical research laboratories.

The two other members, on the contrary, wanted to prepare thoroughly for engineering problems of imme-

diate importance, the solution of which seems indispensable if the money of the Navy is to be spent to best advantage.

They set forth, from their own direct experience, how very expensive such engineering experimental work is likely to be.

Edison, for instance, pointed out the millions he spent in developing some of the details of his inventions; another member identified with the automobile industry stated that one single automobile concern here in the United States had found it necessary to spend half a million dollars in one year for experiments and research.

The modest estimate for a merely chemical and physical laboratory was thus snowed under by the irrefutable evidence of the much larger needs for a suitable mechanical or engineering department.

Of course, it was argued that the Navy possesses already several experimental stations at its different Navy yards, and at the Torpedo Station in Newport, aside from the different testing laboratories for the materials used for ordnance or ammunition; that, furthermore, the excellent laboratory facilities of the Bureau of Standards are available.

The answer to this was that each and every one of the present institutions were more necessary than ever, but were totally insufficient; furthermore, the full cooperation of all of them is needed; all this in view of the fact that, at present, the Navy of this country is facing unusual responsibilities.

EXPERIMENTAL WORK CANNOT BE POSTPONED UNTIL IT IS TOO LATE

If it is deemed urgent to be prepared for defense, then this defense involves problems the solution of which cannot be deferred indefinitely. If something has to be done, it must be done immediately—not in five or ten years hence, when it may be too late.

In all of our present scientific research laboratories, time seems of relatively little or no account; problems which cannot be solved to-day can be solved to-morrow or in ten years or during the next generations; but this is not the case with the problems connected with the contemplated defense of our country; the solution of these problems cannot be postponed. They demand immediate action.

Nor is the condition of our Navy similar to that of an industrial concern that can afford to take chances with machinery or equipment which is not strictly up to date, and still show some commercial success. For instance, recent events have demonstrated that there is no use building the best and newest fortresses against an enemy who possesses guns strong enough to demolish everything in existence.

Nor is there any chance of success in using the very best artillery at anything like equal chances if your adversary can do his scouting and range-finding with aeroplanes provided with reliable engines, while your aeroplanes are equipped with motors which give out at unexpected moments.

In our clumsy war with weak Spain, we went into the field with black powder when all other nations, even Spain, were equipped with smokeless powder. Why? Because we had postponed too long studying the chemistry of the subject.

The fact is that if we require a Navy at all, our Navy cannot afford to use anything but the very best and most efficient means of defense. Not to possess the very best might put us in the same absurd condition as the wooden navies of the world were in after our civil war had established the supremacy of the ironclad vessel.

RESEARCH MUST PREVENT THAT MONEY FOR DEFENSE SHOULD BE SPENT ON OBSOLETE OR INADEQUATE MEANS OF DEFENSE

The contemplated outlay for the Navy for the next five years, for new ships, aviation and reserve of munitions, amounts to about $500,000,000. These tremendous expenditures of money, in order to be of real value, ought to be made as efficient as possible. All doubtful and inferior devices must be eliminated by direct experiment, by research and tests, *before* it is too late to remedy them.

This requires accelerated action; in fact, Mr. Edison's personal opinion was that research and laboratory work in this instance "should go on night and day without intermission" instead of the usual easy-going short-day plan followed in laboratories.

If one single automobile concern in the United States finds it to its advantage to spend in one year half a million dollars on testing, research, or experimentation, how much more important is the business of the United States Navy, where money not spent wisely is better not spent at all, because then at least we shall not have the illusion that we are equipped for defense, when we have merely lost our money on antiquated devices.

MILLIONS OF DAMAGE TO OUR FLEET ON ACCOUNT OF CORROSION OF CONDENSER TUBES

Without mentioning any spectacular problems of modern warfare, it might be stated that such a prosaic detail as the corrosion of condenser tubes of our warships, involves an annual damage of about $2,000,000. If $1,000,000 were spent on research on this problem alone, with the result of reducing the damage to one-half, the total outlay would be compensated in a few months' time, aside of the important fact that our fleet would be stronger because less of our ships would be unavailable for service.

It was brought out that there was little use in spending so many millions on flying machines as long as there was any doubt on the reliability of their engines, and until an absolutely well-tried and standardized engine had been developed. To accomplish this experimental work in a period of a few years would cost quite some money; but to do this rapidly, within a few months, before order is given to build these flying machines, requires enormous outlays of money, alongside of the indispensable engineering talent.

THE NAVY SHOULD FIND IT PROFITABLE TO SPEND AS MUCH FOR EXPERIMENTATION AS ANY PRIVATE INDUSTRIAL CONCERN

Another member brought out the fact that even conservative industrial enterprises found it necessary and profitable to spend at least 2 to 5 per cent of their sales on research and experiments. At this rate, the contemplated expenditure of $500,000,000 in five years, would certainly warrant an expenditure of at least five million for research during that period.

Money for this purpose wisely used, ought to do so much good to the Navy as to increase its efficiency by the value of several battleships costing considerably more. Mr. Edison's arguments were particularly eloquent when he enumerated the enormous expenditures for research in his own laboratories.

In this discussion everybody seemed to be well in accord with the general idea that whatever expenditures were recommended, the contemplated work should be carried out under immediate supervision of the Navy; that this work should not be started all at once—full blast—but should be extended gradually, as fast as circumstances demand it.

In view of all this, two policies were open for obtain-

ing the necessary appropriations—the old time-honored trick of asking from Congress first an appropriation of a few thousand dollars, knowing very well that this would be insufficient, then after awhile ask an additional appropriation and keep on nagging and asking at various intervals.

But the members of the advisory board thought it a more honest policy to state the facts as they saw them and to confront the Secretary of the Navy with the probable maximum expenses for research and experimentation, commensurate to the five years' naval building program now under contemplation. The five-million dollar budget for experimental work to be expended during those five years, or about one million a year, may strike the uninitiated as needlessly large, although it is only about what some industrial enterprises have found necessary to spend on their own experimental work.

LET BLUNDERS BE COMMITTED IN A SMALL EXPERIMENTAL WAY INSTEAD OF ON A LARGE SCALE

But if the nation does not want to go to the expense of developing the latest and most efficient means for defense at the lowest cost by obtaining the necessary information through preliminary experiments, instead of committing mistakes on a large permanent scale; or if our country wants its Navy to keep on building its ships or other means of defense, as were good enough in the past, regardless of the fact that modern war requires the very latest and the most efficient available devices, then let us not be astonished if after incomparably more money has been spent for increased armaments, we find that we are loaded with means of defense which have become obsolete in the meantime and are good for the junkheap of antiquated equipment.

The foregoing is a brief résumé of various arguments which were submitted by some members of the board, and this is the first time that this discussion has been reported in public. Let us hope that its publication may help to dispel some of the ideas of the public which imagines that the board contemplates the immediate erection of a "$5,000,000 laboratory building, where the members of the Naval Consulting Board can experiment to their hearts' content in company with long-haired inventors."

As Mr. Edison expressed it picturesquely: "The money should be spent not on buildings, but on a national junkshop," where means of defense can be tried out first, at relatively small cost so as to learn how to get the most and very best for the money, and so as to avoid making expensive and dangerous blunders on a wholesale scale.

ADMIRAL MELVILLE TWELVE YEARS AGO STRONGLY URGED EXPERIMENTAL WORK IN THE NAVY

More than twelve years ago one of the most distinguished officers of our Navy, Admiral George W. Melville, urged strenuously the necessity of naval engineering experiments; his well based arguments published in the *Proceedings* of the Engineers' Club of Philadelphia (Vol. XX, No. 3, July, 1903) brought out the fact that expenditures for experiments are the best means for avoiding expensive mistakes. What he said then, sounds even more convincing to-day.

The following quotations are taken from his paper:

"The hulls and machinery of these five battleships will cost approximately $20,000,000. The armor, armament, and equipment will require an additional outlay of $15,000,000; so that the actual cost of these battleships will probably be about $7,000,000 each. The annual depreciation of each of these vessels from the time they are launched, taking into consideration wear and tear as well as loss in fighting value, will be at least 4 per cent of their actual cost. The expense attending the establishment of the proposed experimental station, including its operation for several years, will thus be but little more than the annual loss resulting from corrosion, mishaps, and depreciation of military appliances of two of these floating fighting machines."

"The success of Germany can be accounted for only by recognizing the fact that study, reflection, and research must have been expended in the preparation of plans, in the building up and the organization of the shipyards, and in laying out and carrying on the work of construction. It was the high appreciation of the value of original investigation, coupled with experimental work, that has caused Germany to advance progressively and successfully."

"Where research had not been conducted, disappointment resulted from the construction of vessels which were either faulty in design, ill-suited for the purpose intended, or upon which an inferior quality of work had been expended."

"The problem as to whether or not in-turning screws are detrimental to manœuvering qualities would have been solved many years ago if the work planned by Mr. Isherwood had been continued. Our increased knowledge of the theory and practice of screw propulsion since the Isherwood experiments is due, however, almost wholly to the work of Froude, conducted for the British Admiralty. This is confirmatory evidence that such important and difficult work can only be undertaken by official or civilian experts who are able to call upon government resources for data and information. It requires government investigation to solve important problems relating to the powering of vessels, since valuable and far-reaching experiments upon this subject require the use of ships as well as the services of a large number of reliable and competent persons to collect the data requisite for the determination of absolute results.

"If it be true that the battleship of one generation is the junkheap of the next, then an economical race like the German is pursuing a wise policy in conducting experimental research and investigation in the direction of finding out how the weak links in the naval chain can be strengthened.

"Experience has shown that the German engineering laboratories are more than a good paying investment, for there is not an expert in that empire familiar with the work being done at these laboratories who does not beleive that their destruction would be a greater national calamity to the navy and the nation than the loss of one of the battleships of the home squadron. The warship could be replaced in four years. It would take six years to rebuild and put in effective operation the complete installation for conducting experimental research that has been developed and perfected at the Charlottenburg and Dresden technical college.

"There is probably not an eminent naval or mechanical engineer in America or England who has given consideration to this question who is not also of the opinion that the establishment of a national experimental laboratory for naval purposes will vastly contribute to military strength. Probably the majority of these experts also believe that such an institution would eventually contribute more to actual naval strength than the building of a battleship. One does not need to possess vital imagination to realize that much is contributed to the fighting strength of a navy by carrying on research along engineering lines, and thus preventing the design, construction, and installation of appliances that are ill suited for the purposes intended.

"The cost of maintaining a battleship in commission will approximate $1,000 per day, and warships have been tied up for weeks on account of the corrosion of a few hundred dollars' worth of boiler tubes. It will repay the nation for the cost of an experimental station if the staff of the laboratory will simply cause increased length of life of both boiler and condenser tubes."

Standardization of Metallurgical Units.—In the preliminary report of the Committee on Standardization of the Mining and Metallurgical Society of America (page 818 of our issue of Nov. 15) in the paragraph on "mesh of wire cloth" there is an error in regard to the relation of openings in the Tyler standard screen scale, to which the W. S. Tyler Company of Cleveland has kindly called our attention. The paragraph states: "This furnishes a standard screen scale in which the area of each successive opening in the scale is double that of the second preceding." It will be seen that with the ratio of the series the square root of 2, the areas of successive openings double the next preceding, instead of the second preceding.

The Cyanide Plant of the Baker Mines Co., Cornucopia, Oregon

BY ROBERT M. KEENEY

Formerly mill superintendent, Baker Mines Co.

The mill of the Baker Mines Co. was built in the summer of 1914 to treat the ore of the Last Chance mine, formerly owned by the Cornucopia Mines Co. The camp of Cornucopia is situated seventy-five miles northeast of Baker City, Ore., in Baker County. The nearest railroad station is Robinette on the Snake River branch of the Oregon Short Line Railroad. The roads are fair, and the camp is accessible by automobile in the summer, but all freight has to be hauled by wagon or sled. The winters are not cold, but there is a heavy snowfall with all the resulting obstacles to mining. All of the mines of the camp are in a snowslide country, making a careful choice of sites for buildings essential.

The district is very rough and precipitous with a considerable quantity of timber, being a part of the Minam national forest reserve. The rough character of the mountains is shown in Fig. 1 and Fig. 2. In Fig. 1 the mine is at the horizontal white streak at the extreme upper left hand corner of the picture. There are possibilities of numerous small high-head water-power developments in the neighborhood on Pine Creek and its branches, and at a greater distance on other creeks. Power could also be obtained from the Oxbow plant of the Oregon-Idaho Power Co. on the Snake River, thirty miles distant. The Baker Mines Co. mill is at an elevation of about 5325 ft., and the mine at 7000 ft.

The character of the ore milled is quite variable. Depending on the part of the mine from which it comes it may be oxidized, with some free gold, or a heavy sulphide ore. Most of the sulphide is pyrite, with smaller amounts of sphalerite, galena and chalcopyrite. The gangue is quartz. Pockets of telluride ore occur, and there is some copper present in an oxidized form. The battery heads assay from $12 to $16 per ton. The ratio of gold to silver is variable, being from three parts of silver to one part of gold up to a five to one ratio.

FIG. 1—MILL OF BAKER MINES CO., CORNUCOPIA, ORE.

FIG. 2—MINE BUILDINGS AND LOADING TERMINAL OF THE TRAMWAY

The copper contents of the ore milled have varied from zero to 1.75 per cent, and have averaged for a month 0.21 per cent. At first the copper gave considerable trouble, due to fouling the solutions, but now chiefly causes a higher cyanide consumption and a higher zinc dust consumption. The gold extraction is not decreased much when the copper content increases, but the silver extraction is generally lower, probably due to more of the silver being in the form of a complex sulphide with copper.

Tramway

A Bleichert aerial tramway, erected by the Trenton Iron Works, conveys the ore from the lower tunnel of the mine to the mill. All supplies and miners go to the mine over the tramway except in summer when the mine is accessible by road. The upper terminal of the tramway is seen at the right in Fig. 2. Fig. 3 shows the lower terminal at the mill.

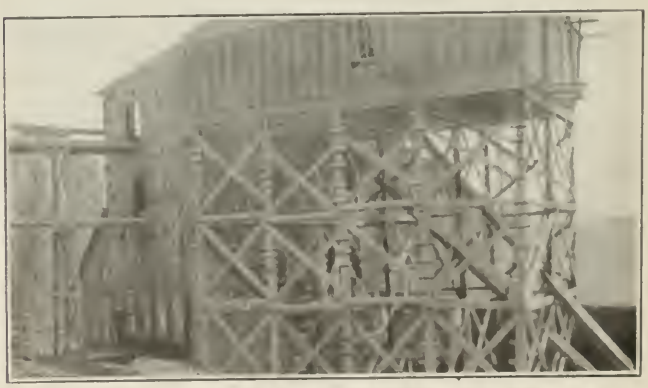

FIG. 3—DISCHARGE TERMINAL OF TRAMWAY AT THE MILL

When operated at full speed the tramway has a capacity of 15 tons of ore per hour. There are 24 buckets, each holding 6 cu. ft., or 625 lb. of ore. At full capacity the buckets run with the distance between them 625 ft., an interval of 75 sec., and speed of traction rope 500 ft. per minute. The length of the tramway is 5500 ft., with the loading terminal at 1675 ft. higher elevation than the discharge terminal. Between the two terminals there are two towers and a tension station. The span between the tension station and the discharge terminal at the mill is over 3200 ft. long, which is said to be the longest aerial tramway span in the United States. The track cable is of three sizes, 1⅜-in. diameter, 1⅛-in. diameter and ⅞-in. diameter. The tramway develops 21 hp. It was erected under very difficult conditions in a rough country, but even with the long span has given no trouble in operation, and after one winter appears to be as intended, immune from snowslides.

Mill Buildings

The buildings are of wood frame with corrugated iron roof and siding. Concrete foundations and retaining walls are used throughout. The mill buildings are shown in Figs. 1, 4 and 5. In Fig. 4 the main mill building and tramway terminal are at the left, and the precipitation building and store house on the right. The tramway discharges into the crusher over the ore bin at the head of the mill.

The mill is built on a hill side with a 15-deg. slope. The precipitation presses, barren solution tanks, melting furnaces and assay office are in a separate building about on the level of the ore bin.

Mill Equipment

In designing the mill several factors influenced the process and equipment, more than the idea of obtaining a very high recovery of values. The principal of these was the amount of power which could be developed locally without a considerable expenditure. If there had been sufficient power available without large outlay, it is probable that an all-sliming plant with tube mills would have been built instead of a sand and slime plant. On ore similar in a general way the Cornucopia Mines Co. obtains a 90 per cent extraction by the all-sliming process. The designers of the mill, John M. Baker and Paul W. Gaebelein, expected to eventually get an 85 per cent recovery, and a little better is now being obtained.

The mill equipment includes the following:

Grizzly—1½-in. openings.

Crusher—No. 3 suspended type Austin gyratory crusher. Speed, 425 r.p.m., requiring 20 hp. Capacity, 10 to 20 tons per 24 hr. through 2½-in. ring.

Battery Feeders—Four supported type Challenge feeders.

Stamp Mill—Twenty 850-lb. stamps. Stems, 3⅜ in. in diameter by 14 ft. long. Two key tappets later replaced by three key tappets. Bossheads, 8¾ in. in diameter by 17 in. long. Chrome steel shoes, 8¾ in. in diameter by 9 in. high; weight, 165 to 170 lb. Cast-iron dies, 7⅜ in. high by 8½ in. diameter steel and iron fake bottoms 9 in. square by 3 in. thick. Four mortars: base, 4 ft. 6 in. by 2 ft. 3 in. Demarest steel guides with the stems 9¼ in. centers. Camshafts, 5⅜ in. in diameter by 14 ft. long. Order of drop, 1-3-5-2-4. Drops per minute, 102. Height of discharge, 2 in. Drop, 7 in. Twenty-five mesh screens. Duty per stamp day, 3.4 tons. Power required, 40 hp.

Amalgamation Plates—Four silver-plated copper plates, 54 in. by 7 ft. 6 in. Grade, 2 in. per foot. Divided into two parts by strips to avoid hanging stamps when cleaning up or dressing the plates.

Dorr Classifier—Model C duplex Dorr classifier with steel tank.

Leaching Tanks—Three fir tanks, 30 ft. in diameter by 10 ft. deep, with 3-in. staves. False bottoms covered by cocoa matting and canvas. Four 14-in. iron circular discharge gates in the bottom of each tank.

Sand Distributors—Three revolving-arm sand distributors.

Dorr Thickeners—Two thickeners in wooden tanks, 30 ft. in diameter and 10 ft. deep, with 3-in. staves. Arms revolving at 1/10 r.p.m. One thickener in wooden tank, 20 ft. in diameter by 10 ft. deep, with 3-in. staves. Revolving at 1/5 r.p.m.

Dorr Agitators—Three-inch wooden tanks, 20 ft. in diameter by 16 ft. deep, with 3-in. staves.

Portland Filter—One filter with drum, 14 ft. long by 9 ft. in diameter. Revolving at 1/6 r.p.m.

Gould's Suction Vacuum Pump—One 14 in. by 10 in.

Gould's Triplex Pumps—Two pumps, 4 in. by 6 in.

Swaby Centrifugal Pumps—One 3-in., one 2-in.

Merrill Clarifying Press—Ten-frame, 36-in. sluicing clarifying press. Capacity, 210 tons clarified solution per 24 hr.

Gold Solution Tanks—Three fir tanks, 20 ft. in diameter by 10 ft. deep, with 3-in. staves.

Merrill Precipitation Presses—One 16-frame, 36-in. press and one 8-frame, 36-in. press. Combined capacity, 300 tons clarified solution per 24 hr.

Barren Solution Tanks—Two fir tanks, 20 ft. in diameter by 14 ft. deep, with 3-in. staves.

Merrill Zinc Dust Feeders and Emulsifiers—Two of each.

Furnaces—One 3-muffle drying furnace. Two Case oil-fired furnaces taking No. 135 crucible.

Water Wheel—One 6-ft. Pelton water wheel.

Air Compressor—Sullivan Class WG3, 14 in. by 12 in., single-stage belt-driven air compressor; 342 cu. ft.

FIG. 4—MILL BUILDINGS AND TRAMWAY TERMINAL

FIG. 5—LOWER END OF MILL

free air per minute; 20 lb. per square inch pressure. Requires 26 hp.

Power

The mill is belt-driven directly from a main line shaft which is belted to the Pelton wheel. The hydraulic installation consists of a pipe line 4000 ft. long, with 1036 ft. of wooden flume feeding the pipe from the east fork of Pine Creek. There is 1000 ft. of 10-in. 12-gage spiral riveted pipe with bolted joints, 1000 ft. of 10-in. 14-gage spiral riveted pipe with bolted joints, and 2000 ft. of 11-in. 16-gage spiral riveted pipe with slip joints. The actual head of water on the wheel is 537 ft., and the gage pressure at the wheel is 221 lb.

The maximum power developed is about 165 hp., but it takes only about 120 hp. to run the mill. After installation of the power plant it was found there was enough water available for development of as much more power, and another wheel is now being installed.

Operation

A flowsheet of the operation of the mill is shown in Fig. 6.

The ore is dumped from the tramway buckets on to a grizzly set with 1½-in. spaces, from which the undersize goes to the battery bin and the oversize to an Austin gyratory crusher, crushing to 1½ to 2½-in. size. Each battery of five stamps is fed from the bin by a Challenge feeder.

Crushing is done in a cyanide solution of 1.5 lb. KCN per ton strength and 1.0 lb. per ton CaO alkalinity. Lime is added in one battery. Ton cap screens of 25 mesh are used.

After passing over the plates the pulp, consisting of about five tons of weak solution to one ton of ore, passes to a duplex Dorr classifier, where the sand and slime are separated. The sand is about 60 per cent of the total ore and the slime 40 per cent.

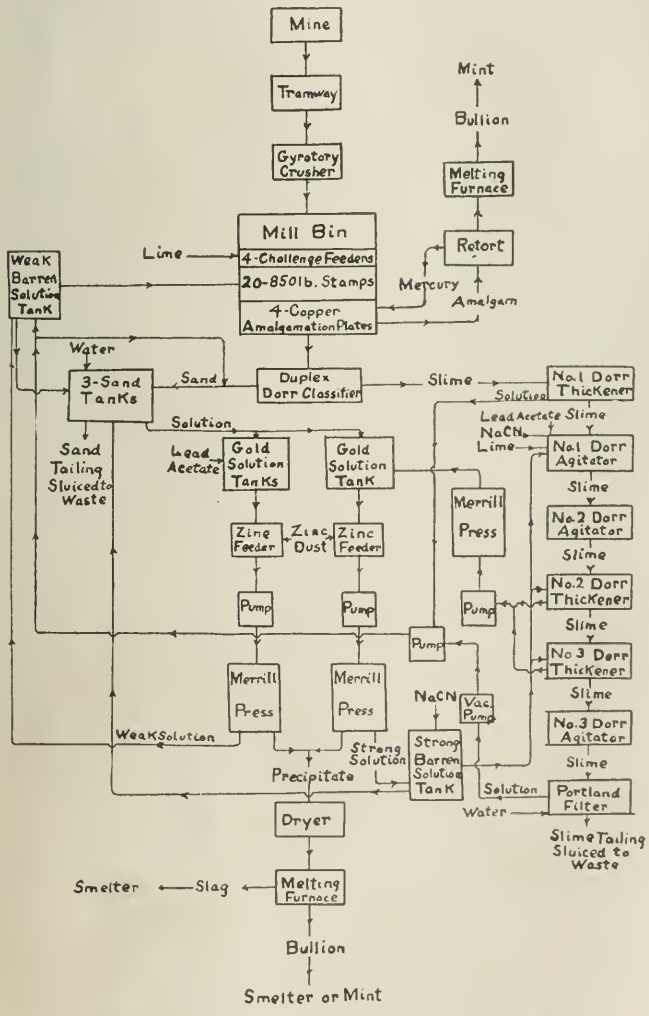

FIG. 6—FLOW-SHEET CYANIDE PLANT OF BAKER MINES CO.

The sand, containing about 25 per cent moisture, is diluted with weak solution as it leaves the classifier, and is lifted by an air lift which discharges to the sand distributors at each leaching tank. The sand is leached with a solution containing 3 lb. per ton KCN and 1 lb. per ton CaO, called the strong solution. The first wash is with 1.5 lb. KCN solution from the weak storage tank, and the final wash is with water. Sodium cyanide is used to keep the solutions up to the required strength. The sand is discharged from the tanks by sluicing with high pressure water into a flume going to a tailings dam. Solutions percolating from the leaching tanks are turned into the weak or strong gold solution tanks as seems advisable and precipitated in Merrill presses. All of the strong solution is precipitated and most of the weak.

The slime leaves the Dorr classifier at a consistency of ten parts of liquid to one of solids, and flow by gravity into No. 1 Dorr thickener, a 30-ft. thickener. The overflow from No. 1 thickener goes to a 3-in. centrifugal pump, which pumps what solution is needed to the sand lift and the balance to the weak storage tank. The pulp from No. 1 thickener, of a 1 to 1 consistency, is lifted to a launder discharging into No. 1 agitator. In the agitator the pulp is diluted with strong solution to maintain a ratio of liquid to solids of 2.5 to 1. Sodium cyanide and lime are added to keep the agitator solution of 3 lb. KCN strength and 1 lb. CaO alkalinity.

The pulp passes from No. 1 agitator to No. 2 agitator and then to a 20-ft. Dorr thickener. Here dilution with strong solution is made 3.5 to 1. The overflow from this thickener passes into the feed box of a 2-in. centrifugal pump, which pumps through a Merrill clarifying press and discharges into the strong gold solution tank. In No. 2 thickener the pulp is thickened to 1.5 to 1, and raised by an air lift to No. 3 thickener, a 30-ft. thickener. In this thickener there is further dilution with strong solution to a ratio of 4 to 1. The overflow from the thickener is pumped through the clarifying press. The pulp is thickened to 1 to 1, and discharges by gravity into No. 3 Dorr agitator, which is used as a storage agitator, and at first was run without air agitation, simply mechanical agitation, but later the pulp was aerated as it appeared to increase extraction.

The pulp runs from the bottom of No. 3 agitator to the Portland filter. The slime from the filter discharges into the tailings flume, and the solution goes to the 3-in. centrifugal pump and enters the weak mill solution. The slime was at first washed at the filter with only one water spray, but now has several.

There is one strong gold solution tank and two weak gold solution tanks. One of the weak solution tanks is used chiefly to receive muddy solution from the leaching tanks when a tank is beginning to be filled, and when the clarifying press is being cleaned. The solution from this tank is precipitated only after it has settled well.

The strong solution containing about 2.5 lb. KCN and 1 lb. CaO per ton is pumped through a 16-frame Merrill precipitation press, which discharges barren solution to the strong storage tank, where it is strengthened with sodium cyanide to 3 lb. KCN per ton.

The solution from the weak gold solution tanks is pumped through an 8-frame Merrill press which discharges barren solution to the weak storage tank. No cyanide is added in this tank but enough is added in the weak gold tanks to keep the strength at 1.5 lb. KCN per ton before precipitation, as experience has shown that with much lower strength there is not a satisfactory

precipitation. Some lead acetate is added in the weak gold tanks and also in No. 1 agitator.

The precipitation presses are cleaned up three times per month, and the precipitate dried in a muffle furnace. The dried precipitate is melted in Case oil-fired tilting furnaces, giving a low grade gold-silver-copper bullion as a product.

Amalgamation

Amalgamation is carried on in cyanide solution with poor efficiency of amalgamation, as is usually the case. While extraction by amalgamation is not high, amalgamation serves a useful purpose in that it catches the coarse gold not extracted by the cyanide solution. Even with amalgamation there is some loss of coarse gold as was shown by a concentration test on the tailings.

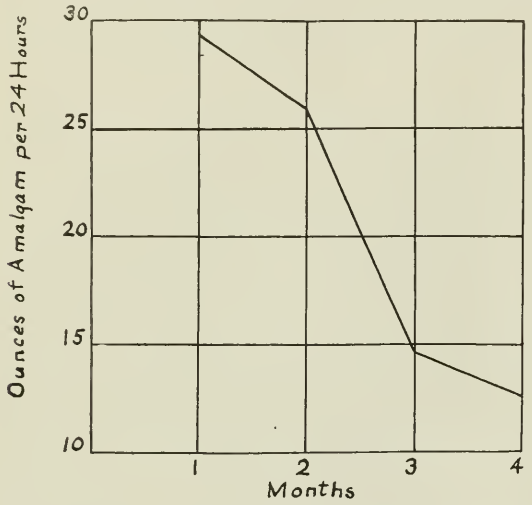

FIG. 7—EFFECT OF AMALGAMATION FOR FOUR MONTHS IN CYANIDE SOLUTION ON RECOVERY OF AMALGAM

During the first month and a half of operation of the mill oxidized ore was milled with the production of a considerable amount of gold by amalgamation. At the end of that period the ore became strongly sulphide with a small amalgam production. In the four months following the treatment of oxidized ore, the average production of amalgam was 20 oz. per day of an average value of $2.62 per ounce.

During the first two months of operation the plates were dressed once per shift, or three times per day. Later they were dressed six times per day, and scraped as clean as possible in the daily clean-up. In spite of this the plates became hard and the recovery by amalgamation dropped off, the percentage of total extraction by amalgamation falling from 9 per cent to 5 per cent.

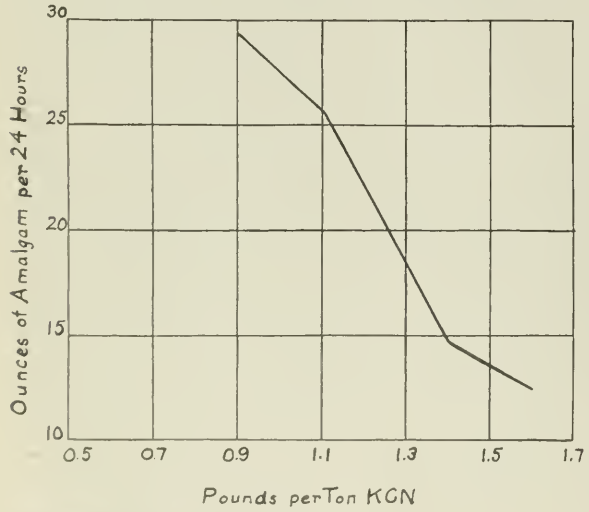

FIG. 8—EFFECT OF STRENGTH OF CYANIDE SOLUTION ON RECOVERY OF AMALGAM WHEN AMALGAMATING IN CYANIDE SOLUTION

The effect of the cyanide solution in hardening the plates and decreasing amalgamation from month to month is shown in Fig. 7. Fig. 8 shows the drop in amalgamation caused by the increased strength of the battery solution. In starting the mill the weak solution was allowed to build up gradually, cyanide being added only to maintain precipitation. The value of ore milled remained about the same during these four months, not varying enough to influence the value of the data. In the second month, where the value of the battery heads increased $2.50 per ton, the efficiency of amalgamation still continued to drop. The tonnage milled varied between 61.8 tons per day and 67.1 tons, the largest tonnage being handled in the fourth month when the average ounces of amalgam per day was at its lowest.

AMALGAMATION IN CYANIDE SOLUTION

Month	Average Value Battery Heads per Ton	Average Ounces Amalgam per Day	Average Strength Battery Solution KCN Pounds per Ton
1	$13.66	29.2	0.9
2	16.22	25.9	1.1
3	13.58	14.8	1.4
4	13.35	12.5	1.6

Leaching

The Dorr classifier delivers a sand product containing 20 to 25 per cent moisture, of which a typical sieve analysis is the following:

		on 40	20.5	per cent
through	40	on 60	24.5	per cent
through	60	on 80	18.0	per cent
through	80	on 100	21.0	per cent
through	100		14.5	per cent

The sand is diluted with weak solution to 5 to 1 before going to the air lift, which delivers it at the sand distributors in the leaching tanks. The use of an air lift for the sand instead of a sand pump has proved very satisfactory, the lift giving no trouble and showing no wear except for one nipple, which is replaced about every four weeks. The lift piping is 2½ in. in diameter. The height of lift is 14 ft., with a submergence of 17 ft. The lift does not discharge into launders, but its piping is continued to the center of each leaching tank. Distributors of the revolving-arm type are in use, made by two concerns, but neither operate satisfactorily because of the small tonnage handled.

In filling a tank the drain valve is left open for several hours, when it is kept closed until the tank is partly filled with solution, so that the sand settles in solution. The solution overflow goes to the 3-in. centrifugal pumps.

When full the sand is leveled and strong solution containing 3 lb. KCN and 1 lb. CaO per ton is turned on so as to keep the surface covered for about 12 hr. Then the tank drains for 12 hr. and the cycle is repeated. The strong solution treatment lasts five days, when weak solution is used for washing, followed by a water wash, both extending over two to three days. The draining solution usually runs into the weak gold solution tank for a day, when it is turned into the strong sump, and finally back into the weak after the weak solution and water washes are applied. The turning point in KCN strength depends chiefly on the tonnage of strong and weak solutions.

The tank charges average 180 tons, and when well drained are sluiced out to the tailings flume with a high pressure water hose, one tank being discharged by a man in about 7 hr. The four discharge gates in

each tank are not well located for sluicing, as shoveling and tramming was first used, but discarded when it was found possible to give a tank only three days' treatment with 3 lb. solution. By this change the cost of removal of tailings was reduced from 10 cents per ton to 3.5 cents and the extraction much improved.

Below are tabulated the results of solution samples taken from a tank during its cycle of strong solution, weak solution wash and water wash. The sample taken 24 hr. after the first application of 3-lb. solution is still low in cyanide, but its value shows the dissolving effect of the 1.5-lb. solution during the filling of the tank. These assays are shown graphically in Fig. 9.

GOLD BEARING SOLUTIONS FROM LEACHING SANDS

Hours After First Bath of 3-Lb. Solution	Pounds KCN per Ton	Pounds CaO per Ton	Ounces Gold per Ton	Ounces Silver per Ton	Per Cent Copper
24	1.3	1.2	0.166	0.19	0.088
48	1.9	1.3	0.134	0.43	0.102
72	2.0	1.0	0.126	0.48	0.099
96	2.0	0.9	0.116	0.53	0.105
120	1.8	1.0	0.102	0.42	0.101
144	1.8	0.8	0.086	0.27	0.092
168	0.9	1.0	0.011	0.17	0.037
192	0.6	0.6	0.022	..	0.024

The soluble values in the sand tailings amount to about 10 cents per ton gold, and 0.15 lb. KCN per ton of ore. A little more washing would cut down losses, but time is not available. The tailings from the above tank contained 0.07 oz. gold per ton and 0.89 oz. silver, or $1.86. The sand tailings average from $1 to $3 per ton, depending on the grade of the heads. The sand is 60 per cent of the ore and the slime 40 per cent, but the total value of sand and slime heads are about equal, as the slime contains 50 per cent more of the values than the sand.

Slime Treatment

The Dorr classifier delivers a slime product of the following sieve analysis:

	on 100	3.31 per cent
through 100	on 150	2.88 per cent
through 150	on 200	8.07 per cent
through 200		85.80 per cent

This slime is a very fine slime and not as sandy as slime from fine grinding. This makes the operation of the thickeners and agitators easy, as the slime does not pack after a shut down. It is, however, a rather difficult slime for the filter, and makes cleaning the filter once a week necessary, although the filter is operated only 8 hr. per day.

The slime assays 0.6 oz. per ton gold, 5 oz. silver and 0.15 per cent copper, as compared with sand from the same ore containing 0.45 oz. gold, 2.5 oz. silver and 0.10 per cent copper. The sulphide is also higher in the slime. The slime tailings contain from $1.50 to $3 per ton, a considerable part of which is silver, on which the extraction is very low. With the single water spray on the filter, as originally installed, the soluble losses have been high at times, and never under 5 cents per ton.

Precipitation

Both domestic and foreign zinc dust have been used for precipitation. The domestic has caused trouble at times because of the metallic shot it contains, which clogs the emulsifiers unless the zinc dust is carefully screened. Also the domestic zinc dust is not well packed, resulting in considerable loss in shipment, which is not the case with foreign material.

At times the zinc dust consumption is high because of copper in solution, and it varies from 0.7 lb. to 1.25 lb. per ton of ore. During a period in which the zinc dust consumption was 0.73 lb. per ton of ore, the consumption per ton of 1.5 lb. KCN solution precipitated was 0.28 lb., and per ton of 2.5 lb. KCN solution precipitated was 0.15 lb. For all solutions precipitated the zinc dust consumption was 0.2 lb. per ton of solution. Per ton of ore milled 3.4 tons of solution were precipitated. Of this solution 1.2 tons was weak solution and 2.3 tons strong solution.

In starting the mill no cyanide was added to the battery solution or weak solution until it began to carry values picked up in washing. When it became necessary to precipitate, an attempt was made to use as little cyanide as possible because of the high price at that time. Lead acetate was used to assist precipitation, but it was eventually found that satisfactory precipitation could only be obtained regularly when the weak solution contained 1.5 lb. KCN per ton. Cyanide is now added at the weak gold solution tank to bring the strength to 1.5 lb. before precipitation.

No cyanide is added to the strong gold solution tank which averages 2.5 lb. per ton before precipitation. About 0.18 lb. of lead acetate is used per ton of ore. Of this 0.04 lb. per ton of ore is added in the weak gold solution tank, and the balance at the agitators.

The difficulties encountered in attempting to precipitate values from solution of low cyanide content are shown in the following table and in Fig. 10. The results given are averages of several months' operation:

ZINC DUST PRECIPITATION FROM WEAK CYANIDE SOLUTION

Pounds per Ton KCN in Solution	Per Cent of Total Value Precipitated	Pounds per Ton KCN in Solution	Per Cent of Total Value Precipitated
0.65	0	1.3	91.4
0.7	0	1.4	94.6
0.8	43.4	1.5	94.9
0.9	64.2	1.6	96.6
1.0	57.8	1.7	98.0
1.1	85.7	1.8	95.0
1.2	89.9	1.9	97 9

Effect of Copper on Extraction

The percentage of copper in the battery heads has varied from zero to 1.75 per cent. For a period of a month it has averaged 0.21 per cent. At first the copper gave considerable trouble, and resulted in a lower extraction, especially of the silver, which seemed to be

FIG. 9—GOLD, SILVER, COPPER, KCN AND CaO CONTENTS OF SOLUTION DURING A LEACHING CYCLE

present in a more complex sulphide form when copper was high. Lead acetate was tried to assist solution, but the character of the ore is so changeable that it is impossible to attribute improved extraction entirely to it.

During the first months of operation cyanide was used as sparingly as possible, costing 40 cents per pound of NaCN, because it was believed that with the low-grade ore being milled it was cheaper to get a lower extraction with weaker solutions than to aim for a higher extraction with increased cyanide and zinc dust consumption, because of the copper going into solution more easily. The cyanide consumption varied from 1.25 to 1.6 lb. NaCN per ton and the zinc dust consumption from 0.75 to 1.0 lb. per ton while copper-bearing ore was milled.

The copper in the ore does not seem to affect the gold extraction much, but does lower the silver extraction. It was found that by keeping the solutions clean by use of excessive amounts of zinc dust at times when the copper was highest, there was little effect by the copper on the total extraction. When the solutions contain around 0.05 per cent copper no difficulty is experienced either in extraction or precipitation. The precipitate contains much copper and gives a very base bullion in the simple melting process used.

Operating Data and Costs

Tables I and II give a summary of operating data and costs for a certain period of operation. The costs do not include melting. The labor requirements for the mill are: One crusherman, one amalgamator, two batterymen, three solution men, one night foreman, one mechanic, and two laborers.

Table I—Summary of Milling Record

Average value per ton	$13.35
Average tons per day	66.1
Per cent of possible time run	97.5
Cyanide consumed per ton of ore, pounds	1.27
Lime consumed per ton of ore, pounds	4.29
Zinc consumed per ton of ore, pounds	0.73
Lead acetate consumed per ton of ore, pounds	0.18
Mercury consumed per ton of ore, ounces	0.19
Per cent extraction, gold, bullion and tails	87.23
Per cent extraction, silver, bullion and tails	43.23
Total per cent extraction, bullion and tails	80.44

Paul W. Gaebelein, the present mill superintendent, has kindly made the following statement regarding changes in plant practice since May, 1915:

"1. *Strength of Cyanide Solutions.*—It was decided that, in order to obtain a better extraction of the silver and possibly the gold, the solutions would have to be strengthened, and this was done starting May 1. The strong solution was raised to an average of 5 lb. per ton KCN, and the weak solution to 2.5 lb. KCN per ton.

Table II—Distribution of Milling Costs

	Per Ton of Ore
Agitation and thickening	$0.052
Amalgamation	0.023
Assaying	0.117
Clarifying and precipitation*	0.233
Classifying	0.009
Cleaning up mill	0.043
Crushing	0.143
Cyanide**	0.509
Experimental	0.080
Filtration	0.038
General mill expense	0.100
Heating	0.058
Leaching	0.041
Lighting	0.031
Neutralization	0.055
Power	0.002
Pumping solutions and handling pulp	0.046
Sampling	0.025
Shoveling in bins	0.004
Stamping	0.289
Superintendence	0.143
Tailings disposal	0.037
Watchman	0.025
Total	$2.103

*Zinc dust, 22 cents per pound.
**Sodium cyanide, 40 cents per p

By adding cyanide to the flow of pulp entering the agitation tanks, the strength of solution in the agitators was kept at about 3.5 lb. KCN. The result of strengthening the solutions became apparent at once. The gold extraction has increased to 89 per cent and the silver extraction to between 50 and 55 per cent. The consumption of cyanide also increased, but not to a great extent. The normal consumption with the strengths of solution given above and with an average value of ore of $24 per ton, averages 2.5 lb. per ton milled.

"2. *Amalgamation.*—The plates at the battery were retained. Some experiments were made with a view to amalgamating the sand tailing as it was discharged from the leaching vats, but the results showed that this could not be done and a saving made which would justify the removal of plates at the battery. At present the plates save a varying amount of free gold. The average for the last four months may be taken at 12 oz. of amalgam per day of an average value of $5.50 per ounce, or a saving of approximately $1 per ton of ore milled.

"3. *Slime Treatment.*—Experiments were being conducted in this department which may be outlined as follows: The filter is served by a 20-ft. by 16-ft. Dorr agitator used as a stock tank. This agitator was being run full, and the increased extraction by this method over the former method of keeping the pulp level lower was noted. The increased agitation showed a saving of approximately 75 cents per ton, accounted for by the fact that the pulp receives approximately 8 hr. longer agitation, and the barren, strong solution comes in contact with the pulp just before entering the agitator.

"4. *Filtration.*—The Portland filter in use gives excellent satisfaction. The washing of the cake, however, was not as good as could be obtained, and to increase the efficiency at this point three lines of spray nozzles were installed. Each line has three nozzles, which force the water under pressure into the cake, and which keep the entire surface of the cake covered with a fine film of water. The use of the sprays has lowered the dissolved loss in the cake considerably, and by manipulation of the nozzles the solutions are easily kept in balance.

"5. *Free Gold in Sand Tailings.*—The sand tailing has been subjected to amalgamation as noted previously. The results have been rather negative. In looking for the reasons for this it was found that the free gold in the tailing was coated and very rusty. For this reason it probably escaped the battery plates. Determinations as to the amount of free gold being lost in

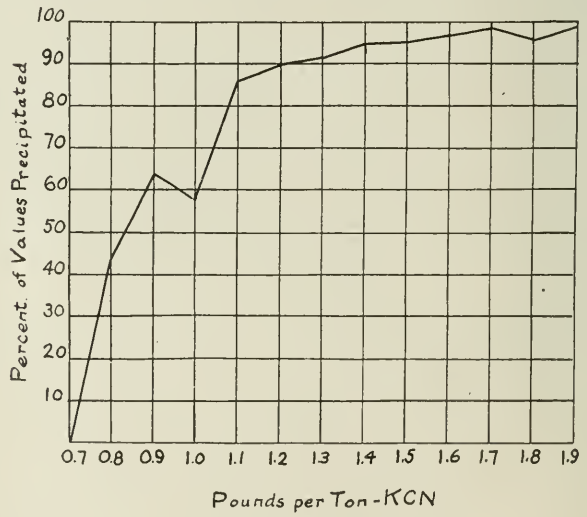

FIG. 10—EFFECT OF STRENGTH OF SOLUTION ON PRECIPITATION OF GOLD AND SILVER FROM CYANIDE SOLUTIONS WITH ZINC DUST

the sand tailing are now being made. The amalgamation of the tailing has shown an average recovery of 2.5 cents per ton of sand. This would tend to show that the loss in the sand tailing in free gold is something over 3 cents per ton.

"6. *Extraction.*—The extraction at the present time, on ore averaging $24 per ton, is 85.5 per cent. With the grade of the ore at $20 or over, the ore carries a very considerable amount of easily soluble copper, and this interferes considerably. With a little lower grade of ore, and a consequent lower copper content, it is expected that the extraction will show an improvement over the figures given above."

Metastability of Metals

BY A. VOSMAER

In continuation of the article on the same subject in the issue of Sept. 1 of this journal, on the metastability of bismuth, antimony, potassium and copper, I shall now give a brief account of the publications of Prof. E. Cohen of the Van't Hoff Laboratory, Utrecht, in the *Transactions* of the Royal Academy of Science, Amsterdam, Holland, on the metastability of other metals.

The importance of the subject may well be judged from Professor Cohen's statement: "Physical constants of metals, as they are given to us for the present, have to be considered as chance values, which are a function of the past thermal history of the material experimented upon." (*Zeitschrift für Physikalische Chemie*, 1915). All of us who have to do with physical constants are fully aware nowadays that the greater majority of figures given in the usual tables are nothing but approximations, good enough for orientation, but no more than that, and certainly they are far away from being as accurate as is suggested by the number of decimals which are usually given. Accurate recent determinations of the electric conductivity of "pure copper" of recent date, range from 62 to 65.2, so we should be very cautious when trusting on figures for properties.

To Cohen we are obliged for the explanation *why* it is that there is such a diversity in the figures for physical constants; indeed there is very little constancy in them. Cohen has conclusively shown that if a sample of a metal is chemically pure, this does not necessarily mean that it is also physically pure; that is, a 100 per cent metal *M* may be composed of *b* per cent alpha *M*, *c* per cent beta *M*, *d* per cent gamma *M*, etc.

The allotropic modifications of a metal exercise a very marked influence on its properties and for this reason a figure for some property is a chance figure, its value depending on the ratio of alpha, beta, gamma, etc., modifications in the sample. Add to this the fact that the state of molecular equilibrium is not the most frequent one in ordinary metals and that, on the contrary, all metals are as a rule in a metastable state, and it will be easily understood that the past history of a metal or alloy is of paramount importance because it determines the mutual ratio of allotropic modifications. It goes without saying that the *thermal* past history is of chief importance in this connection.

Allotropy of Cadmium[1]

Matthiesen's researches on the electric conductivity of metals (1862) are familiar to every student. In fact, notwithstanding the early date of his experiments, his figures are quoted in a great many instances, and some still accept Matthiesen's standard copper = 100, although modern copper has a conductivity higher than 100, according to this scale, and although the modern system of units should be preferred to any arbitrary scale of obsolete character. Even Matthiesen in his day noticed for cadmium a marked molecular change at a certain temperature (80 deg. C.).

Cadmium, like most metals, shows the usual inertia for change, and the retardation is so great that special precautions have to be taken to notice the change; this is probably the cause why the allotropic modifications have escaped the attention of former scientists. The change, alpha to beta cadmium occurs at 64.9 deg. C. The beta cadmium has a larger specific volume than the alpha modification; this explains Matthiesen's observation that at 80 deg. C. his sample of cadmium was so brittle as to fall to pieces.

From measurements with the pyknometer and the dilatometer, Cohen and his pupils concluded that cadmium has a transition temperature at 64.9 deg. C. and that this metal in general is a metastable system in consequence of the very strongly marked retardation which accompanies the reversible change of the allotropic modifications, both below and above their transition points.

Former experiments on copper and zinc pointed to the desirability of investigating whether or not cadmium did or did not exist in more than two allotropic modifications, and further research proved that, like copper and zinc and other metals, cadmium may exist as alpha, beta and gamma cadmium, the proportions of which depend on the past history of the sample, and this being so, the transition point 64.9 is only an apparent one. It seems probable that above 100 deg. C. the gamma cadmium is the stable form and below 50 deg. C. the alpha cadmium, so that in between 100 deg. and 50 deg. cadmium is chiefly beta cadmium.

The exact behavior of cadmium is of paramount importance for the construction of standard cells as each cadmium modification has an electrolytic potential of its own.

Ordinary cadmium has to be stabilised to the alpha form before use in a cell, if not the "standard" voltage is bound to vary, to decrease, until all the metal has been changed to alpha cadmium.

It may be well to mention here that the metastable transition point of the reaction alpha cadmium $\rightleftarrows$ gamma cadmium is 94.8 deg. C., and that if one gram-atom of alpha cadmium is transformed into gamma cadmium, the change is accompanied (at 18 deg. C.) by an absorption of 739 gram calories. Electrolytically deposited cadmium is not the stable alpha but the unstable gamma cadmium. This fact is quite in accordance with what should be expected and is of practical importance since the method of making cadmium cells is to deposit the metal electrolytically. This is another instance of the common phenomenon that it is not the stable modification of a metal that is first formed, but the stable form has to be reached via unstable forms.

The conclusions arrived at are: First, that the metal cadmium, as familiar to us is a metastable system containing more than two allotropic modifications, and, second, many of the mysterious phenomena belonging to cadmium cells can be explained when taking into consideration the above mentioned fact.

Allotropy of Lead[2]

Rather large discrepancies in the physical constants given for lead indicate that here again we have to do with a metal in more than one modification.

The density of purest lead (Kahlbaum 0.001 per cent Cu, 0.0006 Fe) taken as 11.324, increases to 11.341 after treatment at 15 deg. C., it decreases again to

[1]Communications, Oct., 1913; May, 1914; Oct., 1914; Jan., 1915.

[2]Communications of Nov., 1914; Jan., 1915.

11.313 after treatment at 50 deg. C., and it increases again to 11.328 after treatment at 25 deg. C.

The experiments have not yet been concluded, but from what could be observed it is evident that lead, as it has been known up to the present, forms a metastable system containing simultaneously several allotropic modifications of this metal.

The well known form of lead as a lead-tree is one of the metastable modifications.

Allotropy of Zinc[3]

Scientists seem to have recognized as early as a century ago that zinc is not always the same substance. Practical men have known as long as they have used zinc that one of its peculiarities is that in summer time it expands, but after return to average temperature it does not return to its original dimensions.

In a cold winter zinc contracts but never again resumes exactly the original length, and everyone familiar with zinc roofing knows that zinc should never be cut lengthwise, but always crosswise, though the greater length lengthwise would encourage one to do otherwise if he has to make long strips for tubing or other building purposes.

Practical men know that new zinc possesses that property of not resuming again its original length in a much greater degree than old zinc. Real trouble may result from neglecting the fact that zinc, and more especially sheet zinc, is a metal not to be trusted as regards its length. In case we have circular discs, as is often the case with instruments, warping is the effect of said unequal behavior lengthwise and crosswise the direction of rolling.

The researches of Cohen have not elucidated the strange phenomena. They are strange unless they also can be attributed to metastability at ordinary temperatures.

Practical men also know that zinc cannot be rolled unless heated to a temperature of about 120 deg. C., and they also know that zinc can very easily be pulverized when heated to about 200 deg. C. Cohen did find that prolonged heating to 25 deg. C. had a very marked influence on the density of the zinc. A considerable contraction occurred. Further data are promised by Cohen.

For another transition point, temperatures of 350 deg., 321 deg., 330 deg. 300 deg. are given by different authors, also 170 deg., so that for the present it is best to wait until Cohen and his collaborators will have finished their determinations.

Allotropy of Sodium

The change from alpha sodium to beta sodium does not occur, but beta sodium changes to alpha at a temperature of about 95 deg. C. The transformation of sodium evidently is a case of monotropy that means that the change of one modification into the other is not reversible, it goes one way only. For the present this fact is hardly of any technical importance.

The lesson to be learned from these results is that all numerical data bearing on physical constants have to be revised or checked. No figures should be trusted, and experiments should be carried out on pure metals in their stabilized form. Physical "impurities" in the form of allotropic modifications influence the properties quite as strongly as chemical impurities.

The **Explosibility of Acetylene** is the title of technical paper 112 of the Bureau of Mines. Results of experiments on acetylene—air mixtures and their relation to mining are given. The authors are G. A. Burrell and G. G. Oberfell.

Thermal Principles of the Blast Furnace

BY J. E. JOHNSON, JR.

(*Concluded from page* 910)

The Thermal Effect of Loss of Fuel By Solution

This is a subject which has been little understood, although as early as 1879 Gruner stated that the condition of ideal working required the fuel burnt by the blast at the tuyeres to be a maximum and that dissolved by the oxygen of the charge a minimum.

Prof. J. W. Richards in a brief paper before the International Congress at Düsseldorf in 1910 has attempted to refute this theorem in regard to furnaces requiring little hearth heat such as charcoal furnaces working on rich ores and therefore producing little slag. In this case Professor Richards claims that Gruner's "ideal working" would be wasteful, and greater economy is obtained by departing from it as far as possible. I am unable to accept this conclusion for two reasons. First, I have myself run a charcoal furnace on rich ores, and it is a matter of sad experience with me that when the departure from Gruner's ideal working is considerable, as shown by the small quantity of blast required to burn a pound of fuel the fuel economy is poor, and when the quantity of blast to burn a pound of fuel goes up the fuel economy increases in the same proportion, in exact accordance with Gruner's theorem. Second, Professor Richards' conclusions are contrary both to the double thermal equation, which I have outlined above, and to the old-style heat balance, even for conditions entirely outside those of present practice.

TWOFOLD FUNCTION OF THE CARBON

Just why Gruner's theorem should be true is not apparent on the surface. We naturally think that as the purpose of the blast furnace is to reduce iron ore with carbon, the sooner the carbon starts on its task the better. The reason this is not true depends fundamentally upon the fact that the carbon has to perform two functions and that its capacity for the two tasks is very different. One of its duties is to reduce the iron ore by carrying off the oxygen, the other is to supply the heat for this reaction which is highly endothermic and for the other requirements of the process which are just as important. Referring to Table III it will be seen that when carbon burns to CO_2 it develops 5470 B.t.u. per pound of O consumed, while the dissociation of iron oxide absorbs about 7500, this varying slightly with the oxide. If the carbon is burnt only to CO the conditions are much worse since in that case the heat developed per pound of oxygen is only 3280 B.t.u.; less than half as much as the removal of the same qantity of oxygen from the ore requires, so that for purely thermal reasons we must have in this case about twice as much carbon as would suffice for reduction.

From the thermal balances already given it may be seen that the total heat required is about twice as great as the reduction heat, and on this basis the surplus of carbon required for heat development over that for oxygen removal is still greater. The greater includes the less, and our problem is then one of heat development, not of oxygen removal.

Turning then to the heat developed, that per pound of carbon burnt to CO is 4375 B.t.u. and per pound burnt to CO_2 is 14,750 more than three times as much. We have already seen that the carbon necessary for heat development is two or three times as large a quantity as can be oxidized by the oxygen of the ore, therefore in order to burn it with any degree of completeness we must have oxygen from some other source. This source must obviously be the blast. We have seen that the heat developed for one unit of oxygen per unit

of carbon (producing CO) is less than one-third of the heat developed for two units of oxygen per unit of carbon (producing CO_2).

Turning this statement around we may say that the second unit of oxygen develops over one-half more heat than the first or that the rate of heat development after consuming the first unit of oxygen is much more rapid, in proportion to the oxygen used, than the rate up to that point. In other words, the more oxygen we deliver to carbon the more heat we shall get in an increasing degree right up to the point of saturation, CO_2.

These facts are all the results of a single cause, that the addition of the first unit of oxygen to carbon results in its conversion from the solid state into the gaseous with the absorption of a large amount of latent heat of vaporization exactly as when ice is converted to water and the water to steam. The second unit of oxygen develops 10,400 B.t.u. per pound of carbon, if the first did as much the heat developed per pound of carbon burnt to CO_2 would be 20,800 B.t.u., instead of the 14,750 actually developed; the 6050 B.t.u. which disappear represents the latent heat of gasification of the carbon.

THE OXYGEN WHICH CAN BE IMPARTED TO THE CARBON IS LIMITED

Now we are strictly limited in the amount of oxygen we can impart to the fuel in the hearth by the fact that CO_2 cannot exist at all in the presence of incandescent carbon, therefore if we burn *all* the carbon of the fuel to CO at the tuyeres we have reached the limit, and any carbon which is dissolved in the upper part of the furnace and fails to reach the tuyeres deprives us of the power of imparting a corresponding amount of oxygen, which deficiency can never be made up and represents a net loss of heat development when the gas is discharged from the stock.

MINIMUM AMOUNT OF CARBON HAS SUFFICIENT OXYGEN-CARRYING POWER

In order to confirm this conclusion, let us take the case to the limiting condition. Let us suppose that CO could be oxidized entirely to CO_2 by oxygen of the ore, then the heat developed per pound of carbon would be 14,750 B.t.u., and let us assume that the minimum heat requirements are 75 per cent more than the heat of reduction which for Fe_2O_3 is 3145 B.t.u. per pound of iron, so that the total requirements per pound of iron would be 5500. Then 0.373 lb. of carbon would be required per pound of iron, and if this were all burnt to CO at the tuyeres (Gruner's ideal working) it would take up $0.373 \times 4 \div 3 = 0.497$ lb. of oxygen there and would require as much more from the ore to saturate it, producing all CO_2 at the top of the furnace. The oxygen per lb. of pig iron in Fe_2O_3 is $0.95 \times 0.428 = 0.406$ lb., which would convert the CO formed at the tuyeres to 82 per cent CO_2 and 18 CO, about the equilibrium ratio for 900 deg. as we have already seen. In other words, the theoretical minimum of carbon would have oxygen-carrying power sufficient to reduce the ore completely, and if any of the possible oxygen be lost by the failure of a part of the carbon to reach the hearth and take up its share there, the total supply would be insufficient for the oxidation of the carbon to this equilibrium ratio.

COMPARATIVE RESULTS WITH VARYING SOLUTION LOSS

In order to show the facts in regard to this question graphically I have made an analysis of it by taking the solution loss as the independent variable which brings out some facts that are the exact opposite of generally accepted opinion.

For simplicity I have assumed that the iron produced contains no manganese and phosphorus and that the silicon is 1.5 per cent, this assumption gives results practically identical with those which would result from the use of the actual percentages of these three metalloids in ordinary steel-making irons.

Let us assume as the basic case a furnace working with a slag volume of 50 per cent and making a ton of iron containing 1½ per cent Si with a ton of coke (2240 lb.) and blown in four different cases with 50, 55, 60 and 65 cu. ft. of actual air at 70 deg. Fahr. Let us assume that the coke contains 2000 lb. of fixed C and that 80 lb. of this are required for carbonizing the iron, leaving 1920 lb. for combustion. Let us disregard the work done in the hearth altogether and consider the materials which descend to the hearth as discharged from the shaft in the solid condition at the top of the bosh. We have already seen that such a calculation is possible in spite of our complete ignorance of the temperatures at which the gases in the charge are driven off and consequently of how much heat it required to raise them to this unknown temperature. We charge against the total heat received plus that developed in the shaft, the heat required for the chemical reactions of the shaft and that discharged from the bottom of the shaft and by radiation, the balance is then credited to the top gases, and from it we can readily figure the temperature of the latter. The temperatures found by this method in the different cases will evidently give us a measure of the effect of solution loss in the shaft of the furnace.

EFFECT OF SOLUTION LOSS ON HEARTH HEAT

The effect of solution loss on hearth heat is simple, almost obvious. The chart, Fig. 1, gives hearth heats developed not per pound of coke charged, but per pound of coke burnt in the hearth, with oxygen from the blast. Obviously any coke which does not reach the hearth can furnish no such heat at all, and it is further obvious on reflection that oxygen from other sources than the blast even set free in the hearth does not count in the development of hearth heat because any such oxygen involves the dissociation of other compounds, FeO, SiO_2 and the like, and there is not enough heat developed by the combustion of such oxygen with carbon to keep the reaction going without additional heat from some other source. So of course there is none available above the critical temperature, therefore no hearth heat developed at all.

Obviously then the hearth heat developed per pound of fuel is directly proportional to the cubic feet of blast required to burn that fuel, other things being the same, that is, the more blast we blow per pound of coke the more hearth heat per pound of coke we develop in exactly the same proportion.

In making the calculation, I have assumed that the blast was dry since this saves much complication in regard to the shaft heat calculations, and the comparative results are not affected at all thereby.

Now our calculation in detail becomes as follows:

CASE 1.—1920 lb. of carbon for combustion (by blast and ore together) equals 0.857 lb. per pound iron; 50 cu. ft. of blast at 75 lb. per 1000 cu. ft. equals 3.75 lb. and 23 per cent of this gives 0.864 lb. O. Assume the ore to be Fe_2O_3 and the iron to contain 95 per cent Fe and we obtain 0.407 lb. of O per lb. iron from this source.

0.015 lb. Si carries with it 0.017 lb. O, and assuming that 0.1 lb. of H_2O is decomposed in the shaft which is about in accordance with Mathesius' and Cornell's figures we obtain 0.089 lb. O from this source. Then the total O per pound of iron is as follows:

From blast (dry)	0.864
From SiO_2 reduced	0.017
From Fe_2O_3	0.407
From H_2O decomposed in shaft	0.089
Total O =	1.377
O required for .857 C to CO = .857 × 16/12 =	1.143
O left for CO to CO_2 = 1.377 − 1.143	0.234
Carbon to CO = (1.143 − .234) × ¾ =	0.681 lb.
Carbon to CO_2 = 0.234 × ¾ =	0.175 lb.

Assuming that 10 per cent of the oxygen of the ore is removed by solid carbon in the hearth in accordance with our previous conclusion we have the oxygen in the hearth as follows:

From blast	0.864 lb.
From SiO_2	0.017
From 10 per cent of O in ore	0.041
	0.922

The carbon consumed in the hearth is therefore 0.922 × ¾ = 0.691 lb.

The CO resulting from the combustion of this is 0.691 × 29.85 = 20.6 cu. ft.

The nitrogen of the blast is .79 × 3 × 50 × 492 ÷ 530 = 36.9, add 20.6 cu. ft. CO and we have 57.5 cu. ft., total gas coming in from hearth.

The sensible heat of this gas at 2750 deg. = 58.8 B.t.u. per cubic foot.

Heat brought into shaft by gas from hearth 57.5 × 58.8 = 3380 B.t.u.

Of the 0.857 lb. carbon charged there is consumed in the hearth 0.691 lb. leaving 0.166 lb. to be consumed in the shaft by oxygen from the ore.

This requires 0.166 × 1.33 = 0.222 lb. oxygen. The ore contains 0.4070, but 10 per cent is not available in the shaft, so all we have available is 0.407 × 0.90 = 0.366 lb., deducting 0.222 lb. from this we have left 0.1440 O from the ore to which we add 0.1 × 8 ÷ 9 = 0.089 lb., the oxygen from the water dissociated in the shaft, making 0.233 lb. O for converting CO to CO_2.

This checks with the total oxygen calculation given before, which is much simpler but does not separate the C into the two portions that burnt to CO and that to CO_2 in the shaft. We can now figure the heat developed in the shaft very simply.

0.166 lb. C burnt to CO develops .166 × 4375 =	727	B.t.u.
0.233 × ¾ C as CO burnt to CO_2 develops 0.175 × 10,400 =	1820	
Add to this the heat brought in from the hearth	3380	
Total heat for operations in the shaft	5927	B.t.u.
To reduce 0.9 of ore, the heat consumed is	2670	B.t.u.
To decompose ½ lb. stone	405	
To heat slag forming materials (½ lb.) to 2750° F.	300	
To heat iron (1 lb.) to 2750° F.	480	
To heat carbon in iron	45	
To evaporate 0.25 lb. H_2O to steam	280	
To decompose 0.1 lb. H_2O from steam	580	
	4760	B.t.u.

On the basis of our assumption that the water evaporated decomposed is a certain percentage of the weight of the iron these items all depend upon the weight of iron produced and vary with it, when we assume the weight of iron produced per pound of coke to vary as we presently shall.

In addition we have radiation which, on the basis of our previous data is 440 B.t.u. per pound of iron under these conditions but is constant and does not increase with the iron per pound of coke, and the heat required to bring up to the critical temperature the coke that goes down out of the shaft into the hearth which, of course, changes with the weight of coke consumed in the hearth.

In this case it is 0.691 C × total heat of coke, 1159 B.t.u. = 800 B.t.u.

Adding these items we have as the total heat required in the shaft

Constant heat required for pound of iron as above	4760
Required for heating coke	800
Required for radiation	440
	6000
Total heat for operation in shaft	5927
Balance (B.t.u.)	−73

This is 73 B.t.u. *more* than the heat developed in the shaft, but let us ignore this fact for the present and say that it merely corresponds to the fact that furnaces never run with so small an amount of blast as 50 cu. ft. per pound of coke, in other words solution loss is never so bad as we have assumed. Presently we shall see that this is not necessarily true, but we will not consider that now, merely assuming for the present that this represents the impossible case.

To compute the temperature of the top gases we can figure their volume and take their specific heat per cubic foot as 0.02 since this is extremely close and the error introduced by that assumption is not important enough to justify an accurate calculation of this factor.

The total carbon from the coke is 0.857 lb. or 0.857 × 29.85 =	25.6 cu. ft.
Nitrogen as above	36.9 cu. ft.
CO_2 from ½ lb. of stone (12 per cent C) = 0.06 × 29.85 =	1.8 cu. ft.
H_2 from 0.1 lb. H_2O = 0.1 × 1/9 × 178 =	2.0 cu. ft.
	66.3

The specific heat of this at 0.02 B.t.u. per cubic foot is 1.33, hence we get −73 B.t.u. ÷ 1.33 = −55 deg. Fahr.

This temperature is normally measured from 32 deg. Fahr., but if we do that we should take account of the heat of the materials charged and it is simpler to reckon the temperature of the top gas from that of the raw materials which makes no appreciable error. Taking this temperature at 60 deg. we have the top gas passing off in this case at 60 − 55 deg. = + 5 deg. Fahr.

The gas analysis in this case is as follows:

CO_2 from combustion 0.175 × 29.85 =	5.3 cu. ft.	
CO_2 from stone as above	1.8 cu. ft.	
	Cu. Ft.	Per Cent
Total CO_2	7.1	10.7
CO from combustion of 0.857 − 0.175 = 0.682C 0.682 × 29.85 =	20.3	30.66
Nitrogen as above	36.9	55.6
Hydrogen from dissociation of H_2O as above	2.0	3.1
	66.3	100.0

Case 2.—We now assume that the solution loss is less, so that 55 cu. ft. of blast at 70 deg., 10 per cent more than in the previous case, are required to burn a pound of coke, other conditions remaining as before.

The oxygen in the blast now becomes 0.864 × 1.1 = 0.95, and the other sources of oxygen remaining the same, the total becomes 0.017 + 0.089 + 0.407 + 0.95 = 1.463, and the oxygen to burn all the coke to CO remaining as before 1.143 lb., the oxygen available for CO to CO_2 is 1.463 − 1.143 = 0.32 lb., which burns 0.24 lb. C to CO.

The coke burnt in the hearth is ¾ (0.95 + 0.017 + 0.041) = ¾ × 1.008 = 0.756 lb.		
CO formed by this is 0.756 × 29.85 =	22.6	cu. ft.
The nitrogen is 36.9 × 1.1 =	40.6	
Total gas coming in from hearth =	63.2	cu. ft.
Heat brought in by this at 2750 deg. = 63.2 × 58.8 =	3710	
C burnt to CO in shaft = 0.857 − 0.756 = 0.101		
Heat produced by this 0.101 × 4375 =	438	
C as CO burnt to CO_2 in shaft as above 0.32 × ¾ = 0.24 lb.		
Heat produced by this 0.24 × 10,400 =	2495	
Total heat available in shaft =	6643	
Heat required per lb. of iron as before	4760	
To bring coke burnt in hearth to 2750 deg. = 0.756 × 1159 =	877	
For radiation =	440	
Total heat available for shaft	6077	
	6643	
Surplus for gas = 6643 − 6077 =	566	B.t.u.
Gas volume is as before except the nitrogen is increased 10 per cent = 3.7 cu. ft., 66.3 + 3.7 =	70	cu. ft.
Heat required to raise gas 1 deg. at 0.02 B.t.u. per cu. ft. sp. ht. of gas = 70 × 0.02	1.4	

566 ÷ 1.4 = 404 deg. + 60 deg. = 464 deg. discharge temperature of the gas.

The gas analysis in this case is as follows:

Total carbon gas from fuel as before is 25.6 cu. ft., the $CO_2 = 0.24 \times 29.85 = 7.26$ cu. ft. and the CO is 18.4. The carbon dioxide from the limestone is 1.8 which added to 7.2 gives 9 cu. ft., the H_2 as before is 2 cu ft. and the nitrogen is $36.9 \times 1.1 = 40.6$.

Then the percentages are

CO_2	9. ÷0.70 =	12.8
CO	18.4 ÷0.70 =	26.3
H_2	2. ÷0.70 =	2.9
N	40.6 ÷0.70 =	58.

CASE 2A.—Now let us assume that since the hearth heat as already shown is increased in proportion to the blast per pound of coke we increase the burden of ore and stone by 10 per cent also. The oxygen from the blast is 0.95 lb. and that from other sources is increased 10 per cent so becomes

From SiO_2	0.019 lb
From ore	0.448
From H_2O	0.097
	0.564 lb.

which added to 0.95 gives 1.514 lb. total. Deducting from this the oxygen for 0.857 C to CO, 1.143 lb. we have left 0.371 lb. O for CO_2, which suffices to burn 0.278 C as CO to CO_2.

The oxygen available in the hearth is $0.95 + 0.019 + 0.045 = 1.014$, which burns $1.014 \times \frac{3}{4}$ C = 0.76 C, leaving 0.857 — 0.76 = 0.097 lb. C to be burnt to CO in shaft.

0.097 C to CO produces $0.097 \times 4375 =$		424 B.t.u
0.278 C as CO to CO_2 gives $0.278 \times 10{,}400 =$		2895 B.t.u.
CO from hearth $0.76 \times 29.85 =$	22.7	
N from hearth as before	40.6	
	63.3	
Heat carried from hearth to shaft by gas $63.3 \times 58.8 =$		3720
Total heat for shaft =		7039
Heat required.		
For iron, etc., as before $\times 1.1 = 4760 \times 1.1 =$		5236
For heating coke 0.76×1159		881
For radiation		440
Total		6557

Excess available for heating gas 7039 — 6557 = 482 B.t.u. The volume of gas and its analysis are as follows:

Total carbon gas from fuel as before	25.6 cu. ft.		
Carbon as CO_2 from fuel $0.278 \times 29.85 =$	8.3 cu. ft.		
CO by difference	17.3 cu. ft.	24.6 per cent	
CO_2 from stone 2 cu. ft.			
Total $CO_2 = 2. + 8.3 =$	10.3 "	14.7 "	
$H_2 = 2 \times 1.1 =$	2.2 "	3.1 "	
N =	40.6 "	57.6 "	
	70.4 cu. ft.	100.0 per cent	

The specific heat of this at 0.02 is 1.41 and the discharge temperature of the gas is 482 ÷ 1.41 = 340, which added to 60, gives 400 deg.

CASE 3.—Solution loss is so much decreased that 60 cu. ft. of blast are required per pound of coke, other conditions being as in Case 1.

Oxygen in blast is $0.864 \times 1.20 =$			1.037
Other oxygen as in case I $0.017 + 0.407 + 0.089 =$			0.513
Total oxygen $1.037 + 0.513 =$			1.55 lb.
Oxygen for 0.857 C to CO as before			1.143
Oxygen for CO to CO_2			0.407
C as CO to $CO_2 = 0.407 \times \frac{3}{4} =$			0.305 lb
Oxygen in hearth $0.017 + 0.041$, (as in Case I), $+1{,}037 =$			1.095 lb.
Carbon burnt with this			0.823 lb.
Carbon left to be burnt to CO in shaft $0.857 - 0.823 =$			0.034 lb.
Heat developed by this $0.034 \times 4375 =$			119
Heat developed CO to CO_2 $0.305 \times 10{,}400 =$			3171
Volume of CO from hearth $823 \times 29.85 =$	24.6 cu. ft.		
Volume of U from hearth $36.9 \times 1.2 =$	14.3 cu. ft.		
Total volume of gas from hearth	68.9 cu. ft.		
Heat brought in by this $68.9 \times 58.8 =$			4050
Total heat for shaft			7370
Heat required			
For iron, etc., as in Case I			4760
For heating coke $823 \times 1159 =$			955
For radiation			440
Total heat required in shaft			6155
Heat available for gas $7370 - 6155 =$			1215 B.t.u.

Volume and composition of gas.

Total carbon gas from fuel as before	25.6	
CO from fuel $0.305 \times 29.85 =$	9.1 cu. ft	
CO_2 from fuel 25.6 — 9.1 =	16.5 cu. ft.	22.5 per cent
CO_2 from stone 1.8		
Total CO_2 1.8 + 9.1	10.9	14.8 "
H_2 as in Case I	2.	2.7 "
N_2	44.3	60 "
Total	73.7	100.0 "

Specific heat of this at 0.02 per cubic foot = 1.47.

Temperature of top gas = 1215 ÷ 1.47 = 826 + 60 = 886 deg. C.

CASE 3A.—Blast as in Case 3 and burden increased in same proportion, 20 per cent.

Oxygen from blast 1.037, other oxygen as in Case I, $\times 1.2 = (0.017 + 0.407 + 0.089) \times 1.2 =$			0.616
			1.037
			1.653
Oxygen for 0.857 C to CO			1.143
O for CO to $CO_2 =$			0.51
C as CO to CO_2 $0.51 \times \frac{3}{4}$			0.383 lb.
O in hearth from blast			1.037 lb.
From other sources as in Case I, $\times 1.2 = 0.058 \times 1.2 =$			0.070 lb.
Total O in hearth			1.107
This burns 0.832 C to CO and leaves $(0.857 - 0.832) = 0.025$ C to burn to CO in shaft.			
Heat from this $0.025 \times 4375 =$			110 B.t.u.
Heat from 0.383 C as CO to $CO_2 = 0.383 \times 10{,}400 =$			3980 B.t.u.

$H_2 = 2 \times 1.3$	2.6 cu. ft.	3.3	per cent
N_2, as in Case 4	48.0 cu. ft.	61.1	percent
	78.5	100.0	

Specific heat of this at 0.02 per cu. ft. = 1.570.

Temperature top gas = $1745 \div 1.57 = 1110$ deg. + 60 = 1170 deg. F.

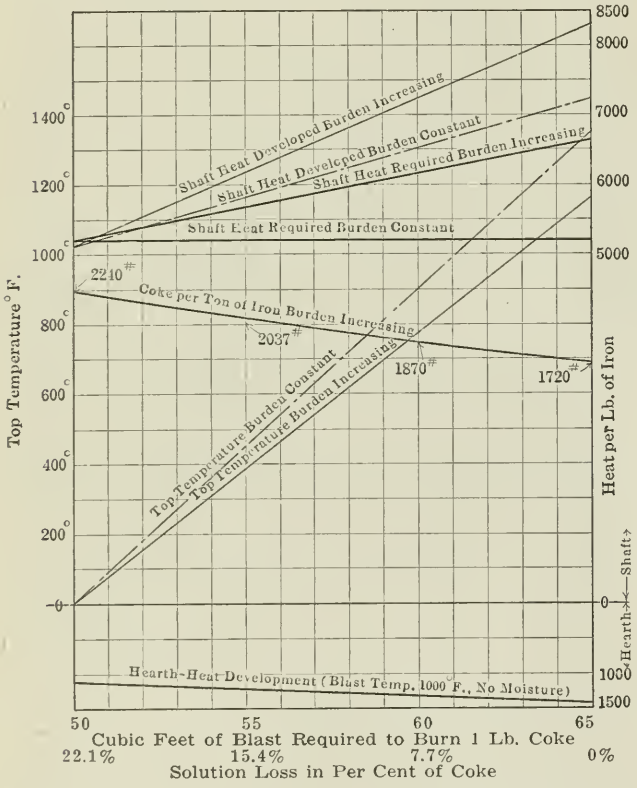

FIG. 3—THE EFFECT OF SOLUTION LOSS ON HEAT DEVELOPMENT AND TOP-TEMPERATURE WITH BURDEN CONSTANT AND WITH BURDEN INCREASING AS SOLUTION LOSS DECREASES

Fig. 3 shows these results graphically. Above the zero line we have the heat developed and that required in each of the four cases and the three sub-cases but in order to have the total correct the heat required to bring the coke up to the critical temperature is deducted from both sides alike. This is perfectly correct, for we could, if we liked, have deducted from the heat brought in by the gases rising from the hearth, the heat required to heat the coke to the critical temperature, and counted the balance as that available for heating the rest of the charge and the gas. We have in fact virtually done this by adding the heat for the coke to the requirement side instead of subtracting it directly from the heat available side. If we left this in on both sides we should be counting the heat required for the coke twice and should not get a correct total by adding the hearth heat to the above quantities.

We can readily plot the hearth heat below the zero line and the total distance between this and the lines of shaft heat requirements gives the total requirements for the given case. We may obviously assume for case 1 representing 1 lb. of iron that the hearth heat developed is 1100 B.t.u. in accordance with the actual data of operation given above. This is derived by the combustion of that coke which is burnt with the oxygen of the blast or $\frac{3}{4} \times 0.864 = 0.648$ lb. C.

Our diagram of hearth heat is based on 0.85 lb. C burnt with blast and 1100 B.t.u. for 0.648 lb. C corresponds to 1440 B.t.u. per 0.85 lb.; assuming 0.5 lb. moisture per 1000 cu. ft. of blast we find that 1000 deg. blast temperature produces the required amount of hearth heat. Assuming these conditions to remain the same, the hearth heat increases in proportion to the blast per pound of coke as explained above, and starting at 1100 B.t.u. in case 1 it rises to 1430 B.t.u. in cases 4 and 4A.

Let me reiterate here that these calculations show what the thermal condition *would be*, if we could have the amount of solution loss assumed in each case, without asserting that this is possible. We can now proceed to interpret these results.

Analysis of Results

HIGH SOLUTION THE LEFT SIDE OF THE DIAGRAM

Let us return now to the impossible top temperature in Case 1, 55 deg. below the temperature of the entering charge which might seem to indicate that a furnace could not operate under conditions even approximating these.

As a matter of fact furnaces can and do operate under conditions very similar to these and strange as it may seem they do it by increasing the blast temperature. Since the blast constitutes about 80 per cent of the gas, an increase of 200 deg. blast temperature will give an increase of about 160 deg. top temperature and so raise the temperature of the top gas to 165 deg. which is still below the top temperature at which furnaces run. But referring to the diagram we find that for 51.25 cu. ft. of blast the top temperature rises to 100 deg. and adding the 160 deg. for a higher blast temperature we obtain 260 deg. for these conditions, which correspond very closely in all important particulars to those under which many furnaces operate when using much Mesabi ore. It is necessary to emphasize the fact that in such a case more heat is developed in the hearth than is needed there, and that the excess passes up into the shaft and does work there which should have been done by heat of lower temperature under more correct conditions of working. This would leave this hearth heat to be utilized for the final smelting of a larger burden.

This is precisely the condition described before, under which the charcoal furnace was working on wet ore.

The chart shows quite plainly that only about one-fifth to one-fourth as much hearth heat per pound of fuel is generated as of shaft heat, so it is obviously a waste of fuel to employ this hearth heat for use in the shaft just as it would be to employ water from hydraulic pumps under 1200 lb. pressure to feed boilers under 200 lb.

This is in accordance with the general law of thermodynamics that any application of heat at a temperature lower than that at which it is developed results in an increase of entropy and a decrease of availability.

Obviously this corresponds to the case of Cornell as against that of Mathesius. In the latter's case only 1000 B.t.u. of shaft heat were developed per pound of iron, in the former's case 1250 B.t.u., because it was doing work in the hearth that should have been in the shaft and this surplus of high-temperature hearth heat was being largely wasted on low-temperature operations. Probably this was due to incorrect filling or a scaffold causing irregular descent of the charge into the hearth since if it were due to excessive solution loss there would be a deficient development of heat in the shaft whereas there is really an excess so far as our figures give reliable indications.

LOW SOLUTION LOSS THE RIGHT-HAND SIDE OF THE DIAGRAM

Passing now to the other side of the diagram, cases 4 and 4A, the oxygen from 65 cu. ft. of blast plus that from the silicon is exactly enough to burn all the coke without leaving any for the 10 per cent of oxygen from the ore which we have already seen is only removed in the hearth and we may therefore safely admit that this case is beyond the limit of present possibility.

From the detailed calculation it appears that 62 cu. ft. of blast is about the maximum that still leaves carbon enough for the removal of the last 10 per cent of oxygen in the ore and a vertical line in the diagram through this quantity of blast indicates approximately the practical limit in this direction of the amount of blast per pound of coke that can be blown for these conditions, but, of course, if the quantity of fixed carbon in the coke were greater than that assumed as the basis of the calculation, then the theoretical maximum limit of blast per pound of coke would be proportionately raised.

We find in this the probable explanation for the excess hearth heat in the case of Reece, for in my first work on this subject (see the report quoted before) I did not realize that at least 10 per cent of the oxygen of the ore was necessarily removed in the hearth, and since my figures for blast volume based on piston displacement indicated that enough blast was blown to burn all the coke I assumed this to be the case; but these figures for blast volume depend on several allowances and the results are not absolutely positive. They must, therefore, give way to the small extent required by the later deduction founded on more accurate data; that 10 per cent of the oxygen of the ore is removed by direct carbon in the hearth with a corresponding loss of carbon.

The minimum loss is represented by the difference between 65 cu. ft. and 62 cu. ft. of blast per pound of coke or 5 per cent, but as a matter of fact the solution loss is probably never less than 10 per cent and a deduction of 10 per cent from the hearth heat in Reece's case, 1170 B.t.u., would bring it down to 1053 B.t.u., virtually identical with that of Mathesius. This reduction in the amount of total oxygen would also reduce the shaft heat to a figure as close to that of Mathesius as such calculation will ever come honestly.

The better agreement, brought about by this correction, between the results of two cases varying widely in time, place, and conditions, seems to me to confirm both the correctness of the thermal calculation as a whole and the accuracy of our conclusion, as to the removal of the final fraction of the oxygen of the ore in the hearth.

I believe it will be generally admitted that these theoretical maximum and minimum limits of blast blown are in exceedingly close agreement with the facts of practice.

It will be seen that the coke consumption for this high limit of blast blown is about 1800 lb. whereas the results reported by Mathesius are considerably lower than this, 1682 lb., and the more recent work of Howland at the plant of the Wisconsin Steel Co. has produced a still lower figure, about 1640 lb.

These facts, however, do not in the least controvert our diagram, but rather confirm it, for we have assumed only 1000 deg. blast temperature, whereas these remarkable results were obtained with blast temperatures of about 1250 deg. corresponding to the production of 23 per cent more hearth heat per pound of coke burnt with blast. Sixteen hundred and forty pounds being only 8 per cent less than 1800 lb., it is obvious that enough hearth heat could be developed with about 15 per cent less coke burnt by blast than in our limiting case with 62 cu. ft. of blast; which would correspond to about 53 ft. of blast; this was in fact the precise amount used by Mathesius. Moreover the total carbon in Howland's practice is 93 per cent against 89 per cent as assumed above, while the sulphur in his coke was so low that the critical temperature was probably lowered by the use of a more siliceous slag.

CONDITIONS OF PRACTICE TO WHICH THE DIAGRAM CORRESPONDS. HEARTH HEAT

The condition represented by cases 1 to 4 in which the blast per pound of coke increases without any increase of burden may be compared with either of two conditions in practice. First, we may assume that the blast temperature falls or the humidity rises as the solution loss decreases so that while more coke is burnt in the hearth only the same amount of hearth heat is developed from it.

Second, we may assume that the weight of slag increases as the solution loss decreases and that as the hearth heat increases the heat required above the critical temperature for slag increases in the same proportion, so that left for iron and other hearth requirements is still the same. In either case no more iron could be smelted per pound of coke with low than with high solution loss, thus producing the conditions as to shaft heat which we have assumed.

The latter condition of larger slag volume and lower solution would correspond with lean lump ores, such as are used in the South as compared with the fine sandy but much richer Mesabis.

Such data as I have of cases with approximately the same full consumption in these two dissimilar cases confirm the results of the diagram absolutely, the top temperature being much higher in the case of the low solution loss.

The former case is approximately that of a furnace on old-range ores but with higher humidity and lower blast temperature, so developing less hearth heat per pound of coke but receiving more coke in the hearth on account of low solution loss and in these cases also confirm in a qualitative way the results of the diagram, the top temperatures being much higher under such conditions than in Mesabi practice on the same fuel consumption.

CONDITIONS OF PRACTICE TO WHICH THE DIAGRAM CORRESPONDS. SHAFT HEAT.

This brings our diagram into absolute agreement with practice as regards hearth heat and we may now turn to the question of shaft heat development.

The chart shows that the temperature of the top gases rises almost as fast when the burden is increased in proportion to the blast blown as it does when the burden is not increased at all. This is without any allowance for the fact that the limestone needed would be reduced in proportion to the increased iron produced because of the smaller amount of coke, ash and sulphur to be fluxed. With reasonable allowance for this factor the temperature would be almost the same

with the increased burden as without. This seems very surprising and the reason for it has an important bearing on the whole subject of thermal principles. This reason is that *the heat generated by the oxidation of CO to CO_2 with oxygen from the ore develops more shaft heat than is required for the preparation of the ore from which the oxygen comes.*

We have already seen that the reaction $Fe_2O_3 + 3CO = 2F + 3CO_2$ is slightly exothermic—7330 B.t.u. + 7650 B.t.u., but in this case it is much more than slightly so, for the CO brings with it a very large quantity of sensible heat due to the high temperature of itself and its accompanying nitrogen; these contribute far more than enough heat for all the other operations outside of reduction and the net result is that *if the solution loss stayed the same* the top temperature in any given case would drop little or not at all by the addition of more ore, *always provided that enough additional hearth heat were furnished to take care of the added burden in the hearth.* As a matter of fact the solution loss does not stay the same, because the approximate equilibrium between the concentration of CO_2, the fuel and the quantity of ore is disturbed and the increased CO_2 dissolves more coke, this solution is a highly endothermic reaction and it cools off the gas quite appreciably. Our diagram shows quite unmistakably, if the solution loss be diminished so that the coke burnt in the hearth is correspondingly increased and the burden increased in this same proportion that the top gas will become hotter and not colder. Solution loss can be affected in two principal ways, first by changing the characteristics of the coke itself by differences in coal used, method of coking, etc., and by changing the type of ore used. I have never had the opportunity to make a test of the top temperature on cokes of different solubility, but I believe it is well established that top heats on low-fuel runs were higher with old-range ores than they are to-day with large percentages of fine Mesabis producing high solution loss, on the same fuel consumption.

Of course, we do not find in actual practice the top heats shown by the diagram for low solution loss, because as the temperature tends to rise the solution loss rises also and automatically checks it.

RECAPITULATION

Let me reiterate here that this diagram is not intended to show what *does* happen under all conditions, but only to show what *would* happen if starting with given conditions we had a varying solution loss.

The exact conditions assumed are impossible at both ends of the scale as already explained, but the indications of the diagram are certainly in good agreement with the facts of practice in the region of the diagram between 51 and 60 cu. ft. of air per pound of coke. The value of the diagram comes not from any claim to arithmetical exactness, for such a claim would be ridiculous, but from the fact that, starting with the best data obtainable, results have been obtained which are at least truly comparative for the conditions and which are certainly in good agreement with the results of practice within the legitimate range of the diagram. This diagram makes it clear that solution has two effects the results of both of which are to diminish the economy of working of the furnace.

First, it prevents a portion of the coke from ever reaching the hearth and thereby reduces the production of hearth heat, directly in the same ratio.

Second, it reduces the total amount of oxygen which can be imparted to a given weight of coke and thereby diminishes in a greater degree, proportionally, the oxidation of CO to CO_2 in the shaft, which is the principal source of heat in that region, so that the development of shaft heat with increased solution loss drops more rapidly than that of hearth heat.

If we were to use some method different from any we now have in operation but nevertheless conceivable, whereby the development of hearth heat per pound of fuel could be noticeably increased we should be under the necessity of increasing the shaft heat just as much, in order to take advantage of it, since we have seen that these requirements for any given case bear a definite relation to each other. The only way we could secure this increase would be by a further oxidation of the top gases and this in turn could only be done by diminishing the solution loss below what it now is.

We seem therefore to be perfectly safe in saying that *for any condition of which we can conceive the higher the solution loss the lower the fuel economy.*

These considerations demonstrate that the oxygen of the ore instead of being a detriment to the smelting process is an asset of great value, for it alone is available to oxidize the CO formed in the hearth to CO_2, the reaction on which the shaft must depend for the major portion of its heat supply. This is a conception which has as far as I know never been advanced before and is worthy of some reflection.

It is interesting to note the possibility that the greater consumption required for magnetite than for hematite ores under similar conditions may be due to the smaller quantity of oxygen per unit of iron carried by that ore, 0.381 instead of 0.428, and the resulting deficiency of heat accompanies heat requirements per pound of oxygen transferred, greater than those of hematite so that a smaller development coincides with a larger demand. There are, of course, other conditions, the probability of a greater heat requirement in the hearth and of more oxygen to be removed by incandescent carbon in the latter region, and these may readily be the controlling factors. Nevertheless the other consideration is worthy of thought.

There are authentic cases on record in which furnaces have been working badly and apparently too cold in the hearth but not yielding to any of the customary treatments for that condition, which have responded perfectly when the burden was increased. At first sight this seems preposterous and I confess that I formerly listened to such stories with scepticism, but in the light of the above reasoning this becomes more comprehensible; if a furnace, admittedly lightly burdened, and therefore with a surplus of hearth heat passing up into the shaft, received an increase of burden the additional oxygen in the shaft would cause a development of shaft heat more than sufficient for the increased burden and would permit the surplus hearth heat to do its proper work on the additional ore with steadying and generally beneficial results. This is an exaggerated case of the general rule well known to most furnacemen that a heavily burdened furnace generally works better than a lightly burdened one, as long as regular conditions are maintained.

The diagram, Fig. 3, designed in the first place merely to show graphically the results calculated above is believed to have possibilities of wider use. It brings out, as nothing else I have found could do, the direct relationship between the heat requirements of the hearth and of the shaft under different conditions. These have a definite and practically unchanging ratio to one another, for any given set of conditions, and if an increase is to be made in the quantity of either kind of heat produced, it must be acompanied by a proportional increase in the other kind if a corresponding saving is to be made.

The original diagram is drawn to show the effect of

solution loss and that is accordingly made the independent variable. Cases 1, 2a, 3a and 4a, however, also correspond to an increase in the iron per lb. of coke proportional to the decrease in solution loss and as this now becomes the independent variable whose effect we wish to examine I have drawn a separate diagram, Fig. 4, of which abscissae represent a wide range of iron-coke ratios, from 0 to 2:1. Ordinates above and below the zero line represent hearth and shaft heat requirements as before.

The quantities of these for 1.1 lb. of iron per pound of coke (corresponding approximately to 2000 lb. of coke per ton of iron) have been taken from Fig. 3 and lines drawn through each from the zero point, OS and OH. It is evident that the ordinates of these lines for any other iron-coke ratio give the requirements of each kind of heat from each pound of fuel for those conditions (and, of course, those only).

It is evident that if the lines of heat development be outside these lines in *both* cases or coincide in one and lie outside in the other, we shall have a workable case; but if *either* line of heat development lies inside the line of corresponding requirements that case is unworkable. I have added to the diagram the line of shaft heat development BAC; the line of hearth heat development with increasing burden, of course, coincides with the line of OH of Fig. 4.

The cases represented by the portion of the line AB outside the line of requirements are workable cases, but those represented by the portion AC inside the requirement line are not workable.

There is one exception to this latter statement to cover the case already described of a surplus of hearth heat utilized to make up a deficiency of shaft heat.

This corresponds to the condition we should have if we increased the hearth heat for cases AC as shown by the dotted line DE as far below the line of hearth requirements as the shaft heat development for those cases is below the shaft requirements.

The slope of the line indicates how impossible it is to go far in this direction.

This corresponds to an equal distortion of both lines of the diagram downward relative to the zero line. The cases so represented are not economical, but are workable, but the cases represented by the distortion of the diagram *upward* corresponding to the utilization of shaft heat for hearth purposes are not workable, being contrary to the second laws both of thermodynamics and the blast furnace.

There is, of course, a possible limitation to the development of shaft heats which must never be forgotten,

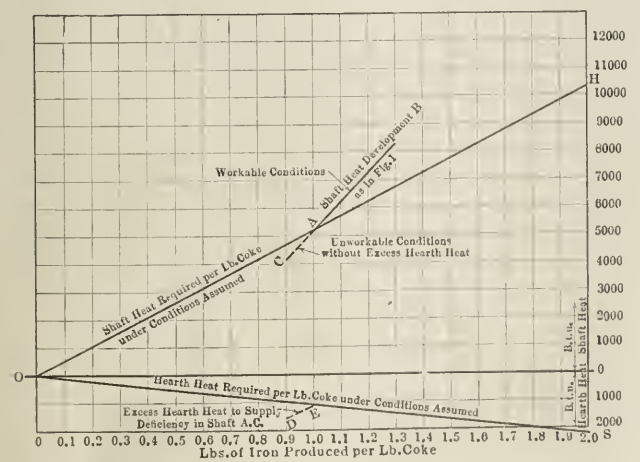

FIG. 4—DIAGRAM SHOWING HEARTH AND SHAFT HEATS REQUIRED PER POUND OF COKE UNDER NORMAL CONDITIONS FOR VARIOUS HEATS OF IRON PRODUCED

though it is further from the furthest limits of practice than we have been accustomed to think, this is the limiting concentration of CO_2 in the presence of ore, irrespective of the presence of carbon, these limits being approximately given above. We must under no circumstances draw our line of shaft heat developed per pound of fuel, beyond the limits set by this limiting ratio; to do so would be to assume that the carbon gas could be oxidized to a degree which is not possible and would lead to a fundamentally incorrect result.

There is no doubt much good work being done with quite high solution loss and some furnace men are inclined to take the stand that high solution loss is not detrimental, but in view of the foregoing demonstration of the facts I believe we are justified in saying that no matter how good work may be done under any given conditions *with* high solution loss, better could be done *without*, and the only limit to this statement comes when we reach the limiting concentration of CO_2 for the given ratio of carbon gas and ore, in the absence of fuel.

It is well to repeat that furnaces which under given conditions could not run for a deficiency of shaft heat may have this deficiency made good by an excess carried over from the hearth. I have run a furnace under such circumstances myself and know it to be true, but it is also true that it is a very uneconomical way to operate and that the hearth heat so utilized is only about one-fifth as valuable as it would be for its proper work in the hearth.

Returning now to Gruner's theorem, remembering that the lower the solution loss the greater the quantity of air required per pound of coke, we may express it tersely as follows: "The lower the solution loss the greater will be the enonomy of the furnace."

This is the conclusion to which our long and somewhat tiresome investigation has irresistibly led us and we can only pay a tribute of respectful admiration to Gruner for his early discovery of a most important law, whose consequences have been too much neglected. Professor Richards' criticism of it may perhaps be said to have erred in laying too much stress on oxygen-carrying power and too little on the necessity of developing heat which can only be successfully done by utilizing the oxygen-carrying power of the fuel to the maximum possible extent.

Conclusions

It may be well to recapitulate briefly the conclusions reached in this chapter:

For maximum fuel economy there are two principal laws.

First: Each pound of fuel must develop the maximum possible amount of heat.

Second: A certain irreducible proportion of this must be developed above the critical temperature, which is the free-running temperature of the slag.

To accomplish these results we must work along the following lines.

A. Impart as much total oxygen as possible to each unit of carbon before it leaves the top of the furnace.

B. Burn the largest possible proportion of the carbon charged with oxygen from the blast.

C. Heat the blast as hot as possible.

D. Remove the moisture from the blast as fully as possible.

E. Keep the free-running temperature of the slag as low as possible since a decrease in the critical temperature has a greater effect than equal increase in blast temperature.

F. Keep hearth requirements low by keeping down slag volume and avoiding excessive cooling for protective purposes.

G. Keep the actual hearth requirements the same as the theoretical by the use of a system of stock distribution which gives minimum solution loss in the shaft with sufficiently intimate contact of fuel and ore in the hearth.

H. Even following these rules, the hearth heat is generally deficient as compared with the shaft heat and, therefore, except in certain special cases, the heat consumption of the shaft can be increased within reason without much, if any, loss of efficiency by the furnace as a whole.

It has been my endeavor to present here as simply as possible the fundamentals of the thermal action of the blast furnace, but the inter-relations between chemical action and thermal action are so numerous that it is not possible to reduce the subject to short and simple unqualified statements.

In conclusion it may be well to warn those who desire to make thermal calculations for the purpose of investigating possibilities of improvement and the like, never to predict the ultimate consequence of a given charge until they have followed it all the way through to see if it involves any chemical or thermal impossibilities. For such purposes a sheet of the general form used in tables V-VII may be recommended as the outcome of days of effort to record the result of such calculations so that their chemical and thermal effects could be followed to the correct conclusions. But this form does not remove the necessity for a quantity of detailed painstaking and tiresome work, in the accomplishment of such purposes.

Faraday Society Meeting

At the annual general meeting of the Faraday Society, held on Tuesday, Oct. 19 last, at the Institution of Electrical Engineers, the following officers and members of council were elected to serve for the year 1915-16: President, Sir Robert Hadfield; vice-presidents, Prof. K. Birkeland, Bertram Blount, W. R. Bousfield, Prof. F. G. Donnan, Dr. Eugene Haanel, Prof. A. K. Huntington, Dr. T. Martin Lowry; treasurer, Dr. F. Mollwo Perkin; council, W. R. Cooper, Dr. C. H. Desch, Dr. J. A. Harker, Emil Hatschek, Cosmo Johns, Prof. Alfred W. Porter, E. H. Rayner, A. Gordon Salamon, Dr. George Senter, Cav. Magg. E. Stassano.

General Discussion on "The Transformations of Pure Iron"

The professional meeting was devoted to a general discussion on **"The Transformations of Pure Iron,"** and it was presided over by Sir Robert Hadfield, president, who introduced the subject under discussion.

The allotropic theory, while interesting and useful in invoking discussion, had broken down, and although the carbonist point of view had not explained all the difficulties met with, it had gone upon more tangible lines. It was to be hoped that Dr. Oxley's point of view would throw new light on the secrets of the hardening and the magnetization of iron. If it did, the discussion would be the starting point of quite a new line of thought that might bring together the allotropist and the carbonist, and offer them a common and correct explanation of the properties of iron.

Dr. A. E. Oxley of the University of Sheffield contributed the opening paper to the discussion.

It is now believed by many metallurgists that the A_2 transformation can be satisfactorily explained without assuming allotropic change; but the A_3 transformation is regarded as involving allotropy.

The crystalline state is one of extreme molecular association (physical aggregates), and if allotropy is determined merely by the extent of this association, substances will show within a finite temperature interval an infinite variety of allotropic forms, so that the attempts of metallurgists to show that A_3 involves allotropic change while A_2 does not, need not have been made. To get over the difficulty some metallurgists recognize two definitions of allotropy: (1) the two-phase (discontinuous) type, (2) the one-phase (continuous) type. The burden of distinguishing between (1) and (2) is here thrown on our experimental refinements, and it is not hopeful that a definite solution can be found.

Defining allotropy as a difference of atomic structure of the molecule (consistent with the oxygen to ozone transformation), a distinction can be made between it and crystalline grouping (physical aggregates). Allotropic modifications will usually have different crystalline symmetry; but it does not follow that difference of crystalline symmetry necessarily implies allotropy, for, according to Barlow and Pope, identical molecules can be close packed together in different ways. We must distinguish between the forces holding the molecules together so as to form a definite crystalline structure and those holding the atoms together within the molecule.

From a magnetic and thermal point of view it is concluded that the transition at A_3 involves a re-grouping of the molecules, similar to that which occurs in the ordinary process of crystallization, rather than a rebuilding of the internal structure of the molecule.

Mr. F. C. Thompson of Sheffield contributed a paper to the discussion in which he arrived at the following conclusions:

1. Sudden changes in the directions of one or more curves showing the relationship of the physical properties of iron to temperature, indicate with certainty the existence of α, β, γ, and δ iron with change-points at 768° C., 900° C., and 1400° C., while another slight change has been detected magnetically and dilatometrically at about 830° C.
2. The A_3 point in iron taken as typical of all the changes is shown to obey the same laws as hold for other acknowledged allotropic transformations.
3. Magnetic evidence is available that the molecule of β iron is Fe_3, of γ iron Fe_2, and of δ iron Fe.
4. A distinct mode of packing of the α, the β and the γ molecules is indicated crystallographically.
5. Thermally it may be shown that changes occurring in iron are of the same nature as those which occur in other cases of allotropy in metals, e.g. tin and cadmium, and also as in the case of the change from rhombic to monoclinic sulphur.

The author is therefore strongly of the opinion that the transformations in iron are essentially allotropic. At the same time he dissociates himself entirely from the view that to any of the allotropic forms *per se* is the hardness of hardened steel due. Some of the modifications will dissolve carbon as Fe_3C and some to all intents will not; but in this fact alone does the allotropy of iron bear on the constitution of steel. Whether iron is allotropic or not, it is to the solution of Fe_3C that the characteristic properties of hardened steels must be ascribed. The views of Arnold expressed in 1895 are essentially accepted to-day by the majority of metallographers, and the "hard β iron" to which the strength of hardened steel was due according to the allotropic school is dead.

Prof. Pierre Weiss of Paris, in a communication which was read to the meeting, referred to his recent work on the magnetization of iron at different temperatures, by which, through adopting newer values for the Curie constant, he has shown that there are at least three transformations in iron: the A_2, which has a physical character, the A_3, which presents a discontinuity in the susceptibility, and a third transformation in the β region, pointing to the existence of a β_1 iron with 12 magnetons and a β_2 iron with 10 magnetons in the atom. The latter change is intra-atomic and not—adopting Dr. Oxley's definition—allotropic.

M. H. le Chatelier of Paris, also sent a communication to the discussion, in which he deprecated giving a new definition to the word "allotropy." Two allotropic states were merely two clearly defined states of the same composition presenting discontinuity (Benedicks), but coexisting at the same temperature and pressure. Thus fusion and vaporization could be classed as allotropic transformations, and equally so could the A_3 and even the A_2 transformation in iron.

Prof. Frederick Soddy of Glasgow, in his communi-

cation, referred to the work of the Braggs on crystalline structure, which showed that the conception of a molecule has no meaning as applied to a solid, because the atoms of the solid are anchored and do not exist in freely moving groups, i. e. molecules, at all. Oxygen and ozone seem to be the only allotropes that survive gasification. There is little evidence that sulphur and phosphorus, or still less that the metals, behave in an analogous way.

Mr. J. E. STEAD of Middlesbrough, in a written communication, considered that a new definition of allotropy was called for after the work of the chemical crystallographers, and they had to consider whether the new definition was not open to criticism. Could Dr. Oxley explain in his own terms the breaking up of large crystals of iron into small ones when they are heated through the Ac_3 range? There must be a profound internal physical breaking down and rebuilding of the crystalline structure, accompanied by an absorption of heat.

Prof. THOMAS TURNER of Birmingham did not think that to regard changes in iron as more allied to change of physical state than to true allotropy interfered with the view that there are three distinct phases in solid iron, each possessing characteristic properties.

Dr. CECIL H. DESCH of Glasgow discussed the bearing of "dynamic allotropy" and allotropic change as defined in a narrower sense by Honda ("a change in a substance from one phase to another at a definite temperature") on the problem of the transformations in iron. From a purely chemical point of view γ iron and the modification into which it changes on passing through Ar_3 are distinct phases. He agreed with Dr. Stead as to the complete decrystallization at the A_3 point. Dr. Oxley's thermal comparisons were open to criticism as the latent heats of fusion were expressed in gram-calories per gram of metal, while the thermal evolutions accompanying allotropic and isomeric changes were given in gram-calories per gram-molecule. The correction considerably reduces the disproportion suggested. The heat evolution accompanying the change from gray to white tin, which is certainly allotropic, is 1133 gram-calories, which is less than the latent heat. Moreover, the evolution of heat in iron, apart from the necessary correction, was too low as given by Dr. Oxley, for it should include the whole area of the peak in the inverse rate in the derived differential curve. As corrected it would approximate to that for tin. He therefore concluded that there was no reason for removing the $\gamma \longrightarrow \alpha$ and $\gamma \longrightarrow \beta$ changes from the category of allotropic transformations.

Mr. A. MCCANCE of Glasgow laid down the condition that a definition must be independent of a theory, and Dr. Oxley's was not so. He also dealt with the modern conception of the molecule, touched on by Professor Soddy, and on the definite crystallization change in iron at the A_3 point emphasized by Dr. Stead. This was something more than mere closeness of packing.

Mr. T. G. ELLIOTT of Sheffield thought that Dr. Oxley's test of allotropy, involving the withdrawal of restraining forces, demanded a hypothetical condition in the material to be tested. Could crystals be built up of distorted molecules?

The President pointed out that a knowledge of the transformations of iron was essential for the successful production of hardened steel. He mentioned the interesting fact that many of the iron alloys at the temperature of liquid air attained a tenacity of 160 tons per square inch.

Prof. H. C. H. CARPENTER thought it preferable to say that iron existed in one phase below and in another phase above 900 deg. C. It was not certain that the molecule of iron was polyatomic. Judgment must be suspended until Professor Bragg had examined a well-formed crystal with the x-ray spectometer. He did not see how cooling through A_3 could lead from a more open to a closer packed cubic system, seeing that there was an expansion during the transformation. Finally, he exhibited slides illustrating the remarkable crystallographic changes that occurred when iron of exceptional purity was heated for some time at 915 deg. C. and then allowed to cool. Whether allotropic or not, very profound physical changes took place at the A_3 point.

Dr. J. A. HARKER expressed his surprise that so little work had been done in the determination of the thermal constants of pure iron. He outlined a possible method for the determination of the latent heat of fusion of pure iron.

The President offered to defray the cost of the work if it could be carried out at the National Physical Laboratory.

Prof. J. W. NICHOLSON thought the idea of a sort of atomic allotropy the really new thing in Dr. Oxley's conceptions. The fact was there were many varieties of allotropy, which needed subdivision into several groups. Bragg's work might be used in support of Dr. Oxley's hypothesis.

Prof. ALFRED W. PORTER could not understand how Dr. Oxley's definition could receive practical application, as the only method of removing the restraining forces from the molecules of a substance was by vaporizing it.

Dr. T. MARTIN LOWRY protested against altering Berzelius' definition of allotropy, which had been in use for seventy years. If a new definition was required it should be attached to a new word. He was content to think that different modifications of iron might be made up of the same molecules arranged in different ways, but in the case of an element, such as sulphur, this would still be allotropy. Dr. Oxley's thermal data were unconvincing. He might have selected changes, such as the inter-conversion of certain isomerides, in which the thermal changes were small.

Dr. E. K. RIDEAL referred to Partington's work on the vapor pressure of copper sulphate crystals, carried out by the method of passing dry air over the crystals. The differences between these values and those obtained by the static method might be explained by taking into consideration the space lattices of the crystals. Similar work might be done in the case of iron.

Dr. J. R. PARTINGTON pointed out that the atomicity of metals in the solid space could be determined from measurements of specific heat. Nernst found that nearly all the metals were monatomic.

Dr. H. BORNS asked Dr. Oxley why he had ignored Weiss's recent work, which proved that iron was polyatomic and that β iron differed from γ iron in atomicity.

Dr. A. E. OXLEY in reply said that Bragg's work was not necessarily opposed to his views, because Bragg himself agreed that in the case of complex molecules it was possible to draw a boundary round a certain group of atoms in a crystal and say that they belonged to a particular molecule.

The linear expansion found by Benedicks to occur in iron when it cools through the A_3 point was not opposed to a closer packing of the molecules in the direction of spontaneous magnetization.

With regard to the definition of allotropy, it was obvious that examples of the type of oxygen and ozone should not be classed with cases which could be explained by loose molecular association.

His definition of allotropy was theoretical to a large extent, but the idea could be followed by considering the case of ozone and oxygen. In the crystalline state these substances were different from each other; on removing the restraining forces by fusion or vaporization, they

were still more different from each other and were therefore allotropes.

Weiss's work on the magnetic properties of iron was no proof either of the atomicity of the different kinds of iron or of the magneton theory, as he assumed the truth of one to prove the other.

A paper on **"The Transference of Electricity by Colloidal Particles,"** by F. Powis of Leeds, was read by title.

An attempt is made to calculate the charge carried by the particles of a colloidal solution produced by sparking, (1) from a modification of Stokes's formula, (2) from the increase in conductivity on making the solution. Although the data available for the calculations are not very satisfactory, the second method gives a value much greater than the first. The author believes this is because the particles are not like the ions of an electrolyte solution, but that anions and cations are absorbed on their surface in such a way that the concentration of each gradually decreases with increasing distance from the particle, until each finally becomes equal to that in the bulk of the surrounding medium; the ions are so arranged, however, that with a negative colloid the layers nearer the particle contain an excess of anions, and those further away an excess of cations, whilst with a positive colloid this is reversed.

A paper on **"Electrolysis of Nitric Acid, Sulphuric Acid and Orthophosphoric Acid, Using a Gold Anode,"** by F. H. Jeffery, of the University Chemical Laboratory, Cambridge, was then presented.

(A) The platinum cathode was inclosed in a porous pot and the acid used for catholyte was of same concentration as that used for anolyte. Acids of various concentrations were obtained by diluting conc. nitric acid Δ 1·42 with distilled water. The experiments were performed at the temperature of the laboratory, 15° to 20° C. In all cases the soluble gold compounds formed contained the gold as complex anion; no gold was deposited on the cathode.

In an acid formed from 1 c.c. conc. HNO_3 to 1 c.c. water soluble compounds were alone formed. The gold went into solution, forming aurinitric acid, $HAu(NO_3)_4$, and an aurous compound, perhaps $HAu(NO_3)_2$, which deposited gold on being left in a closed flask. The anolyte was hydrolysed by water, giving a mixture of hydrated auric and aurous oxides such that $Au_2O/Au_2O_3 = 0{\cdot}02$. The anolyte changed in color from deep olive-green to dark yellow-brown on prolonged electrolysis, owing to changes in the ionic dissociation of the compounds.

In acids of concentration ranging from that corresponding to 1 c.c. conc. acid to 2 c.c. water to that corresponding to 1 c.c. conc. acid to 20 c.c. water there were solid products formed at the anode. These were mixtures of hydrated auric oxide and aurous oxide for the more concentrated acids and hydrated auric oxide alone for the less concentrated acids; for 1 c.c. conc. acid to 2 c.c. water, $Au_2O/Au_2O_3 = 0{\cdot}07$; for 1 c.c. conc. acid to 4 c.c. water, $Au_2O/Au_2O_3 = 0{\cdot}05$; for 1 c.c. conc. acid to 10 c.c. water, hydrated Au_2O_3 is alone formed; the same is true for 1 c.c. conc. acid to 20 c.c. water.

The current density did not appear to determine the composition of the compounds formed at the anode.

In the case of the dilute acids, such as 1 c.c. conc. acid to 10 c.c. water, undissociated ammonium nitrate diffused into the anolyte from the catholyte, and if the concentration of the ammonium salt was allowed to rise, compounds were formed at the anode which were explosive when heated; apparently complex cations containing gold were formed, giving a deposit of gold on the cathode.

In all cases the solid compounds gave a trace of nitric acid on heating, even when they had been previously stirred with water for weeks. This was probably due to the presence of a small quantity of a basic nitrate.

(B) In an acid formed from 1 c.c. conc. H_2SO_4 Δ 1·84 to 1 c.c. water soluble compounds were formed containing the gold as complex anion; finely divided gold was formed throughout the anolyte. The soluble compounds were at first green, becoming dark brown on prolonged electrolysis. No gold was deposited on the cathode except at the end of a long electrolysis, and then only in very small quantity. The anode potential remained constant throughout the electrolysis. When the anolyte was hydrolysed a solid was obtained consisting principally of hydrated auric oxide and aurous oxide, but it was impossible to free it from a trace of basic sulphate. The gold went into solution, forming both aurous and auric compounds. In an acid formed from 1 c.c. conc. H_2SO_4 to 7 c.c. water a solid was formed at the anode, which was a mixture of aurous oxide and hydrated auric oxide with a trace of basic sulphate. No free gold was formed in the anolyte.

(C) The quantity of soluble gold compound formed in the anolyte was very small, and the gold was present as anion alone. A solid was formed at the anode consisting of hydrated auric oxide and aurous oxide, but even after stirring with water for twenty-four weeks it could not be freed from a trace of some compound giving H_3PO_4, with water.

In an anolyte containing 15 per cent H_3PO_4 by weight the solid product corresponded to $Au_2O/Au_2O_3 = 0{\cdot}07$, and in one containing 20 per cent H_3PO_4 to $Au_2O/Au_2O_3 = 0{\cdot}09$.

A paper on **"Electrolysis of Concentrated Hydrochloric Acid Using a Copper Anode,"** by F. H. Jeffery, was then presented.

The platinum cathode was inclosed in a porous pot, and all experiments were performed in nitrogen or carbon dioxide.

The copper dissolved in the cuprous condition and as complex anion alone, there being no deposit of copper on the cathode. No chlorine was evolved at the anode. The anion appears to be $CuCl_3''$, and if the electrolysis was prolonged CuCl was precipitated according to the relation.

$$CuCl_3'' = CuCl + 2Cl'.$$

If a platinum cathode in dilute hydrochloric acid inclosed in a porous pot was used with an anolyte of KCl solution of concentration 30 grams KCl per 100 c.c. water, crystals of K_2CuCl_3 were obtained from the anolyte, the copper went into solution entirely in the cuprous condition, and no chlorine was evolved at the anode. No copper was deposited at the cathode. As before, cuprous chloride was precipitated after the electrolysis had proceeded for a considerable time.

"The Thermal Decomposition of Hydrogen Peroxide in Aqueous Solution" was the title of a preliminary note by William Clayton, of the Muspratt Laboratory of Physical and Electro-Chemistry of The University of Liverpool.

1. The rate of thermal decomposition of aqueous solutions of hydrogen peroxide is extremely sensitive toward extraneous organic matter in the colloidal state. Mechanical factors, such as volatility and the presence or absence of stirring, do not exercise an appreciable influence.

2. The chief factor in the decomposition has been shown to be the degree of purity of the water. Thus in tap-water the rate of decomposition is fully fifty times that in the purest specimen of water we have yet prepared.

3. In the light of these results, previous work upon the thermal decomposition of H_2O_2, especially the comprehensive research of Lemoine, must be considered as of doubtful value, as no special precautions appear to have been taken in regard to the solvent.

4. In view of the marked effect produced by the solvent it remains an open question as to whether the surface of the vessel exerts an appreciable effect or not; it is possible that effects previously attributed to the surface may have been due to slight variations in the organic-matter content of the solvent.

The **Burdett Oxygen Company**, with main office at Chicago, has opened a station at Fort Worth, Tex., this being the ninth station of this company.

A **Rennerfelt electric steel furnace** has been installed in the new plant of the Old Dominion Iron & Nail Works Co., Richmond, Va. This is the second of these furnaces to be used by this company.

The complete report of the Selby Smelter Commission, by J. A. Holmes, Edward C. Franklin and Ralph A. Gould, issued as *Bulletin* 98 of the Bureau of Mines, is one of the most interesting and valuable documents of the kind yet published. Methods of procedure in analyzing gases are given in detail, and supplemented by tabulated data and conclusions. Illustrations in color show the effect of sulphur dioxide on vegetation of various kinds. A bibliography is appended, prepared by the Chemists' Club Library, on the effect of sulphur dioxide on vegetable and animal life.

Extraction of Radium, Uranium and Vanadium from Carnotite

From an official advance notice on Bulletin 104 of the Bureau of Mines, entitled "Extraction and Recovery of Radium, Uranium and Vanadium, by **Charles L. Parsons, R. B. Moore, S. C. Lind** and **O. C. Schaefer**, we take the following interesting information:

This bulletin gives the results of the coöperative work with the National Radium Institute, which has been mining carnotite claims in the Paradox Valley and studying the concentration of low-grade ores at that point. The present bulletin, however, describes only the methods of extracting radium from carnotite ore as carried out in the plant at Denver.

The methods devised have proved highly successful. They depend essentially upon the fact that strong, hot nitric acid has a high solubility coefficient for radium and barium sulphates. This enables the carnotite ores to be treated directly with hot nitric acid, removing the values therefrom at a single operation. The method follows in brief:

The carnotite ore pulverized to 20 mesh is treated in a special earthenware leaching pot with 38 per cent nitric acid; 500 lb. of ore being used to 121 lb. of 100 per cent HNO_3. The acid is brought near to boiling by means of steam passed through a glass tube and the ore gradually stirred in. Heating is continued for 15 minutes when the acid is filtered from the ore in a stoneware filter. This is followed by a second treatment in the same leaching pot with somewhat weaker hot nitric acid, after which the whole is washed with hot water. Nearly all of the uranium, about 50 per cent of the vanadium and over 90 per cent of the radium are carried into solution by this method and separated from the bulky residues, which are then discarded. The acid solution is nearly neutralized with sodium hydroxide, barium chloride and sulphuric acid added in proper quantities and held in settling tanks with conical bottoms for three days to settle out the radium barium sulphate. The supernatant liquid is then syphoned into an excess of boiling sodium carbonate solution to separate the uranium and vanadium from iron, aluminium and calcium. The radium barium sulphate left in the tank is run on to a stoneware filter, filtered, washed and dried, the washings being also added to the sodium carbonate solution already mentioned.

The soluble sodium uranyl carbonate and the sodium vanadate are filtered from the iron calcium precipitate in filter presses and run into uranium precipitation tanks. The sodium carbonate is then nearly neutralized with nitric acid and sodium hydroxide added to complete precipitation of the uranium as sodium uranate. The filtrate containing the vanadium is carefully neutralized with nitric acid and iron sulphate added to precipitate vanadium as iron vanadate. Both the sodium uranate and the iron vanadate are separated from their solutions by means of filter presses. The filtrate from the iron vanadate consists almost wholly of a solution of sodium nitrate containing, of course, a small amount of impurity. This filtrate is evaporated, sodium nitrate recovered and used again for the manufacture of nitric acid. The radium barium sulphate, without further treatment, is reduced in large graphite crucibles by charcoal, a very efficient conversion (90 to 95 per cent) into barium radium sulphide being obtained. The sulphides are dissolved in hydrochloric acid and the residue of unchanged sulphates re-treated.

The chloride solutions are crystallized in the plant in silica-lined kettles, care being taken to keep the solutions acid with hydrochloric acid as the separation of radium from barium is much more rapid under these conditions. The concentrated chlorides carrying from 4 to 10 mgs. of radium per kilogram are taken to the laboratory, filtered from any insoluble impurities and crystallized again in strong acid solution until the bulk has been reduced to a small volume, when they are converted into bromides. This is done after first neutralizing with ammonia and precipitating with hydrogen sulphide to remove lead, which always accumulates and which is not precipitated by hydrochloric acid from strong barium chloride solutions. After removal of the lead the barium and radium are converted into carbonates by the addition of ammonium carbonate, washed and dissolved in hydrobromic acid. From this point on crystallization takes place in pure quartz dishes in solution strongly acid with hydrobromic acid.

The fractional crystallization of radium from the original chlorides to the finished product is neither tedious nor difficult but takes place rapidly when acid solutions are used and proper apparatus is available which will withstand their action. The efficiency of the process is high.

In connection with the radium plant, a nitric acid plant has been erected which produces over 5000 lb. of nitric acid per day. Owing to the recovery of sodium nitrate the cost of the nitric acid used has been very low, averaging under the present cost for nitrate slightly less than 2½ cents per pound. To Sept. 1 4774 mgs. of radium were produced in the form of sulfates and 1947.5 mgs. of element had been delivered in the form of bromide. Deliveries are continuing at the rate of 300 to 400 mgs. per month.

The cost of radium element figured on the basis of all the radium produced to Aug. 1, which includes the higher costs of the earlier operations, was $37,599 per gram of radium element. This includes the cost of ore, 20 per cent plant amortization, Bureau of Mines coöperation, and operating costs of all kinds, including repairs. The bulletin gives full details of operation, including detailed drawings of the plant and halftone illustrations of the plant and equipment. The radium produced is being used in the Howard A. Kelly Sanatorium at Baltimore and the General Memorial Hospital, New York City, for the treatment of cancer and other malignant growths. It is not for sale.

General Meeting of the German Bunsen Society for Applied Chemistry

The twenty-second general meeting of the German Bunsen Society for Applied Physical Chemistry was held in Berlin on Oct. 17 and 18, 1915. The president, Dr. **Hans Goldschmidt** of Essen-Ruhr, presided at the meeting. He pointed out in his speech of welcome that while most other societies were simply transacting business matters at their general meetings on account of the war, the Bunsen Society was continuing its work as in peaceful times. He thanked Professor Nernst, in whose institution the meeting was held, mentioned those who had fallen in the war and referred to the death of Professor Hittorf, whose noble personality he sketched in some detail. It was decided to leave the selection of the next meeting place to the executive committee. An invitation to come to Karlsruhe has already been extended.

A great variety of subjects, both practical and theoretical, were taken up in the papers presented.

Electrochemical Processes

A paper on the **"Electrolytic Preparation of Perborate"** was presented by Prof. K. **Arndt** of Charlottenburg. This paper described a process of the author, in which a borax soda solution is electrolyzed.

Sodium perborate $NaBO_3 + 4H_2O$ is a well-known oxygen bleaching agent. It was first produced by Tanatar in 1898 by combination of sodium metaborate with hydrogen peroxide. Sodium peroxide has later been used in large-scale manufacture. In 1898 a communication from Tanatar stated that he had obtained perborate by electrolysis of a concentrated borax solution. In 1910 M. A. Pouzenc obtained a French patent on the electrolytic production of perborate in a diaphragm cell, using a cooled orthoborate solution and rapidly circulating same. In repeating these experiments Polock could only obtain a very small output with strongly concentrated solutions and could not duplicate Pouzenc's results.

Professor Arndt's process consists in electrolyzing a solution made up of 45 grams borax and 120 grams sodium carbonate to a liter of water. In the laboratory he used a platinum gauze anode and a water-cooled tin-tube cathode; the latter is arranged in zig zag form on both sides of the anode, the distance between anode and cathode being 4 mm. At 20 amp. and 6 volts a temperature of 17-18 deg. C was maintained. The strong evolution of gas helped to keep the electrolyte in motion. The loss due to cathodic reduction was small. When the content of the bath in active oxygen is high enough the current is interrupted. After some time sodium perborate will crystallize out and can be removed and washed, forming a pure and stable product. The mother liquor may be again electrolyzed.

A paper on "**Aluminium Nitride**" was presented by Prof. **Paul Askenasy** of Karlsruhe. He mentioned the great interest which attached to the discovery of the reaction between an alumina-carbon mixture and nitrogen, in which aluminium nitride is formed at 1800 deg. C. Professor Askenasy recited the work of Serpek, the Badische Anilin and Soda Fabrik, Giulini Brothers, and the researches of Dr. W. Fraenkel and Prof. F. Fichter. Aluminium nitride, when treated with water or alkali is converted into ammonia and alumina, and a tremendous field awaits the successful execution of such a process. The author reports on the continued researches of Dr. Walther Fraenkel, with special reference to the effect of different kinds of carbon on the reaction velocity. The researches show that acetylene black was especially capable of helping the reaction. Next in order were charcoal and graphite. With coke the reaction proceeds more slowly. The alkali content of the charcoal accelerates the reaction. When larger additions of alkali are intentionally made, the acceleration of the speed of reaction is remarkable, especially when coke is used.

Temperature Scale and Atomic Weights

A paper on the "**Temperature Scale of the Reichsanstalt and the Standardization of Temperature Measurements,**" was presented by Geheimrat Professor **Holborn** of Berlin. This paper dealt with the use of gases in thermometry and pointed out that different results had been obtained with different gases, whereas it had been thought by Regnault that it was immaterial which gas was used. Differences exist already between hydrogen and nitrogen thermometers between 0 and 100 deg. which influence the measurements. The temperature scale was founded on hydrogen because this gave the lowest zero point. The International Commission of Weights and Measures adopted the hydrogen scale in 1887 between 0 and 100 deg. for the special purpose of calibrating international units of length and weight. It has also been used by the Physikalische Technische Reichsanstalt for thermometer testing. Attempts to use the hydrogen scale above 100 deg. have met with difficulties because the hydrogen attacked the glass container and penetrated metal containers. Nitrogen and air have been tried. The result has been a number of different scales which do not agree so that it was always necessary in the literature to state what kind of a scale was used. At the boiling point of sulphur there exists already a difference of several tenths of a degree.

In order to remedy these differences the Reichsanstalt made the proposal in 1911 to refer all results to the thermodynamic scale, the variations of which from other scales were known. A second proposal was made to make a practical scale which would be as near as possible to the thermodynamic scale and which would be determined by the already fixed points. Besides the fixed points the practical scale should be formed by the platinum thermometer in the range from 40 to 450 deg. C. (boiling point of sulphur). In this range the platinum thermometer forms a very simple scale if 0 deg., 100 deg. and the melting point of sulphur are fixed. It is not necessary to have especially very pure platinum. It is noteworthy that no serious differences occur between this scale and the old hydrogen scale. It is important, however, what value to use for the melting point of sulphur. Results vary between 444.54 and 444.56. The Reichsanstalt has adopted 444.55. Definite fixed points in the new scale are the melting points of Hg, Sn, Zn, Cd, and the boiling points of naphthelene and benzol. From the boiling point of sulphur to 1000 deg. any desired scale may be used. For higher temperatures radiation pyrometry comes in.

In the temperature range below 0 deg. C. many measurements have been made lately with hydrogen and helium thermometers and a close agreement has been found. It would be desirable to have melting points in this range because they are better standards than boiling points.

A paper on the "**Atomic Weights of Thorium and Ionium**" was presented by Prof. Otto Hönigschmid of Prag, Austria, in which the author gives the results of two determinations made in the atomic weight of thorium. On account of the isotropy of thorium and ionium and their occurrence together in uranium ores, the author concludes that thorium separated from uranium-containing minerals is a mixture of thorium and ionium and must have a lower atomic weight than ordinary thorium which has been isolated from minerals free of uranium. By a method using proportions between thorium bromide, silver bromide and silver, the value found for pure thorium from monazite sand was 232.151 $\pm$ 0.015 from 24 determinations. This value is 0.25 lower than the formerly determined international weight of thorium. A thorium preparation from St. Joachimsthal pitch blende was also treated to produce thorium oxide and examined spectroscopically. It was found to be identical chemically and spectroscopically with the purest thorium from monazite sand. The average of six determinations on the atomic weight gave 231.507 $\pm$ 0.012, which is 0.65 lower than ordinary thorium. The bromide of this thorium isolated from uranium ore appears intensively violet in the dark, similar to radium bromide and gives off strong alpha rays, differing in both these properties from common thorium bromide. The author says the differences in the atomic weights are due to the presence of ionium. The ionium content is figured as 30 per cent.

Other Papers

A paper on the "Reaction Between Ferrous Oxide and Carbon and Carbon Monoxide and Iron," by Dr.

V. Falcke, of Leipzig, dealt with the author's redetermination of the equilibrium between CO and Fe and C and FeO.

A paper on the "Combining of Chlorine and Hydrogen" was presented by Professor Bodenstein of Hanover, dealing with the influence of light, heat and alpha radium rays and oxygen, on the reaction velocity, as investigated by Drs. Taylor and Dux. Their work was interrupted by the war, but their results are given as far as obtained.

Two papers on analysis were presented, one by Prof. W. Böttger of Leipzig, on the determination of small amounts of mercury salts in weak solutions, and a paper on metallic calcium and its application in gas analysis by Professor Sieverts of Leipzig. Prof. Walter Nernst demonstrated the application of alternating currents to bridge measurements, for instance, for determining dielectric constants. By the use of the loud-speaking Siemens telephone and inductor of the Telefunken-Gessellschaft a loud sounding system can be arranged suitable for demonstration purposes. The physical chemistry of food was taken up in a paper by Geheimrat Prof. Theodor Paul of Munich, who described the use of carbonate of lime for neutralizing the acid in wine. A paper by Prof. G. Meyer of Freiburg described the results of Dr. H. Stocker on the surface tension of pure water and salt solutions. The double refraction of vanadium pentoxide was discussed in a paper by Prof. H. Freundlich of Braunschweig. The reaction velocity of ideal gases was discussed in a paper by Prof. Max Trautz, of Heidelberg. A paper on passivity phenomena in the anodic production of halogens and the cathodic deposition of iron metals in solution was presented by Hofrat Prof. F. Foerster of Dresden. Colloidal gold was discussed in a paper by Prof. Richard Zsigmondy, and Prof. H. Goldschmidt of Kristiania, presented a paper on the alcoholization of salts. The darkness of ink on paper was discussed in a paper by Dr. W. Mecklenburg, of Berlin-Lichterfelde. A paper on the parallelism between electric light effect and Volta effect was presented by Prof. Krüger of Danzig. A paper on capacity of liquid insulators was presented by Professor Holde of Berlin. A paper on the gas content of the Taunus rocks and its relation to the springs of Wiesbaden was presented by Prof. F. Henrich.

The General Chemical Co. has just awarded to John W. Ferguson Co., engineers and contractors, Paterson and New York City, a contract for the construction of a manufacturing building at their Hudson River Works, Shadyside, N. J., across the Hudson River from New York City. This building will be two stories high 54 ft. by 55 ft. A 20-ft. by 20-ft. sq. tower rises from one corner, 30 ft. above the main building.

The Williams Apparatus Co. of Watertown, N. Y., has been formed to take care of the increased business of the Williams improved gas apparatus, as well as other high-grade specialties which the company is bringing out. The need of a compact, portable instrument by which an accurate gas analysis could be made quickly has been felt for some time and the popularity which the Williams apparatus has attained in a comparatively short time is an indication that it meets a real want. The Williams Apparatus Co. has expert glass-blowing and repair facilities both for the manufacture of its own products and special service of its patrons. In view of the present European war conditions these facilities are of particular timely value.

The **tin smelter** erected by the American Smelting & Refining Co. at Maurer, N. J., to smelt Bolivian tin ores, will be ready to operate in January.

The Character and Extent of Atmospheric Pollution in English and Scotch Towns

With Notes Upon a New Type of Recording Actinometer

BY JOHN B. C. KERSHAW

The issues of METALLURGICAL & CHEMICAL ENGINEERING for June and November, 1913, contained a detailed account by the present writer of the aims and work of the London Committee for the Investigation of Atmospheric Pollution, together with an illustrated description of the standard type of soot and dust collecting gage.

The method depends upon the use of an enlarged type of rain gage for the collection of the whole of the monthly rainfall at selected localities in each town. The soluble and insoluble impurities contained in the collected rainwater are then separated and are estimated by chemical methods. In some towns only one gage is installed, but in London, Glasgow, Birmingham, Sheffield and Manchester there are several gages placed at different points. Manchester, indeed, has ten gages in use in different parts of the city and its surrounding districts, and is also undertaking another investigation which will be referred to later.

The observations have now been carried out in sixteen English and Scotch towns for twelve months, and valuable information has been collected bearing upon the amount and character of the pollution existing in the air of the larger industrial cities. An official report upon the whole of the collected figures will be published by the committee at a later date, but the present article represents the writer's analysis of some of the figures and the conclusions drawn from them. The importance of knowledge of the local conditions existing in each town is shown by the comments on the Liverpool results.

RESULTS IN TEN ENGLISH TOWNS FOR THE SIX WINTER MONTHS OF 1914-1915

Table I contains a summary of the more important figures for ten English towns covering the six winter months, October to March, 1914-1915. It will be seen that Oldham occupies the place at the head of the table, with a soot and dust fall in the six months of 532 tons per square mile, equivalent to 1064 tons per square mile per annum. Birmingham (central) comes next, with a fall of 382 tons in the six months, while Bolton, Sheffield, Liverpool, Newcastle, Manchester and London follow in the order named.

TABLE I—THE SOOT AND DUST FALL OF ENGLISH TOWNS
FALL OF SOLID MATTER, OCTOBER, 1914, TO MARCH, 1915.

Name of Town or City	Tons per square mile. Total Solids	Tar, Soot and Ash
Oldham	532	364
Birmingham (Central)	382	252
Bolton	346	131
Sheffield (Attercliffe)	321	193
Liverpool	286	167
Newcastle	265	156
Manchester (Technical School)	263	156
London (Golden-Lane)	249	128
York	158	78
Malvern	32	5.88

York and Malvern occupy, as might be expected, the places of honor at the bottom of the table, with total soot and dust falls of 158 and 32 tons respectively. The latter figure is only one-eleventh that of Bolton and only one-seventeenth that of Oldham, and it shows what great scope exists for improvement in the atmospheric conditions of the Lancashire manufacturing towns.

London occupies a comparatively good position, ranking below all the Lancashire and other manufacturing towns of the north in the cleanliness of its atmosphere.

Examination of the deposit shows that the insoluble solid matter that has fallen during the winter months in the ten towns dealt with is composed of tar, solid car-

bonaceous particles and ash, and that the relative proportions of these three constituents do not vary very considerably in the different towns. Thus at Oldham, the insoluble solid deposit contained 1.5 per cent of tar, 29 per cent of carbonaceous matter, and 69 per cent of ash, while at York the percentages were 2, 30 and 68.

As a general rule, the percentage of ash is highest and the percentage of tar and soot lowest in manufacturing districts, since when fuel is burnt under boilers or in furnaces there is a tendency for the smaller particles of unconsumed fuel to be carried up the chimney and to be discharged as fine ash into the atmosphere. The temperature of the furnace is (or ought to be) sufficiently high to consume all the hydrocarbon gases and to prevent the formation of smoke and soot. In residential districts with old-fashioned grates, the opposite conditions prevail, and the proportion of tar and carbonaceous matter present in the smoke is generally higher than in factory districts.

The figures showing the percentage composition of the solid deposit collected by the standard gages in ten English towns and cities are gathered together in Table II, and on the whole support this view.

Table II—The Soot and Dust Fall of English Towns.
Proportions of Insoluble Solids, October, 1914, to March, 1915.

	Tar		Carbon		Ash	
Name of Town or City	Weight in tons	Per cent of total fall	Weight in tons	Per cent of total fall	Weight in tons	Per cent of total fall
Oldham	5.57	1.5	109	29	249	69
Birmingham (Central)	3.20	1.3	67	26	182	72
Sheffield (Attercliffe)	2.46	1.3	61	32	129	66
Liverpool	4.37	2.6	35	21	128	76
Newcastle	2.05	1.3	59	37	96	61
Manchester (Tech. School)	1.80	1.1	51	33	103	66
Bolton	1.63	1.2	31	24	99	74
London (Golden-Lane)	1.15	.90	49	38	78	61
York	1.60	2.0	24	30	53	68
Malvern	0.05	1.0	2	34	3.83	65

The average percentage ash fall in the five typical manufacturing towns, Oldham, Birmingham, Sheffield,

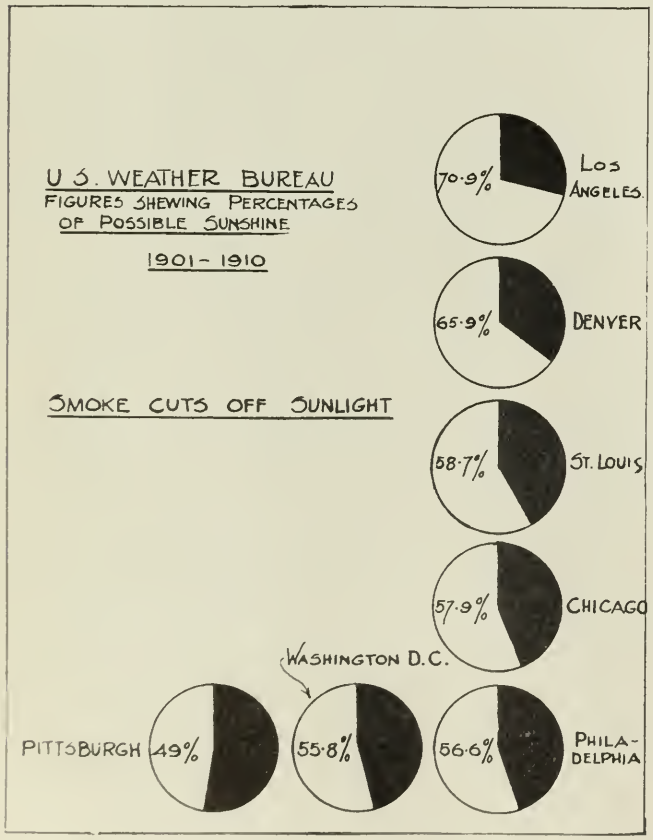

FIG. 1—SUNSHINE DIAGRAMS FOR SEVEN AMERICAN CITIES

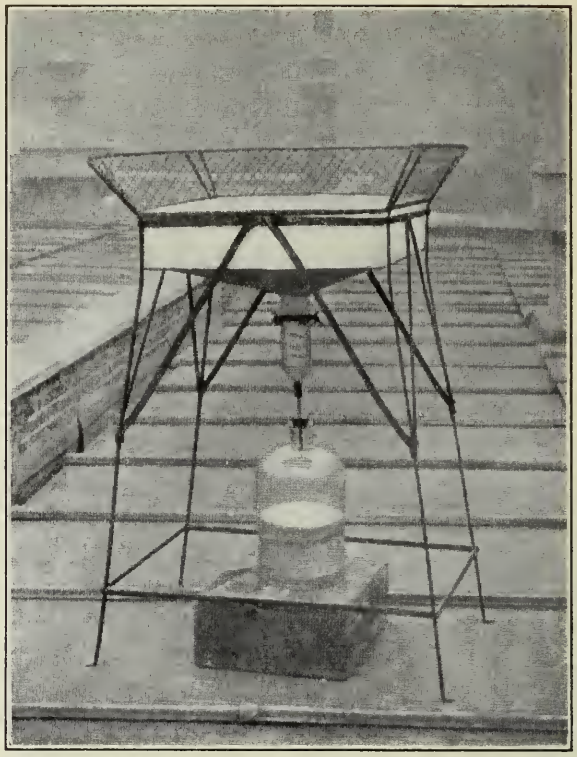

FIG. 2—THE ORIGINAL SOOT AND DUST GAGE USED FOR THE LANCET EXPERIMENTS IN LONDON, 1910-1911

Manchester and Bolton, is 69 per cent, as compared with 64 per cent for the four towns which may be classed as seaports or as residential in character, namely, London, Newcastle, York and Malvern. The tarry and carbonaceous constituents of the soot and dust fall in the four latter towns amounted to 36 per cent of the whole deposit, as compared with 31 per cent for the five manufacturing towns.

Liverpool seems to occupy an isolated position in this respect, for the percentage of solid matter in its soot and dust fall was higher than that of the manufacturing towns and its percentage of carbonaceous matter extremely low. This peculiarity is most probably due to the fact that in hot weather, under certain conditions of the wind and tide, a large quantity of fine sand is carried over the city from the sandy shores that lie on its north and northwest side. This fine sand falls by its own weight or remains suspended in the atmosphere until carried down with the rain, and tends to increase the incombustible solid portion of the deposit.

RESULTS IN SIX SCOTTISH TOWNS FOR THE WINTER MONTHS, 1914-1915

Turning now to a consideration of the returns that have been received from Scotland, we find that only six towns have carried on the observations during the winter of 1914-1915. These observations were interfered with greatly by frost and by breakage of the collecting bottles, and therefore they do not cover the whole period, nor are they strictly comparable with the English results.

The figures, so far as they are available, have been calculated out as tons per square mile, and are gathered together in Table III.

Assuming that the soot and dust fall for the shorter periods would increase proportionately for the whole of the winter, we find that the relative positions of these five towns are Glasgow, Paisley, Greenock, Stirling and Leith. Glasgow (Blythswood Square) possesses a total soot and dust fall of 327 tons, and ranks equal to Shef-

field (Attercliffe) in Table I, while Leith has a total fall of 147 tons in the six winter months, and would be placed below York and Exeter in Table I. The observations made by Chief Inspector Fyfe in the winter months of 1910-1911 gave the same relative positions for the four towns—Glasgow, Paisley, Greenock and Stirling—and are thus confirmed.

TABLE III—FALL OF SOLID MATTER IN SIX SCOTCH TOWNS DURING THE WINTER MONTHS OF 1914-1915.

Name of Town or City	Tons per square mile Total Solids	Tar, Soot and Ash	Remarks
Glasgow (Blythswood Square)	109	49	Two months
Glasgow (average of 7 stations)	79	28	Two months
Greenock	116	55	Three months
Stirling	84	38	Three months
Paisley	174	96	Four months
Leith	98	55	Four months

SUMMER AND WINTER RESULTS COMPARED

In view of the greater amount of fuel burnt in all large towns during the winter months of the year, and of the longer hours of darkness, during which it is possible for lazy or negligent firemen in factories to emit thick black smoke without being caught or fined, the soot and dust fall might be expected to be much heavier in the winter than in summer, and the observations confirm this expectation.

TABLE IV—THE SOOT AND DUST FALL OF ENGLISH TOWNS THE TOTAL FALL OF SOLID MATTER IN THE WINTER AND SUMMER MONTHS COMPARED.

Town	Tons per square mile in six months Summer Months April to September, 1914	Winter Months October, 1914, to March, 1915	Percentage Increase or Decrease
Liverpool	299	286	— 5
Newcastle	209	265	+ 27
London (Golden-lane)	145	249	+ 72
York	120	158	+ 32
Malvern	34	32	— 7

Table IV contains a summary of the results obtained by adding together the soot and dust fall in several towns for the six summer months of 1914, and comparing the aggregate with the fall during the six winter months.

Only five towns had completed twelve months' observations in last March, and three of these, namely, Newcastle, London and York, showed a considerable increase in the aggregate soot and dust fall for the six winter months of the year, the increase ranging from 27 per cent in Newcastle up to 72 per cent in London.

Liverpool provides an exception to the general rule, the winter soot and dust fall being lower than the summer one. This unusual feature of the Liverpool returns is due probably to the same cause as that noted earlier, namely, the fine drift sand which adds to the incombustible solid matter of the Liverpool deposit. This drift sand is carried the greatest distance during the summer and early autumn gales, when the hot sun has dried the surface sand on the shores of the Mersey estuary. In the winter time the sand is never sufficiently dry to be swept up in the air and carried long distances by the wind.

COMPARISON OF THE ENGLISH AND PITTSBURGH RESULTS

The figures given in the above tables may be usefully compared with those collected in Table V and given in the course of an article by Mr. J. J. O'Connor upon Pittsburgh's soot and dust fall, which appeared in this journal in April, 1914 (Vol. XII, page 247). The principle of the method used for collecting the soot and dust was similar, but the Pittsburgh gage was much smaller in size than that used in England.

TABLE V—SOOT AND DUST FALL IN TONS PER SQUARE MILE PER YEAR IN PITTSBURGH, U. S. A. (BREMNER), APRIL, 1912, TO MARCH, 1913

Station No.	Composition of Soot: Tar Tons	Fixed Carbon Tons	Ash Tons	Fe_2O_3 Tons	Total Tons
1	13	131	306	145	595
2	16	713	809	412	1,950
3	10	202	189	269	670
4	19	417	844	380	1,660
5	21	357	704	548	1,630
6	4	322	343	309	978
7	8	300	309	195	812
8	7	286	419	210	922
9	5	211	344	188	748
10	3	274	336	108	721
11	8	391	378	218	995
12	7	200	333	153	693

Average of twelve districts.....1,031 tons

The worst of the English towns, namely, Oldham, with a winter soot and dust fall at the rate of 1064 tons per square mile per annum, has, therefore, an atmosphere as dirty as that of Pittsburgh, with an average fall of 1031 tons per square mile per annum; whereas Sheffield, the center of the English steel-making industry, even in its dirtiest district of Attercliffe,

FIG. 3—THE STANDARD SOOT AND DUST GAGE AT LIVERPOOL, 1914

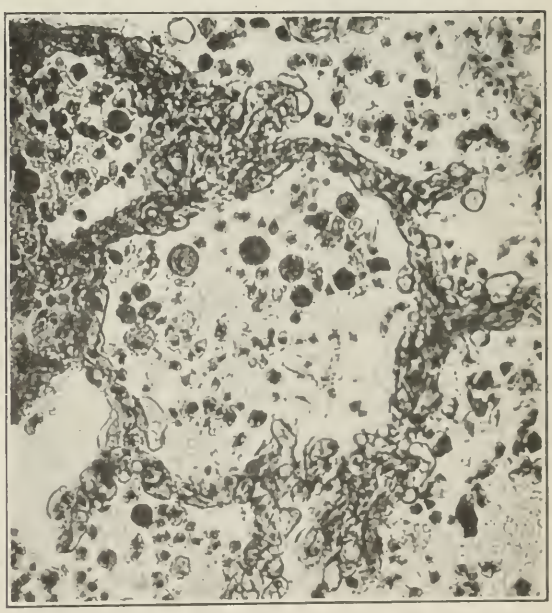

FIG. 4—A SECTION OF THE HUMAN LUNG, SHOWING SOOT DEPOSITS

shows a fall of only 642 tons in the twelve months, and is therefore far cleaner as regards its atmosphere than Pittsburgh. Possibly had the observations been carried on over a wider area at Sheffield, especially on the eastern side of the city, the results would have approximated more to those of Pittsburgh, for the prevailing winds at Sheffield are from the west and southwest.

In view of these results and facts, it is interesting to note that at the International Conference for the Prevention of Smoke, held in Pittsburgh in September, 1913, a committee was appointed to co-operate with the London committee in order to arrange for the introduction of the standard method of making these soot and dust observations in America. Mr. E. P. Roberts, the chief smoke inspector of Cleveland, was made chairman of this committee, and it may be hoped that shortly figures similar to those given in Tables I, II, III and IV will be available for some of the leading towns and cities of America.

THE SPECIAL INVESTIGATIONS AT MANCHESTER

The sanitary committee of the Manchester City Council in December, 1912, appointed an air pollution advisory board for the purpose of investigating and reporting upon the conditions of air pollution within the city area, and the first report of this advisory board to the sanitary committee, which has been recently published, forms a most valuable contribution to the literature of air pollution in towns. The board consists of the members of the sanitary committee, strengthened by other members of the City Council, and by a number of outside members of engineering and scientific societies especially interested in the smoke problem. It has no administrative powers, but is concerned solely with research and educational work.

For the purpose of more fully carrying out its objects, four sub-committees have been appointed, dealing with the *chemical, statistical, legal* and *engineering* branches of the problem. The chemical sub-committee, of which Prof. H. B. Dixon of Manchester University is chairman, has made observations upon the loss of light due to the suspended solid impurities in the air of the city by three methods. A recording actinometer devised by Prof. Haldane Gee and Mr. W. C. Jenkins of the Godlee Observatory was used for some of the observations. The results obtained with this instrument at three different observation stations during July, August and September (1914) showed that the average intensity of the sunlight at Crewe was nearly 20 per cent greater than in the Whitworth-street Garden in the city of Manchester, and that on the roof of the School of Technology (100 ft. high) it was 12.6 per cent greater than at the ground level. In order to obtain records from some place well outside the local area, it has been arranged to install one of these recording actinometers at Abergele, in North Wales.

The instrument (see Figs. 5 and 6) consists of a fixed metal cylinder, 6 in. in diameter and 3½ in. long. This cylinder is open at the bottom, but is closed at the top with a lid, having on its circumference a scale of hours and around its edge a scale of one-quarter hours. By the use of a clamping device photographic paper can be secured evenly on the surface of the drum. The lid is fixed to a curved metal upright supported on the wooden base of the instrument. The top of the upright is graduated from 50 to 55 deg., corresponding to local values of latitude. This enables the axis of the cylinder to be fixed at the required latitude by moving the curved arm until an index mark is at the right angle.

Concentric with the fixed cylinder is a movable one of a little larger size. On the bottom is a clock, with its driving axis passing through a hole in the metal bottom of the cylinder. This axis passes into a hole in a rod, and when the axis is held by turning a clamp screw, the outer cylinder, with its clock, revolves around the inner cylinder once in twenty-four hours. The clock runs for seven days, and after adjustment keeps good time. It may be noted that in the actinometer the axis is held and the clock rotates. This arrangement is the reverse of an ordinary clock.

To keep the cylinders concentric, a central rod is fixed to the center of the upper cylinder, and pivots in a central hole in the top of the clock case. On the rotating drum there are two fixed metal jaws provided with a slit between them. This slit is wider at the middle and tapers each way.

When in use the instrument must be placed with its axis in the geographical meridian, and the slit is brought opposite to the mark indicating solar time. The motion of the slit will then follow the sun, and the

FIG. 5—NEW FORM OF ACTINOMETER

FIG. 6—NEW FORM OF ACTINOMETER—WORKING PARTS

intensity of the light will be indicated by the degree of blackening of the paper.

The type of paper best for the purpose has been the object of many experiments and inquiries. So far as the experimental work has been completed, it has been found that a gas-light paper that has been treated with a 5 per cent solution of resorcin, containing ½ per cent of glycerine, is the most suitable paper for general use. The paper is sensitive to ultra-violet light, and to a certain extent toward the red end of the spectrum. The standard paper is prepared by the Ilford company.

It is proposed that all the exposed papers be sent to the School of Technology for examination and scaling. Much information can be obtained by the simple inspection of the records, but in order to obtain numerical values the surface brightness is measured by the aid of a portable photometer called a lumeter. The surface brightness is found to be, within certain limits, inversely proportional to the intensity of the received light. Where there is much variation in the daily record, the average value can be obtained by rotating the paper by means of an electric motor, and then reading off the resultant tint with the lumeter.

The ideal position for the actinometer is close to the ground, and such that the light is not obstructed from sunrise to sunset. It is difficult to obtain such a situation, especially in the city and suburbs, and although desirable it is not absolutely necessary, for useful observations can be taken even when freedom from obstruction is only for a part of the day. It is essentially important to place the instrument in the charge of persons who are accustomed to the regular use of instruments. The actinometer gives the intensity of the light directly received from the sun.

THE CONNECTION BETWEEN SUNLIGHT, PURE AIR AND HEALTH

In concluding this article a quotation may be given from the words of a famous scientist as to the intimate relation that exists between sunlight and health, and as to the effects of the soot and dust suspended in the atmosphere in screening off the active rays of sunlight from crowded city streets and tenements. Sir Oliver Lodge, the principal of Birmingham University, has stated:

"Under present conditions the greater part of humanity in England lives under a thin pall of obscure material, through which a certain amount of light and heat can pass, but which effectually screens the health-giving and disease-destroying actinic rays of the sun. Accordingly, frequent excursions in the country are needed for the preservation of even a moderate or residual amount of robust health, while the multiude condemned to live under unwholesome conditions suffer both in themselves and their children to a grievous extent."

This screening effect of a dust-polluted air is far greater than is imagined, for direct experiments in Manchester have proved that on a sunny day *no less than* 12 *per cent of the sunlight is cut off in the last* 100 *ft. of the atmosphere.*

There are three essential factors in the preservation of good health, namely, pure water, pure food, and pure air; and it is satisfactory to find that at last the importance of the third factor is being recognized. The soot and dust suspended in the atmosphere are disadvantageous and harmful to the living organism in several ways. In the first place by diminishing the amount of sunlight which falls upon the earth they directly lower the vitality of the human organism and diminish its power of resisting disease. Cohen has shown that in Leeds the smoky atmosphere cuts off from 25 per cent to 40 per cent of the sunlight, and the Pittsburgh and Manchester investigations have confirmed these results. The soot and dust suspended in the atmosphere also enter and choke up the pores and cells of the lung tissue to such an extent, that the rapid assimilation of oxygen by the blood, and discharge of CO_2 and other waste products, is checked. Doctors can always tell, by a post-mortem examination, from the color of the lung tissue whether the man has lived chiefly in the town or the country during his lifetime, and the shortened life of town-dwellers is partly due to this cause.

Finally, direct sunlight and pure air are now recognized as natural germicides, and the soot and dust suspended in the atmosphere therefore aid the propagation of all infectious diseases by promoting the conditions which are favorable to bacterial life.

The writer's thanks are due to Mr. J. J. O'Connor and to the directors of the Mellon Institute, of the University of Pittsburgh, to Professor Beattie and to Dr. Hope of Liverpool University, and finally to Professor Gee and Mr. W. C. Jenkins of Manchester, for information and for the loan of the photographs used in the preparation of this article.

Liverpool, England.

Recent Chemical and Metallurgical Patents

Iron and Steel

Low-Phosphorus Steel from High-Phosphorus Iron.—According to a process of ALVA C. DINKEY low-phosphorus steel is cheaply produced from iron containing phosphorus above the permissible or specified limit, as follows: A quantity of limestone and ore or other oxide of iron is charged into a furnace, the limestone amounting to about 5 per cent and the ore or oxide to about 15 or 20 per cent by weight of the metal to be treated. The charge is heated until it is at a red heat or is pasty and even fused. The charge of pig iron in a molten condition is then poured into the furnace as rapidly and as nearly at one time as possible. This causes an active reaction and a rapid production of basic slag, and the materials being at a comparatively low temperature, the iron oxide oxidizes, the phosphorus, silicon and manganese in the pig iron with extreme rapidity and at the same time oxidizes a slight portion of the carbon. At the end of about one hour, the phosphorus will be substantially eliminated, that is, reduced to about 10 per cent of its original content. The furnace is then tapped and the partly refined metal removed therefrom to a mixer or storage vessel for subsequent treatment in acid Bessemer converters. The iron will be treated in the preliminary furnace in about 50 to 100-ton lots and as the storage vessel has a much greater capacity (500 or more tons), a large quantity of partly refined or semi-finished metal can be stored therein. (1,162,755, Dec. 7, 1915.)

Sulphuric Acid

Contact Process for Sulphuric Acid.—In the contact process of making sulphuric acid it has been the custom to preheat the sulphur dioxide and air to about 400 deg. C. before passing them through the converter which contains trays of the catalytic mixture, usually $MgSO_4$ with 0.2 per cent platinum. The platinum acts as the catalyser. In the process there are three distinct steps, (1) the drying of the gaseous mixture, (2) the heating of same, (3) the treatment with the catalyser. In order to perform all these operations in one step a process has been patented by CLARENCE J. BROCKBANK of Niagara Falls, Ontario, Canada (assigned to the Carborundum Company). The gases are passed

through an acid-proof pipe in which is placed a porous diaphragm made of fine carborundum crystals (such as described in patent 992,698 of Frank J. Tone, May 16, 1911). This carborundum diaphragm is previously impregnated with platinum by immersing it in a solution of platinum chloride and heating whereby the chlorine is driven off and the platinum remains. This diaphragm is heated by joining it to electric terminals, as shown in Fig. 1. This process provides a means of controlling

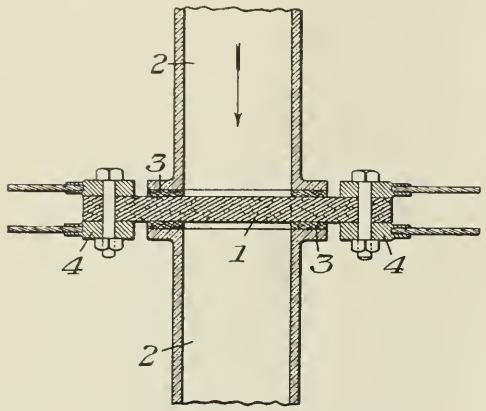

FIG. 1—CATALYTIC DIAPHRAGM

the temperature accurately (between the limits of 400 and 800 deg. C.) and the gases are instantly converted and a better yield is claimed to be attained. The carborundum plate is not attacked by fuming sulphuric acid and in case it is fouled by arsenic may be restored by immersing in aqua regia and heating. (1,157,293, Oct. 19, 1915.)

Gold and Silver

Hydrolysis of Alkaline Cyanides.—In addition to the action of cyanicides in destroying the efficacy of alkaline cyanides as solvents for gold and silver, "the principal loss is due to the formation of hydrocyanic acid by hydrolysis of the simple cyanide solution," according to letters patent granted to Mr. Hugh M. Leslie, of Glasgow, Scotland. The patentee states that he has arrived at this conclusion as the result of extensive experiments to determine the loss of cyanide in the treatment of ores. The hydrocyanic acid evolved as the result of this hydrolysis is constantly passed into the atmosphere and lost. It is claimed that the presence of a large excess of caustic alkali in the ore pulp will not prevent this hydrolytic action. The inventor proposes, therefore, to recover this hydrocyanic acid and make it available for further dissolution of metal by covering the tanks used in the cyanidation of ores and conducting the evolved gas to absorption tanks where the hydrocyanic acid may be fixed in alkali. When thus recovered the cyanide is useful for further work on ores. A modification of his proposal is to arrange covered agitators and dewaterers in such a way that the pulp is gradually raised from one machine to the next by means of air-lifts, the hydrocyanic acid gas collected being introduced to the agitators with the air at each lift and thus caused to act on the pulp. (1,158,513-4, Nov. 2, 1915.)

Filter.—A filter of the drum type, for separating solids and liquid contained in an ore pulp, is shown in section in Fig. 2, being the patented invention of William P. Lass of Treadwell, Alaska. The filter leaves 79 are stationary, resting on rollers 80 and supported between guides 83. Spray pipes 87 are provided for the purpose of spraying the leaves and discharging therefrom the cake formed in the filtering operation. Pulp to be filtered enters the bottom of the drum at 33.

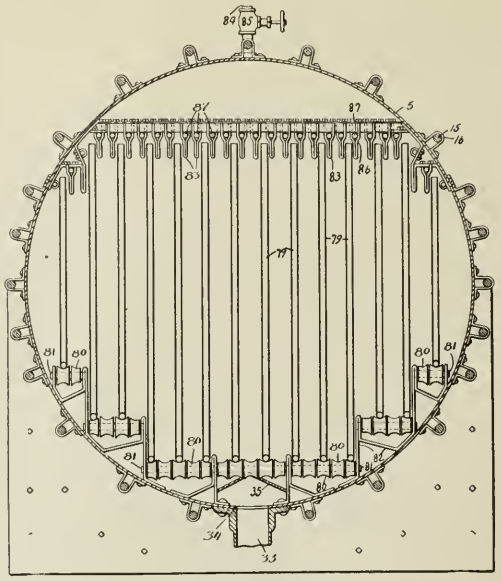

FIG. 2—FILTER

Compressed air is supplied to the drum by the pipe and valve 84, 85. When the pulp has filled the drum to a point above the filter frames, a valve is opened to permit the filtrate to run from the press through a pipe not shown. After a cake has been formed of the desired thickness, compressed air is admitted through 85, forcing the remaining pulp back out of the press through an exit pipe. Wash solutions may be introduced into and removed from the drum in the same manner, and after the cake has been washed it is blown from the filter leaves by reverse pressure of air or steam, and the discharge is facilitated by sprays of water from the pipes 87. The tailing pulp can be removed from the drum by screw conveyor or sluiced by the water sprayed from the pipes. (1,144,854, June 29, 1915.)

Copper

Flotation of Sulphidized Minerals.—A method of treating low-grade oxidized copper ores is disclosed in the specifications of a patent granted to Henry B. Hovland of Duluth, Minn. He proposes to dissolve the copper in sulphuric acid, and then sulphidize the metal by adding to the pulp a mixture of calcium sulphide and ferric sulphate, the latter to facilitate the conveyance of the sulphur to the metal to be sulphidized. The copper thus treated can then be recovered as a concentrate by flotation. Calcium sulphide is mentioned as the sulphidizing agent as it is a cheap material, easily prepared from lime and sulphur, or by reducing gypsum. (1,159,942, Nov. 9, 1915.)

Precipitating Copper from Solution by SO_2.—A suggestion for recovering metallic copper from its solution as a sulphate is contained in a patent granted to George D. Van Arsdale of East Orange, N. J. After the copper is dissolved from its ore the solution is separated from the gangue in any desired manner, and is then saturated wth sulphur dioxide to effect a precipitation of metallic copper under certain conditions of heat and pressure. Sulphuric acid is regenerated in the precipitating process and can be used for the treatment of additional ore. In the treatment of ores containing practically no soluble constituent except copper, an excess of free sulphuric acid is generated. It is advantageous to neutralize this excess of acid, or part of it, and thereby control the amount of copper precipitated. Since two molecules of H_2SO_4 are formed for every molecule of copper precipitated, and if it is de-

sired to neutralize one of these by the use of CaO, it will be necessary to add CaO in the ratio of the molecular weights of copper and lime, or 63:56. The proportionate amount of lime used will vary with the conditions which it is desired to maintain in the solution, or in other words, in accordance with the yield of copper required or the amount of free acid which is to be left in an unneutralized condition. (1,147,466, July 20, 1915.)

Synopsis of Recent Chemical and Metallurgical Literature

Chemical Engineering

Development of an Acid-Resisting Alloy.—An interesting paper on a new acid-resisting alloy was presented by Prof. S. W. PARR of the University of Illinois at the meeting of the American Institute of Metals at Atlantic City, Sept. 28, 1915. The increasing cost of platinum prompted the author to attempt to find an alloy that could replace it in some uses. The problem contained many difficulties as so many properties were required viz.: resistance to acids, density, strength, workability and resistance to corrosion. The "cut and try" method had to be resorted to for the most part, although the guiding theoretical consideration was to arrange the constituents so that as far as known the electro-positive and electro-negative properties would neutralize each other and produce a potential of zero. The lack of practical working data on this question and the ever presence of impurities and their great effect made exact applications of the theory out of the question.

An alloy was, however, found with a degree of resistivity which had hardly been thought possible. The unit of reference for measuring the amount of corrosion was adopted as follows: A standard disk of the alloy was prepared having 10 sq. cm. of surface. This was submerged for a given length of time, usually twenty-four hours in nitric acid of approximately 25 per cent HNO_3. The loss in weight was calculated to the amount which would be represented for an area of 100 sq. cm. per hour.

In test No. 23 a small casting of simple form was secured from which the test piece showed a loss in weight referred to this unit of surface and time of 0.03 mg. In test No. 40 a casting of more difficult form was secured weighing about 10 lb., the test piece from which gave an equally high degree of resistivity. In the last seven castings of similar size, Nos. 133 to 136 inclusive, six out of the seven standard disks did not show a weighable loss after contact with the nitric acid for twenty-four hours.

The casting and working properties of the alloy had to be promoted in all of the modifications. At first thought this would seem to multiply the difficulties. On the contrary it proved to be more of an advantage than otherwise. That is to say, each additional element would tend to lower the melting point of the alloy and reduce the tendency to form an open texture or coarsely crystalline structure. If the resulting composition seems to be unnecessarily complex, the above statement may be a partial reason for that result.

An analysis (by S. A. Braley and F. E. Rowland) of a representative sample is as follows:

Cu	6.42
Mn	0.98
Si	1.04
W	2.13
Ni	60.65
Al	1.09
Fe	0.76
Cr	21.07
Mo	4.67
	98.81

Carbon and boron not determined.

The casting of the alloy proved to be quite as serious a problem as the development of the composition. The melting point is approximately 1300 deg. C. The furnace must be capable of readily attaining the temperature of molten nickel, say 1600 deg. When thoroughly liquid the alloy pours readily and fills the mold perfectly but the freezing point is so quickly reached that feeding of the casting from risers, to make up for shrinkage, is practically impossible. Moreover the shrinkage is so excessive that cracks and hollow spots are very difficult to avoid. This feature can be perhaps better appreciated when it is noted that the most important instrument in mind for use of the alloy was a calorimeter bomb, which consists essentially of a chamber of approximately 35 cu. in., which must retain absolutely without leakage, a gas at an average pressure of 25 to 30 atmospheres.

Here again the very complexity of the composition has probably been the chief factor in securing a metal which could by any means be cast in the dense, homogeneous form required. It works about the same as tool steel. The interior surfaces of the bomb and cover show no trace of corrosion after use in over 1500 determinations using the apparatus in determining the heating value of coals. In each determination there is generated a considerable quantity of nitric and sulphuric acids which condenses on the interior surfaces of the bomb. Under the prevailing conditions of heat and high oxygen pressure the best possible conditions exist for the promotion of corrosive action.

Attempts to draw the alloy into wire and roll it into sheets have been only partially successful, but sufficient to show the likelihood of success when the conditions for proper annealing are better understood. The tensile strength of the cast metal is approximately 50,000 lb. per square inch. The name suggested for the alloy is "Illium."

Gold and Silver

Zinc-Dust Precipitation Tests.—An A. I. M. E. paper presented at San Francisco gives a discussion of observations made by NATHANIEL HERZ on laboratory tests of a large variety of zinc-dust samples. The author used the efficiency test of W. J. Sharwood, as follows:

"A solution of potassium silver cyanide is prepared by dissolving 10 grams silver cyanide (AgCN) and 5 grams of 90 per cent potassium cyanide in a little water and diluting up to 1000 cc. It is then adjusted by addition of a little more KCN or AgCN until the solution indicates from 0.12 per cent to 0.15 per cent free KCN by titration with standard silver nitrate. The titration is best made by using a 10-cc. or 20-cc. sample, adding 1 cc. of 2 per cent potassium iodide, and a slight excess of ammonia; the end point is then sharper. Or 1.5 grams of pure crystallized $KAg(CN)_2$ may be dissolved in a liter of water and 1.5 grams KCN added.

"Weigh out 0.5 gram zinc dust into a 300-cc. beaker. Add a few cubic centimeters of water and stir until zinc is well mixed, then pour in 250 cc. of the prepared solution, stirring vigorously. See that all lumps are broken up, and continue stirring for fully five minutes. Stir occasionally (at least every 10 minutes) until the end of two hours from the addition of the solution. Then filter upon an 11-cm. filter, wash precipitate thoroughly, sprinkle with test lead, wrap it carefully in the paper, place in a scorifier with about 20 grams test lead, burn paper cautiously in muffle, scorify five minutes, cupel at low temperature and weigh silver. Milligrams silver obtained from 0.5 gram zinc × 0.0606 = percentage precipitating efficiency."

Substitution of sodium for potassium cyanide gave no variation in results. Precipitation of gold solution gave only about one-half to one-third the efficiency observed with silver solutions. Mixed gold and silver solutions gave efficiency intermediate that of silver and gold alone, the beads containing four atoms silver to one gold. Slight variations in free cyanide present do not affect results materially, but the quantity cannot be reduced to 0.01 per cent without giving very different results. In some cases exposure of the zinc dust to moist air for several hours seemed to increase efficiency of precipitation. Other tests indicated that the oxidation of zinc dust by exposure to dry air is practically negligible. In moist air, on the other hand, oxidation may amount

to as much as 2 or 3 per cent per day, falling off as oxidation proceeds. The efficiency of precipitation is not reduced as much as commonly supposed.

Lead increases the activity of zinc in cyanide solutions, and cadmium would probably also help, though not as much as zinc. Analyses of samples showed the lead content to vary from 0.15 per cent to 5.2 per cent, and cadmium from *nil* to 3.9 per cent. Zinc oxide varied from 6.3 per cent to 17.85 per cent. Some carbonaceous matter occurs in some samples, but is inert. Carbon dioxide also occurs, but in such small quantities as to be of no material effect in precipitating calcium carbonate and thus preventing contact of zinc with cyanide solution. Some dusts contain an oily material of some kind, and such dusts are improved by exposure to air.

The author gives the following requisites in zinc dust for satisfactory precipitation: Most of it should pass a 200-mesh screen, and the fine portion should be much finer than the screen opening. Oxide should be low, although this does not necessarily indicate a good dust. Lead should be present at least over 1 per cent, and 4 per cent may do no harm. The value of the dust for precipitating purposes can be determined rapidly by testing with standard silver cyanide. If the efficiency is well over 40 per cent, the dust is satisfactory; if under 30 per cent, the dust may give poor results.

Lead

The Newnam Mechanical Lead Hearth.—A successful effort to mechanicalize the ore hearth for smelting galena is recorded by Mr. William E. Newnam of Collinsville, Ill., in a paper prepared for the next meeting of the American Institute of Mining Engineers. The field of the ore hearth in lead smelting is confined to the treatment of non-argentiferous galena containing over 68 per cent lead. The advantages of this method of smelting are the lower cost of pig lead, the immediate reduction of 55 to 65 per cent of the lead content of the concentrate, with simultaneous roasting, thus producing a small tonnage of gray slag which is an ideal feed for the blast furnace. The disadvantages of the method are the limited size of units, 4 ft. to 5 ft., requiring two men per eight-hour shift; small product per man; hot and laborious work with danger of lead poisoning from dust and fume; large flue and bag-house system required to catch dust and fume which must be re-treated.

After a careful study of the hand-hearth operation, it was decided that three things were necessary to perfect it, namely: A cool and sanitary hood; a mechanical rabbler which would effectually replace the continuous and laborious use of the hand rabble, and a lead-well attachment that would mold clean lead direct from the hearth basin with little attention on the part of the furnacemen.

Experiments were carried out on the ordinary 4-ft. hand hearth. The hood problem was taken up first; and soon a double hood was devised which gave the furnace room a clear and fume-free atmosphere, at the same time reducing the direct and radiated heat to the workmen 50 per cent. A complete cessation of sickness and an increased output were at once noted.

After a few trials a simple and effective lead well and molding device was installed.

A traveling rabbler was next put on the 4-ft. furnace, and, after numerous changes, a successful type was worked out.

This rabbling machine is hung from a carriage which travels on an overhead track, and it rabbles in one direction only, for a reason given later. The machine being in such a position that the rabble arm is at the extreme end of the furnace, a releasing lever is pulled, which starts the machine, causing the rabble arm to describe a motion which is similar to that of the hand rabble, but more effective, since there is more power behind it. As the rabble arm is withdrawn from the fire, an eccentric connected with a ratchet wheel moves the carriage forward about 4 in. for the next stroke of the rabble arm. This motion is repeated until the other end of the furnace is reached, when the machine automatically stops and withdraws the rabble arm from the fire.

Two men, a charger and a helper, operate the furnace. The helper follows close behind the rabble arm and with a long-handled shovel pushes back the loose charge, picking out the gray slag as he goes along. Close behind the helper comes the charger, who spreads a thin layer of ore on the charge as fast as it is shoveled back by the helper, adding coke breeze as needed.

Thus the fire is exposed for an instant only, and by the time the trip down the furnace is completed the end first charged is ready for the rabbling machine. It is for this reason that the rabbling is performed in one direction only. The first trip being complete and the gray slag removed from the apron, the throwing-in of a clutch causes the carriage to return without rabbling to its original position, where it automatically stops in readiness for a second rabbling trip.

Thus on each trip the fire is rabbled twenty-four times in forty-eight seconds, the return motion require twelve seconds. One horsepower is required under full load, and is supplied by a 1-hp., alternating-current 220-volt motor. The rabbling machine is simple, strong, and durable, and only requires a few minutes' attention daily.

From the data compiled it was determined that the hearth could be increased to 8 ft. in length, that it would then produce two and one-half times as much pig lead as the hand hearth; and that two men could operate it with less fatigue than that sustained by two men on the ordinary hand hearth. An 8-ft. hearth was at once constructed and from the first day of its operation it has not only realized our expectations but considerably exceeded them.

The following table is a comparison of the two types of hearth, operating side by side on the same ore, showing the average results per eight-hour shift over a period of four weeks, the labor being the same on each type. Ore charged, galena concentrates, containing 72.5 per cent lead, and 15.1 sulphur.

	Newnam Hearth, Pounds	Hand Hearth, Pounds
Dry ore charged	13,179	5,091
Lead contents	9,554	3,691
Pig lead made	6,443	2,030
Gray slag made	3,318	1,329
Per cent of coke breeze used	3.6	8.8
Rabble trips per hour	37.2	....
Percentage of Total Lead in Products		
Pig lead	67.44	55.00
Gray slag	15.18	16.20
Dust and flume	17.38	28.80
	100.00	100.00

Analysis of Gray Slag

	Pb	FeO	CaO	S	Insoluble
Newnam hearth	43.7	12.8	9.9	1.9	12.6
Hand hearth	45.0	12.2	9.0	2.6	12.2

Taking the above average runs as a basis, the sulphur elimination is calculated as follows:

Ozone for Ventilation

The following is a report of the test of a Westinghouse air ozonizer, together with the results of the experiments on air ozonization which have been carried out by Mr. SHEPPARD T. POWELL for Messrs. Wehr and Walden, engineers, of Baltimore, Md., during the past year. The investigation was carried on under conditions ordinarily encountered in a chemical laboratory, and for this reason the results obtained may be somewhat at variance with the results of other investigators who worked under local conditions more favorable for such work. Notwithstanding this fact, the results of the tests reported are instructive in determining the efficiency of air ozonization.

The investigation was conducted to determine:

1. The efficiency of the generator in respect to the production of ozone, especially in reference to its operation under varying weather conditions and air velocities through the tubes.

2. The effect of the gas upon odors in the air and to determine the failure of ozone to remove or mask odors caused by certain compounds.

3. The efficiency of ozonized air in the destruction of bacteria and similar micro-organisms present in the atmosphere.

It was not within the scope of the laboratory to touch upon all phases of air ozonization, so that the investigation was narrowed down to these three points, as these are the all important aspects of the purification of air by means of ozone.

LABORATORY APPARATUS AND METHODS EMPLOYED

The ozone generator used in this work was the standard Westinghouse air ozonator. This generator consists of a cylindrical metal case containing four glass tubes, 2 in. in diameter and 9 in. long, on which there is a metallic coating and within the tubes is wire gauze. In the lower portion of the case is placed the step-up transformer, the high-tension leads from which are connected, one to the wire gauze on the interior of the glass tubes and the other to the metallic coating on the outside of the glass tubes, the glass tubes thus serving as the dielectrics between the metallic electrodes. The production of ozone is controlled by means of a switch so that one or more tubes can be operated at the same time.

For this work the lower half of the generator was inclosed within a practically airtight wooden box, and over the top of the generator was a metallic hood serving the purpose of a container or reservoir for the collection of samples of the gas.

A ⅛-hp. blower was used for varying the air velocity through the generator tubes, the outlet of the blower being connected directly to the wooden case of the ozonator by means of a 4-in. metal pipe. When the blower was in operation the air entering the apparatus was filtered by means of an absorbent cotton felt mat. A sketch of the apparatus is shown in Fig. 1.

The method of analysis used in determining the concentration of the gas was a modification of the Treadwell Hall method.[1] The method consists in aspirating a known volume of the ozonized air through a $2N$ potassium iodide solution contained in a specially designed absorption bottle (the volume of the sample depending upon the concentration of the ozone). To the ozonized KI solution are then added 5 cu. cm. of 1 to 3 sulphuric acid and titrated immediately with $\frac{N}{24}$ sodium thiosulphate, finishing the titration by means of starch. The concentration of the gas is reported in milligrams of ozone per liter of ozonized air, which is equivalent to grams of O_3 per cubic meter by the following formula:

$$O = \frac{AN}{R}$$

in which O is the number of milligrams of ozone per liter of ozonized air, A the number of cubic centimeters of thiosulphate solution required, N the strength[2] of the solution, and R the number of liters of gas that passed through the KI solution.

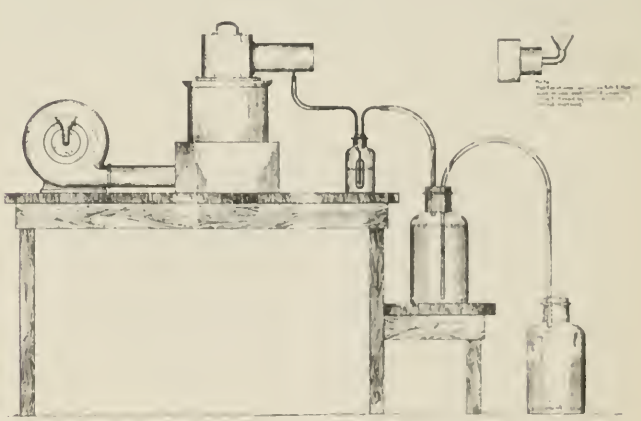
The culture medium used in the bacteriological work that was done was nitrient gelatine prepared according to the methods recommended by the A. P. H. A. for water and sewage analyses. The culture plates were incubated for forty-eight hours at a temperature of 18 deg. to 20 deg. C. There are no methods known to-day which will give an accurate count of the total number of organisms present in the air, but in all probability the method employed will give quite as accurate and reliable results as many of the more elaborate methods that have been used by investigators recently in similar experiments.

RESULTS OF EXPERIMENTS TO DETERMINE THE YIELD OF OZONE FROM THE GENERATOR

The heat generated by the transformer as well as that from the brush discharge warms the air within the ozonator so that the air entering the bottom of the drum rises, causing the ozone to leave the generator at the top of the apparatus. However, as ozone has a specific gravity somewhat higher than that of air the gas must be heated to such a temperature as to overcome the tendency of the gas to leave from the bottom of the apparatus. A number of tests were made to determine if there was any uniform rate of heating of the tubes, or uniform time element in the reversal of flow of the gas through the machine.

As it was not possible to obtain any accurate temperature reading within the tubes of the ozonizer, these tests were made by means of moistened starch iodide paper. Strips of this sensitized paper were placed opposite the openings at the bottom and top of the generator and the presence of the gas noted by the blue color formed.

In every instance the ozone passed from the bottom of the generator when the apparatus was first put in service irrespective of the setting of the switch. After running the apparatus for a time, varying from one minute to twenty minutes, the flow of the gas was reversed and flowed from the top as long as the ozonator was in operation. As would be expected, there is apparently a critical temperature at which this change



GENERAL ARRANGEMENT OF THE OZONATOR, BLOWER AND SAMPLING OUTFIT USED IN THE OZONIZING EXPERIMENTS

[1] Treadwell Hall's Analytical Chemistry, Vol. II, page 676.

[2] $\frac{N}{24}$ thiosulphate solution 1000 c.c. = 1.0 gram of O_3

1 c.c. = 1.6 milligram of O_3

takes place, but there is no uniform rate of heating the tubes under uniform atmospheric conditions and current consumption.

A great number of determinations were made of the concentration of the gas generated with each setting of the switch. From these tests it was clearly demonstrated that the yield of ozone is in direct proportion to the setting of the switch, as has been stated by the manufacturers.

The average concentration in milligrams of ozone per liter of ozonized air for each setting was as follows:

Setting	1	2	3	4
Concentration	0.0150	0.0900	0.1500	0.1800

These concentrations are very constant, the greatest variation being about 5.0 per cent, covering all tests under various atmospheric conditions.

Although it is a well-known fact that humidity in the atmosphere has considerable effect upon the yield of ozone from large installations, still tests of this apparatus in the laboratory gave no evidence of this upon the concentrations produced with very great change in the humidity of the air, as can be seen from Table I:

Table I.—Varying Humidity

Setting		1	2	3	4
Humidity	58	0.0150	0.0910	0.1500	0.1750
Temperature	68				
Humidity	76	0.0151	0.0900	0.1500	0.1800
Temperature	72				
Humidity	84	0.0150	0.0910	0.1450	0.1900
Temperature	76				

Tests made by varying the velocities of air passing through the tubes showed conclusively that the concentration of ozone was affected by the volume of air passing through the tubes. In Table II are given concentrations effected by various air velocities.

Table II.—Effect of Air Velocities Upon the Amount of Gas Produced

Setting of Switch	Temp. of Air	Humidity of Air	Concentration of O_3 Grams per cb. M.	Cu. Ft. of Air Passing Through Tubes per Minute
4	70° F.	68	0.0075	7.46
4	70° F.	70	0.0019	18.63
4	70° F.	70	0.0006	37.31
4	72° F.	70	0.0001	74.62

EFFECT OF OZONE UPON ODORS

In undertaking laboratory experiments to determine the effect of ozone upon various odorous compounds, Mr. Powell approached the subject with some doubt as to the ultimate success of the undertaking, considering the complexity of the subject.

Technical papers within the past year have been filled with lengthy reports as to the value or futility of ozone as a deodorizing agent, but as yet the results seem futile; but at least the fact has been demonstrated that practical tests are of far greater value than laboratory tests, no matter how complete or scientifically they may be conducted. For this reason the experiments that were undertaken were merely to note if ozone in sufficient concentration could remove certain of the common odors to be met with in daily work.

Temperature, humidity or other conditions are seldom, if ever, identical in different places; nor is it reasonable to expect to find the same odors present, either alone or in combination, in the same degree of intensity or in similar mixtures, so that broad conclusions have not been drawn from these tests, but they are merely reported to show the possible deodorizing effect of ozone upon certain organic compounds.

The substances used in these tests were mercaptan, skatol, oil of cloves, oil of violets, bullion cultures inoculated with sewage bacteria, cigar smoke, decayed fruit, sour milk, cheese, ammonia and hydrogen sulphide.

The details of these various tests are given in Table III.

In reviewing the foregoing work it is evident that many of the compounds causing their characteristic odors are easily oxidized by ozone, and that the products of oxidation are inodorous. As a result ozone can be depended upon to remove them from the atmosphere. Others are not so readily oxidized, but in the presence of ozone are not detected, but after the ozone has been completely used up are again evident, due to incomplete oxidation. Or as a third possibility the products of oxidation possess characteristic odors which persist in the atmosphere after ozonization.

EFFECT OF OZONE UPON THE BACTERIA OF THE AIR

In studying the sterilizing effect of ozone upon the bacteria of the air a number of determinations were made before and after ozonization. In the first series of tests a number of sterile petri dishes were exposed to the air of a room for given periods of time, varying from five hours to twenty-four, at different elevations, so as to obtain as near as possible a fair average of the number of organisms that were present in the air. Gelatine media were then put into the plates and the cultures incubated for forty-eight hours at 18 deg. to 20 deg. C. The average results of the tests are given in Table IV.

Table IV.—Effect of Ozone Upon Bacteria in the Air. Average of Ten Tests

	Time Plates Were Exposed— 5 Hours	15 Hours	24 Hours
Bacterial colonies counted before ozonization	30	41	83
Bacterial colonies counted after ozonization	3	4	5
Percentage reduction in bacteria	90	90.2	94.0

(Concentration of ozone during test 0.1500.)

The second series of tests that were made to check the figures given above consisted in passing a measured volume of air through an absorbent cotton filter and determining the number of organisms in a cubic foot of air of the room by washing a square inch of the filter material in sterile water, plating a portion of the water and counting the colonies developed upon the culture

Table III.—Effect of Ozone Upon Odors

Compound Causing the Odor	Concentration of Ozone	Intensity of Odor— Before Ozonization	After 3 Hours	After 5 Hours	After 24 Hours	Control Test (After 24 Hours)
Skatol	0.1800	Strong	Fairly strong	Fairly strong	Very faint	Positive
Mercaptan	0.1800	Strong	Strong	Strong	None	Positive
Oil of cloves	0.1500	Strong	Strong	Odor changed	None	Positive
Bacterial culture	0.1800	Strong	Strong	Very faint	Very faint	Positive
Tobacco	0.1800	Strong	Fairly strong	Faint	None	Positive
Decayed onion	0.1750	Strong	Strong	Strong	Fairly strong	Positive
Ammonia	0.1800	Strong	Strong	Strong	Fairly strong	Positive
Hydrogen sulphide	0.0900	Strong	Faint	None	None	Positive
Cheese	0.1500	Fairly strong	None	.....	.....	Positive
Oil of violet	0.0900	Strong	None	None	None	Positive
Sour milk[3]	0.1500	Fairly strong	None	.....	.....	Positive

Note—All control tests gave characteristic odors of substances used after standing twenty-four hours in a room in which there was no ozone.

[3]Although in these tests it was noted that the odor of sour milk was eliminated by the use of ozone, it has been shown that when fresh milk is sterilized by the use of ozone the odor of the gas is retained by the milk, so this has not proven a practical method of sterilization.

plates. Such a procedure is open to error, but within reasonable limits of accuracy for comparative results.

The third method employed was similar to the second, with the exception that the filter medium used was sterile sand in place of a cotton felt. This method is the one in vogue generally in making ventilating investigations.

The results of both tests are reported in Tables V and VI.

TABLE V.—EFFECT OF OZONE UPON THE BACTERIA OF THE AIR

Concentration of Ozone Used in Tests	Bacteria per Cu. Ft. of Air in Room: Before Ozonizing	Bacteria per Cu. Ft. of Air in Room: After Ozonizing for 5 Hours	Per Cent Reduction After Ozonizing
0.0075 grams per Cb. M.....	32	14	56.2
0.0019 grams per Cb. M.....	28	24	14.2
0.0006 grams per Cb. M.....	39	40	+2.5

TABLE VI.—EFFECT OF OZONE UPON THE BACTERIA OF THE AIR (SAND FILTER METHOD)

Concentration of Ozone Used in Tests	Bacteria per Cu. Ft. of Air in Room: Before Ozonizing	Bacteria per Cu. Ft. of Air in Room: After Ozonizing for 5 Hours	Per Cent Reduction of the Bacteria
0.0068 grams per Cb. M.....	41	12	70.7
0.0014 grams per Cb. M.....	36	31	13.8
0.0007 grams per Cb. M.....	46	42	8.6

Note—In tests made in the office of the same company, 100 West Fayette Street, Baltimore, Md., it was found that the total number of bacteria was reduced after ozonization by 88 per cent, while the B. Coli content of the air was reduced 96 per cent.

CONCLUSION

In summing up the results of laboratory tests of this character due consideration must be given to the fact that the conclusions reached are based upon the results of tests conducted under conditions not usually present in other places. Such results are, therefore, only relative and are of value only when considered in this way.

Regarding the production of ozone by the machine, it is believed that within reasonable limits constant at the various settings of the switch that the yield of gas is but slightly, if at all, affected by temperature and humidity conditions, or at least to so slight an extent in a small generator of this type as to be negligible. The velocity of the air passing through the tubes, however, has a direct bearing upon the amount of the gas generated, the figures obtained showing that the slower the velocity of air passing through the tubes the greater the yield of ozone.

In reference to action of ozone upon the bacteria of the air, it has been demonstrated in these tests that comparatively high concentration acting for a long period of time has a great germicidal action upon organisms in the air, but the efficiency is lessened as the concentration is reduced. The tests made, however, clearly demonstrated that even low concentrations can be depended upon to eliminate to some extent the bacteria in the air of a room.

As to the effect of ozone upon various odors, it has been shown to the satisfaction of the author that the gas will rapidly remove odorous compounds from the atmosphere, provided the substances are oxidizable and the oxidation products are inodorous. All odors are probably not oxidizable, and under such conditions there may be a masking effect due to the more powerful odor of ozone, which has been noted in so many investigations. Also the complete removal of a substance causing a characteristic odor will require a given amount of gas to complete the oxidation reaction, and if the ozone is not sufficient to accomplish this then it cannot eliminate the odor.

Concerning the effect of ozone upon the health of persons, the subject cannot be dealt with here other than to state the effect upon the author. Very high concentrations have caused a dull headache and a feeling of irritation in the throat, but under this condition the author has been subject to very high concentrations in a closed room for long periods of time. Lower concentrations, however, have not been objectionable in any way, and the author has worked for several weeks, five to seven hours a day, in an atmosphere where the odor of the gas was perceptible at all times with no detrimental effect.

In tests made at the large ozone plant there has been no complaint made by the operators as to the detrimental effect of ozone upon the health of these men, yet they have been working in an atmosphere of ozone highly concentrated eight to ten hours a day for many months; but in this case they have access at all times to outside air and do not stay continuously in the ozonizer house. The only comment that has been made by these men is to the effect that they are freer from colds since operating the ozone plant and are exposed to the gas than they were before the installation of this plant.

Oil Drying and Purifying Outfits

To obtain the best service as well as to economize in the use of oil for cooling and insulating transformers, high-tension switches, circuit-breakers, electrolytic lightning arresters, and similar apparatus, it is necessary to employ some method of cleaning and dehydrating the oil from time to time. If means for thus treating the oil are not available, it must be discarded at the time and replaced by new oil free from dirt and moisture.

Both the capacity and the voltage of transformers have been steadily increasing, making it necessary that the oil used be of extremely high quality as regards its purity and freedom from moisture.

It is well-known that the presence of moisture in transformer oil, even in the most minute quantities, very seriously affects the dielectric strength of the oil. Carefully conducted tests made by the Westinghouse Company have shown that 0.001 to 0.005 of 1 per cent (1 part in 100,000 to 20,000) will reduce the dielectric strength below the standard test value of 30,000 volts between ½-in. spheres spaced 0.15 in. apart, and 8 in. below the oil surface. Particles of dust, or other foreign matter in suspension also reduce the dielectric strength and in addition form undesirable deposits, necessitating that the oil be kept free from sediment as well as moisture.

After careful investigation of the problem of reclaiming all insulating oils whose deterioration has been caused by physical changes, or the presence of moisture, carbon or foreign substances, the Westinghouse company has developed a special type of filtering outfit for this service. In this outfit the oil to be purified is forced through several layers of specially prepared filter paper. The sediment is strained out by the first layer of paper

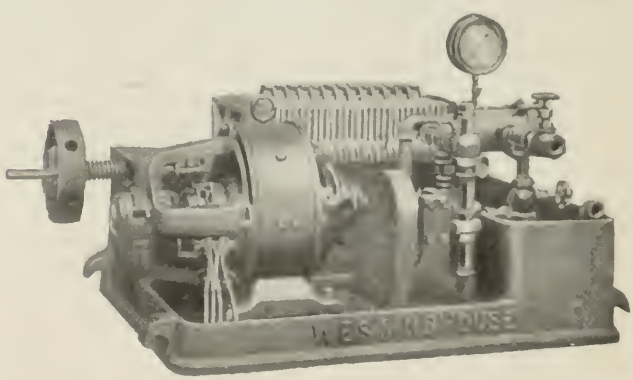


FIG. 1.—TYPE A-10 OIL DRYING AND PURIFYING OUTFIT

and the moisture is taken up by the capillary action of the paper.

While the principal class of service for which these outfits are developed is for the treatment of insulating oil, there are numerous applications for which they are well fitted. Insulating varnishes, compounds, etc., that have a sufficiently low viscosity may be cleaned and dehydrated. Machine oil of all kinds, petroleum, benzine, etc., may be effectively cleaned and dehydrated.

The complete outfit consists of filter press, motor, pump, oil strainer, pressure gage and piping. The sizes up to and including 10 gal. per minute are mounted on a neat iron base cast with a high rim that forms an enclosure and serves as a drip pan. The 20-gal. and 30-gal. per minute sizes are mounted on a structural iron base and have a sheet-metal drip pan. Electric drying ovens are supplied for drying the filter paper. The apparatus is manufactured by the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Turbine Vacuum and Low Pressure Boiler Feed Pump

A combined turbine vacuum and boiler feeder pump, designed primarily for vacuum steam-heating service, has recently been placed on the market. This pump may be used equally as well on any service where both air and water, either hot or cold, have to be handled under a vacuum. The air pump and water pump are both on the same shaft and inclosed within the same casing. The air and water are separated before reaching the pump, each material being handled by itself. Other steam-heating vacuum pumps receive the water and air mixed, the separation being made under boiler pressure after leaving the pump.

The pump is shown in Fig. 1, and the complete outfit

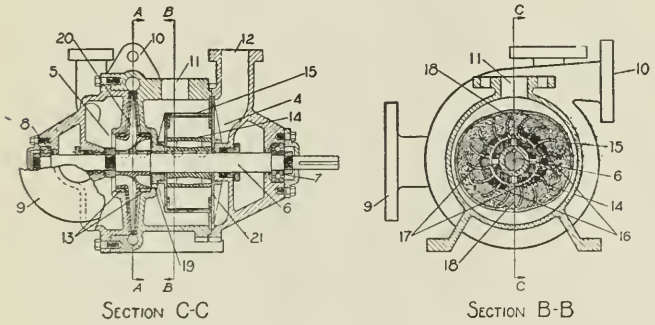

FIG. 1.—SECTIONS OF PUMPS

in Fig. 2. The pump is simple, consisting of a Nash hydro-turbine air pump and a Jennings centrifugal water pump combined in one casing. Fig. 1 shows the interior construction of the combined pump and a section of the air compressor. The air pump is at 4, the water pump at 5, both the air rotor and the water impeller being mounted on the same shaft 6, which is supported by annular ball bearings. The water inlet is at 9, the water outlet at 10. The air inlet is at 11, the air outlet at 12.

The air pump is positive in action and will give a maximum vacuum of 20 in. of mercury. A description of this pump was given in our issue of July, 1915. It consists of a rotor 14, turning freely in an elliptical casing 15. The rotor carries water around with it, the water following the casing due to centrifugal force. The water alternately receding from and surging back into the rotor, acts as a piston, drawing the air in and expelling it through ports 16 and 17, cut in the sides of the casing. A small amount of water is carried over with the air, and water is therefore constantly supplied to the pump through 19.

The water pump is a Jennings centrifugal pump, the liquid being rotated in an impeller. The interior of the pump requires no lubrication, a considerable saving in lubricant is effected, and what is more important, there is no danger of putting oil from the pump into the boiler.

In operation the heating returns, air and water, pass through strainer *B* into separating tank *C*. The water falls to the bottom of the tank *C* and passes into the centrifugal through the pipe *D*, driving the air out of the centrifugal through the pipe *L*. The pump fills with water and begins to pump, emptying tank *C*. The cen-

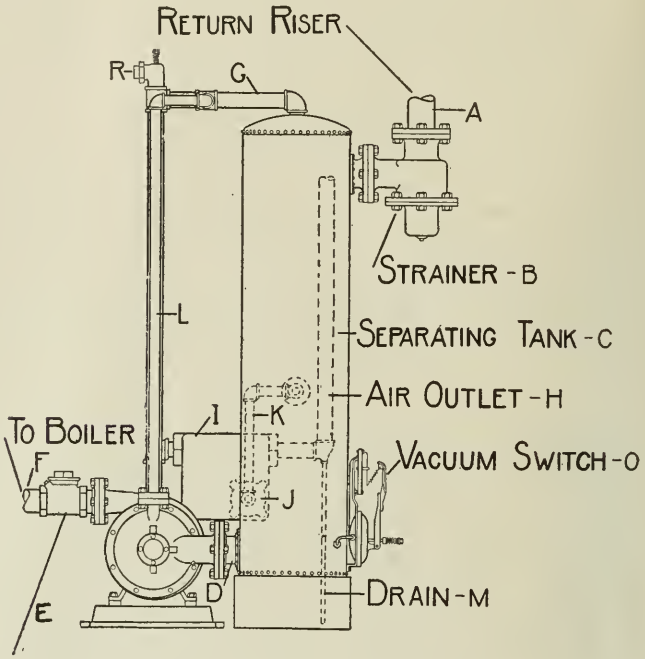

FIG. 2—PIPING CONNECTIONS

trifugal then stops as it cannot handle air, the check valve *E* preventing a back flow. The air is drawn out through *G* by the hydro-turbine.

Automatic control is furnished both for vacuum and water head. This is accomplished by means of switch shown at *O*. *I* is a separator for receiving the small quantity of makeup water from the centrifugal. The relief valve *R* is provided to prevent the vacuum from ever rising above the predetermined amount.

The pumps are furnished in five different sizes, ranging from 6 to 42 cu. ft. of air per min. and 11 to 90 gal. of water per min. at 10-in. vacuum and 10 lb. pressure. They are made by the Nash Engineering Co., South Norwalk, Conn.

Personal

Mr. **W. M. Archibald** has succeeded J. M. Turnbull as manager for the Consolidated Mining & Smelting Company of Canada, Ltd., at Trail, B. C.

Mr. **F. K. Cameron,** formerly of the U. S. Geological Survey, has been retained as chief chemist for the Utah Potash Co., which has acquired alunite deposits in Utah.

Mr. **J. V. N. Dorr** has returned to his New York office after an extended visit in San Francisco and Denver.

Mr. **Harry A. Guess,** engineer for the American Smelting & Refining Co., is on a professional trip in Chile.

Mr. **J. E. Johnson, Jr.,** has been elected chairman of the New York Section of the Mining and Metallurgical Society of America.

Mr. **Woolsey McA. Johnson** is now consulting metallurgical engineer for the American Spelter Corporation, 61 Broadway, New York City, with works at Kusa, Okla. He is acting in an advisory capacity. The American Spelter Corporation makes a high-grade spelter, zinc 99.90 per cent or more, suitable for cartridge brass, and is now producing with a capacity of eight tons of virgin spelter per day.

Mr. **Benjamin B. Lawrence** has purchased the Pelton-Doble water wheel and the Pelton-Francis turbine which were exhibited by the Pelton Water Wheel Co. of San Francisco at the Panama-Pacific International Exposition and presented them to the Columbia School of Mines. Mr. Lawrence was a member of the class of '78.

Dr. **John A. Mathews**, general manager of the Halcomb Steel Co., Syracuse, N. Y., has been elected president of the company, succeeding Mr. H. S. Wilkinson, who has resigned.

Mr. **L. H. Norton**, of Silverton, Colo., has gone to San Francisco and will spend some weeks at Douglas, Ariz., before his return.

Mr. **C. H. Vom Baur** has taken charge of the sales in this country of the Rennerfelt electric furnace, of which Hamilton & Hansell, 17 Battery Place, New York, are exclusive agents.

Dr. **J. A. Udden**, geologist of the Bureau of Economic Geology, University of Texas, has been appointed Oct. 26, 1915, director of the Bureau, the former director, Dr. **William B. Phillips**, having resigned to become president of the Colorado School of Mines.

Captain **Fred H. Wagner**, chief engineer of the Bartlett-Hayward Co., Baltimore, Md., will deliver a lecture before the Franklin Institute, Jan. 6, 1916, on "Coal Gas Residuals."

Dinner to Director Van H. Manning of the Bureau of Mines

The staff of the Bureau of Mines and the staff of the U. S. Geological Survey tendered on Nov. 20, 1915, a complimentary banquet at Washington to Mr. Van H. Manning, the new director of the Bureau of Mines, in honor of his appointment.

Mr. E. W. PARKER, who acted as toastmaster, opened the proceedings with a silent toast to the memory of the first director of the Bureau of Mines, the late Joseph A. Holmes: "He gave all that he had."

Dr. GEORGE OTIS SMITH, director of the Geological Survey, was the first speaker, taking as his theme the U. S. Geological Survey as an institution of higher learning and its graduates. Among them he mentioned John Hays Hammond, who started thirty-five years ago as an assistant in the Geological Survey, and Herbert C. Hoover, who began his career twenty years ago as a geologic assistant. The Geological Survey has supplied eminent geologists and mining engineers not only to private corporations, but to the chairs of geology in many great universities from Cambridge to Palo Alto, to the geological surveys of many States, and to many celebrated scientific institutions. Van H. Manning is a graduate of the Geological Survey of the class of 1910. "While I cannot claim credit for the Geological Survey all that Director Manning is, I am glad that the rest of his career is to be credited to the Bureau of Mines. While all of us in the Geological Survey have taken great pride in the career of Topographer Manning and Chief Clerk Manning, we are now even more proud of Director Manning, and to him we pledge our heartiest support."

The toastmaster then read a note from Dr. HOWARD KELLY of Johns Hopkins Hospital in Baltimore, expressing his regrets of being unable to be present:

"I hope this public recognition of your conspicuous services and recognized fitness for a great trust will but inaugurate a long, happy, and successful term of service. I cannot wish you better than that the mantle of the beloved Elijah may fall with increasing blessing upon the shoulders of Elisha. I love to think of your department, more even for the spirit of friendship and harmony prevailing there than for the great scientific work you are all doing."

Mr. SANFORD, editor of the Bureau of Mines, spoke for the bureau, sketching Mr. Manning's firm yet charming personality.

U. S. Senator THOMAS J. WALSH of Montana spoke in part as follows:

"A few evenings ago I opened a Bible that lay on my desk near my elbow, and, rather curiously enough without searching for it at all, I ran across the passage covering the temple of Solomon and the treasures of David which were stored therein by Solomon. The reflection would suggest that in this primitive day the earth had already given up so much of its metallic wealth that the time might come when we would see the earth's storehouse entirely exhausted.

"There is offered consolation in the fact, however, that as mining and metallurgy improve, deposits that under other circumstances were mere drops, are made available and that the percentage of the metallic extraction is continually increasing. By the best methods that were available to the Anaconda Copper Company at a period no more remote than three years ago, there was left in the tailings of its ore 0.70 per cent of copper. By treating these tailings now by the oil flotation process and by the modernized leaching process lately introduced, this loss has been reduced until now there is only 0.14 of 1 per cent of copper unrecovered, signifying a saving on every ton of ore treated by that company of 11.2 lb. of copper, which at current prices would amount to about $2, or an added extraction by that company of a daily value of not less than $25,000. By the substitution of electrical energy for steam power that company saves fifty cents per ton on every ton of the four million tons of ore that it treats annually. By this saving it is possible for that company to treat with a profit ore that carries five pounds of copper less than the lowest grade of ore that could be worked commercially before the more economic system was established and installed. Enormous amounts of low-grade ore in the Butte camp that heretofore could not be considered as a part of the company's reserve of that valuable metal have yielded enormous profits. An interesting peculiarity of that region is that the mineralization in past geologic ages was carried on so generously that very often the walls of the veins are utterly obliterated. The solutions carrying the metals penetrating through the adjacent country were such that they become ore as well as the veins, following, as a matter of course, the more remote from the main ore channels.

"So that under these improved processes and modern methods it is possible to mine a wider and wider body of ore in the neighborhood of almost all of the great ore channels in that camp, and for the same reasons the depth to which economic mining can be carried on has extended so that by the development of these processes and the installation of these new methods practically new and highly productive fields have been opened up as available just as though new deposits had been discovered. In the same way most of the great producing porphyries could not be worked at all except by the application of these new processes. The Utah Comper Company mines, mills, and markets its ore at a cost not to exceed $1.25 per ton, and at that rate it can profitably treat copper ores carrying not more than 1 per cent of copper. It annually takes more than 150,000,000 lb. of copper out of a hole that twenty years ago was entirely negligible in any account that might be taken of the world's supply of copper ore. The Conrad Placer Company operates five great gold dredges in Alder Gulch. The fabulous richness of its ore gave rise to the first stampede to Montana. The enterprise was started by Professor Shaler of Harvard. At its inauguration steam was used for power with such meager results that it was scarcely able to make expenses. In after years they have operated with electricity, with the consequence that they have been reaping such profits that they have cleaned up the entire gulch.

"Montana is to-day indeed a great factor in the production of zinc, not because of any new discovery at all, but because processes have been developed within the last three or four years under which refractory ores might be suc-

cessfully treated. As has been suggested here this evening, the world's wealth in agriculture under wise husbandry has experienced no diminution, but the world is suffering constant exhaustion with respect to its mineral wealth. I am advised that the great steel companies are making provision against the day of a dearth of iron ore in this country by securing large deposits in Chile and Cuba. In my opinion, the prime object of the existence of the Bureau of Mines is the conservation of the lives of the men who toil in the mines. And next to that is the conservation of our mineral wealth by making available to man the deposits which, although known, are unworkable at this time. Might I be pardoned for suggesting that the most intimate kind of relationship ought to be cultivated between the Bureau of Mines and those who are actually engaged in carrying on the business of mining. We may rely upon the ingenuity and the enterprise of the mining engineers to apply known processes and recognized methods to the treatment of ores that will render a profit, but we must rely upon the researches of the Bureau of Mines for the development of new processes. They must find the key that will unlock these locked treasure houses and place their great deposits at the service of mankind. Friends of the Bureau of Mines indulge in the expectation that it will meet every reasonable hope that may be entertained for it under the capable management of Mr. Manning, worthy successor to Dr. Holmes, who was loved, respected, and admired by all who were fortunate enough to know him in life."

Mr. J. E. Callbreath, secretary of the American Mining Congress, spoke of the history of the establishment of the Bureau of Mines, and advocated most generous treatment on the part of the Federal Government.

Secretary Franklin K. Lane said it had been a matter of very great pride to him "to be identified with a department which has in its service men of such large information and ability and such self-sacrifice as some of the chemists and engineers we have in the Bureau of Mines." He mentioned Rittman, Parsons, Moore, Cottrell. "It is a great pleasure for me to stand here and speak with such appreciation of the men who are in this department and who are doing the kind of work that has not been done in the United States before, and as Edison outdid the rest of the world in invention, so we will outdo the rest of the world in chemistry, though we are but babies now."

In verses of Kipling Secretary Lane paid a tribute to the late J. A. Holmes, and concluded:

"Mr. Callbreath spoke of safety first. I rather like the toast of the President, 'America first.' And these two are one and they are linked together in the Bureau of Mines and what it stands for. Safety for ourselves and safety for our country—the pre-eminence of our country. And what is to stop our country from being pre-eminent when we have the men who can find out the secrets of nature, and having reserved more of this foundation material which goes to make a great industrial people of our or any other nation, because we have passed now into an industrial world and war seems to be the chief industry? At least, it is an industry by itself and to-day it is being conducted as an expression of the most intense industrial life. There was a time when a war was just a meeting of a lot of men with swords, and then they sang to the man who made the sword. But the sword plays no part to-day. Down at the bottom it means immense mineral reserves from development and from most intensive use. Barbed wire, mechanics, chauffeurs, railroads, cannon, high explosives, automobiles, everything that a great industrial nation has, constitutes the army now when comes the war, and we are an army pre-eminently great in leading any onslaught, because we have mineral resources greater than those of any other country.

"We can build a battleship out of the mines of the United States, and no other country can make that boast. And it is the plan to make the Bureau of Mines a great conservation institution, saving from waste, putting in use; and I have no doubt but that the President was wise, as wise as usual, when he selected to direct the work of that bureau, Mr. Manning."

Mr. Van H. Manning replied in part as follows:

"There has been more or less discussion as to who is responsible for the propaganda of 'Safety First.' The Bureau of Mines has never claimed responsibility for the safety-first movement in the mines, but it has very properly claimed the responsibility for the national movement. . . .

"I wish it were possible for me to speak to you from the fullness of my heart, but this is impossible. The inspiration of this scene, surrounded as I am by friends, old and new, rejoicing with me, is a strong incentive to a renewed courage in the performance of my duties as Director of the Bureau of Mines. The Director of the Bureau of Mines has been entertained from the Atlantic to the Pacific Coast, from the Great Lake on the North to the Mexican boundary line. These entertainments were given in honor of the officer, but to-night it is the man that you honor by your presence.

"One of the mottoes which I have followed through life has been said: 'He who does the best his circumstance allows, does well, acts nobly. Angels could do no more.' I have been commended for the loyalty I have always maintained to those to whom I am responsible for my work. I would have it said of me: 'His loyalty is e'er the same, whether it is to lose or win the game.' I have been on both sides of the game, having won and lost through my loyalty to a cause I felt to be just.

"I want your friendship among the material things of life, and to make my administration successful I must retain it. I am grateful to the President of the United States for my appointment as Director of the Bureau of Mines; grateful to the Secretary of the Interior, who has assumed great responsibility in my appointment, and grateful to you for the confidence you have expressed in me to-night by assembling here to do me honor.

"When the day is done, I will be satisfied if it is said of me: 'Living he did gain men's good opinions; and now dead leaves his work to the care of noble friends.' "

Obituary

Charles H. Kiessig died at his home in New York City at the age of 65 years. He was born in Leipzig, Saxony, and came to the United States in 1879 to establish the manufacture of ultramarine blue. For the last twenty years he conducted a business as importers' agent. He was well known and universally liked in chemical and paint circles, but his friends in the chemical fields will probably best remember him for the unforgotten smokers on Saturday nights in the old Chemists' Club in Fifty-fifth Street, which he arranged in his quiet, genial manner while chairman of the house committee of the Chemists' Club for several years.

Book Reviews

Mechanical Drawing for Colleges and Universities. By **James D. Phillips** and **Herbert D. Orth.** 284 pages, 295 illustrations. Price, $1.75. New York and Chicago: Scott, Foresman & Co.

A similar book for high schools is to be issued by the same authors, the two books to constitute a complete course. This work, however, seems fairly complete in itself; it lays out a graded course very suitable for college students, with the many practical points and details carefully worked out. The two books together should find a wide use, where the high school can be induced to co-operate to that extent with the college or university. The publishers announce that this is one of their vocational series intended for use in the vocational courses that are now becoming so large a part of public education. Prof. F. D. Crawshaw, of the University of Wisconsin, is editor of the series.

Laboratory Work for Coal Mining Students. By **J. Sim** and **A. M. Wylie.** 4¾ x 7¼ in., 136 pages, 17 cuts. Price, 90 cents. London: Edward Arnold.

A useful little book, well adapted to its purpose. The five chapters concern coal analysis, washing and coking tests of coal, testing of oils, gas analysis and fan tests. While the contents appear well written and useful to coal miners, yet methods of testing the average velocity of air in a gallery or shaft and the ignition point of various mixtures of coal gas and air would appear to be subjects that should not have been omitted, even in a most elementary course.
